The f0 pattern of base recordings of *blue* was manipulated to include both dynamic f0 and plateau contours, and crossed with a continuum of duration manipulations leading to changes in relative duration of the words *blue* and *green*. Assuming that *blue* being longer than *green* cues more B-GP responses, and that dynamic f0 cues longer perceived duration, then we might predict dynamic F0 in *blue* likewise to cue more B-GP responses: results of duration and grouping perception tasks, in other words, should be largely overlapping. However, if, like in Brugos & Barnes 2012a [14], the effects of pitch go beyond their modulation of perceived duration, results from the two tasks are expected to diverge.

2.1.1. Stimuli

Manipulations of pitch and duration were performed to an identical base recording of *blue*, and these same resultant resyntheses were used in both the grouping perception and duration perception tasks as described below. A single version of the complete phrase was used as a base file for additional manipulations of f0 and duration to produce stimuli in the experiments. In order to see whether pitch manipulations modulate grouping perception by way of timing perception, it was necessary first to create a neutral condition in which timing manipulations alone might shift perceived grouping. A female native speaker of American English (the first author) produced multiple versions of the phrase, and the eventual base file token was selected through an extensive process of evaluation, resynthesis, and concatenation of naturally spoken words. Durations and intensity of each of the words were adjusted to produce a natural-sounding concatenation that did not strongly cue either B-GP or BG-P grouping. Base durations and duration continuum points were chosen based on a pre-experiment screening with 12 subjects via web form.

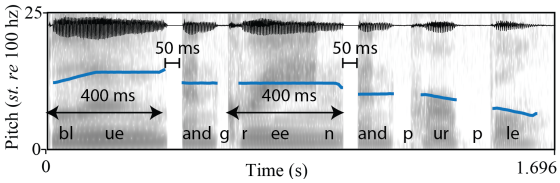

Figure 3: *The base/neutral file. The words* blue *and* green *are ~ 400* ms *long. The f0 contour of* blue *is a plateau with a 2* st *rise, and then level f0,* and green *is level f0, 2* st *below the max f0 of blue,* and purple *starts another 2* st *lower, and ends in a 4* st *fall.*

Pitch and timing manipulations: The base recording of *blue* was resynthesized to create 3 f0 contour shapes at 5 durations, and at 3 steps affecting f0 range. All tokens of blue began with a rise similar to what was seen in natural productions: the 2 *st* rise began at the onset of voicing, through the [l] and into the beginning of the vowel [u]. In order to reduce segmental variation in the onset that might cue differences in perceived prominence and grouping, all manipulations for duration and contour were done only to the /u/ portion of the word following this pivot point (at 158 milliseconds into the word). From this point, the f0 did one of 3 things: 1) stayed level to the end of the word ("plateau"), 2) rose an additional 2 *st* to the end of the word ("2-st-rise") or 3) rose 4 *st* from the pivot ("4-st-rise"). 5 duration manipulations were performed on this same post-pivot interval such that the total duration of the word equalled 300 *ms*, 350 *ms*, 400 *ms*, 450 *ms*, and 500 *ms*, creating 15 time-by-contour manipulations (Figure 4, left).

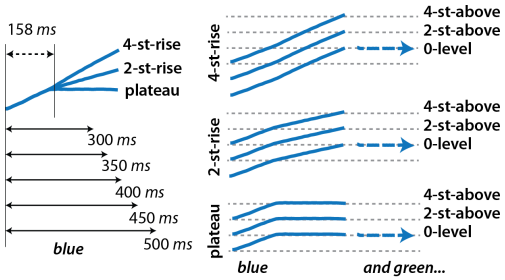

Figure 4*: The base file* blue *was resynthesized to create 3 contour shapes at 5 durations, and duration of the initial 2* st *rise was held constant (left). F0 contours for* blue *were each shifted to 3 f0 steps.*

Unfortunately, introducing a comparison of dynamic vs. static pitch into an experiment such as ours turns out to be far from simple. As Figure 5 shows, any attempt to alter f0 dynamicity during the word *blue* in our sequence necessarily alters the pitch gap across the following boundary also. Given the results of Brugos & Barnes (2012b)[14], this turns out to be a serious potential confound for any investigation of the effects of dynamic pitch on perceived duration.

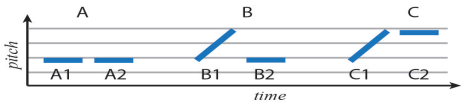

Figure 5: *Schematic showing how dynamic f0 can introduce pitch differences across phrases.*

[1] It should be noted that there is controversy in the literature as to whether it is primarily just relative boundary size, rather than categorical identity of the boundaries involved, that matters most for interpretation (Price et al. 1991 [24]; Clifton et al., 2002 [25]; Jun, 2003 [15]; inter alia). We remain agnostic here as to whether the prosodic phrases used in this study are instantiations of specific levels of the Prosodic Hierarchy (Selkirk, 1986) [26], or instead recursive or gradiently-sized groups (Ladd, 1986 [27]; Wagner, 2005 [28]; Shreuder, 2006 [29]; Kentner & Féry, 2013 [30]). The points we wish to make regarding the implementation of phrasing hold equally well under both scenarios.

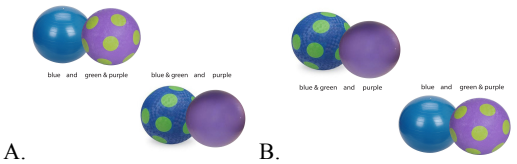
In order to control for this confound, we chose to actively manipulate pitch step orthogonally to the manipulations of dynamic pitch so that we could better separate the effects. Each resulting contour/time combination was resynthesized at 3 different f0 ranges ("pitch steps") based on the pitch relationship between the end point of *blue* and the f0 of the immediately following words in the grouping experiment (*and green),* which were always level at 202 Hz. 3 pitch steps were chosen: 1) 2 *st* above *green* (the level of the neutral condition for the plateau contour shown in Figure 3, above), 2) ending 4 *st* above *green* and 3) ending level to *green*. In each case, the entire contour was shifted up or down in pitch space.

Because manipulations to *blue* alone were not sufficient to cue grouping differences for all listeners in a pre-experiment screening, and as it was obvious to some listeners when the post-*blue* phrase was unchanging, manipulations to the duration of *green* were also added. Base *green* was approximately 400 *ms* in duration, and additional manipulations yielded *green* at 350 and 450 *ms* as well.

2.1.2. Subjects, presentation and task

16 native speakers of American English (age 18 to 22 years) participated in Experiment 1 for a payment of $10. 9 of these subjects additionally participated in Experiment 2 for an additional $10. (Experiment 2, the duration task, was always presented to subjects after completion of Experiment 1.) Subjects faced a laptop and listened to stimuli over headphones. Both experiments were forced-choice tasks, with responses indicated via a button box or designated keys on the laptop. Each experiment took about 25 minutes, including breaks and training. Subjects read a brief introduction to the study, then proceeded to a training section, to ensure that they understood the task. For Experiment 1, subjects were presented with natural examples of prosodic grouping (of repeated digits) produced by a naïve speaker. Subjects proceeded to the experimental phase after answering at least 75% correct of at least 10 training trials. For Experiment 2, training consisted of presentations of plateau tokens of differing durations, using only duration differences of 100 *ms* or greater. Subjects proceeded to the experimental phase upon correctly answering 5 training trials in a row.

Experiment 1: Grouping perception. The screen presented 2 images representing two grouping choices: 1) One solid blue ball, and another purple with green spots (B-GP) and 2) one blue ball with green spots, and another solid purple (BG-P). The text "blue and green & purple" and "blue & green and purple" accompanied each image. For each trial, subjects were played a recording of the complete phrase *blue and green and purple*, and asked to indicate whether they heard the phrase as corresponding to B-GP or BG-P. They were not instructed to attend to any specific aspect of the signal. Trials included phrases with the 45 blue manipulations (3 contours x 5 durations x 3 time steps), paired with the phrase completion,



A. B.

Figure 6: *Images presented to subjects for Experiment 1, with text and images suggesting the 2 groupings. Subjects either saw only A, or only B.*

including 3 durations of green (350, 400, and 450 *ms*): 4 repetitions with 400-*ms green*, and 2 repetitions each for the other 2. These 360 trials were randomized for each subject.

Experiment 2: **Duration perception**. Target versions of the word *blue* identical to those in Experiment 1 were compared to level-f0 standards of the same base file *blue*. Standards were completely level-f0 versions of *blue* at 202 Hz (the level of *and green* in the grouping experiment), and presented in the same 5 durations of the targets (300, 350, 400, 450 and 500 *ms*). Trials consisted of a target followed by a standard, with 200 *ms* of silence interceding. Each pairing was also presented in the opposite order, that is, standard followed by target (45 targets x 5 standards x 2 orders = 450 trials). An additional repetition of each of the 2 rise contours in the target-standard order was included to maximize repetitions of the comparisons of greatest interest, for a total of 600 trials, randomized for each subject. Subjects were asked to indicate which of the two repetitions of the word *blue* sounded longer.

3. Results and analysis

Experiment 1: Results presented are from 5598 experimental trials for 16 subjects. Figure 7 displays proportion of B-GP responses as a function of duration difference between the words *blue* and *green* (durations of *and* & *purple* remain constant for all conditions). Positive time values indicate that *blue* is longer than *green*, and negative that *blue* is shorter. At left, individual lines represent the 3 contours (plateau, 2-st-rise, 4-st-rise), and at right the 3 pitch steps (0-level, 2-st-above, 4-st-above). The upward diagonal trend of the lines in both graphs shows that responses are strongly correlated with duration difference between *blue* and *green*. Bigger time values show more responses that *blue* is grouped separately (B-GP), and smaller time values more responses that *blue* is grouped with *green* (BG-P). The three lines by contour (left) show virtually no separation, but the 3 lines by pitch step (right) show clear separation such that trials where the pitch of *blue* ends level with the following words show proportionately greater responses that *blue* grouped with *green* (BG-P), and higher pitch steps show increasingly more responses that *blue* is grouped separately (B-GP).

Results were analyzed using mixed-effects logistic regression, implemented through the lme4 package (Bates & Maechler, 2009 [31]) in R with response ("B-GP" or "BG-P") as dependent variable, and time step, pitch step and f0 contour as fixed factors. Subject was included as a random effect (Baayen et al., 2008 [32]). The result was a model (N = 5598, log-likelihood = -3269) showing an expected significant main effect of time step (Wald Z = 29.57, $p < .001$), as well as main effects for pitch step, with 2-st and 4-st differing from 0-level (2-st: Wald Z = 5.371, $p < .001$; 4-st, Wald Z = 7.54, $p < .001$). There was a weak effect of contour (between plateau and 2-st-rise (Wald Z= 1.98, $p < .05$), also pushing responses toward B-GP. There was also a somewhat complicated series of interactions between contour and pitch step such that dynamic pitch contours showed a slight tendency at the 2-*st* and 4-*st* steps to produce fewer B-GP responses, which will be addressed in the discussion section.

Experiment 2: Results are presented for 9 subjects for 3360 trials (only target-standard order trials are included, being closest to conditions of Experiment 1.) Figure 8 displays the proportion of "target longer" responses as a function of duration difference between target and standard.

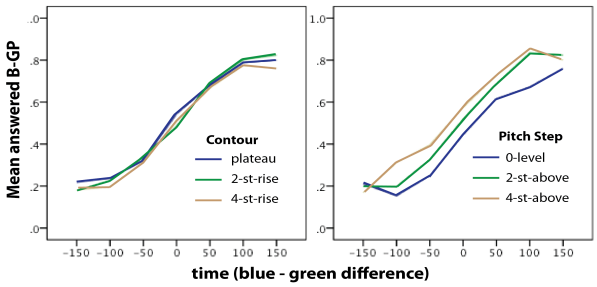


Figure 7: *Experiment 1 results: Mean responses B-GP grouping by time, with lines by contour (left) and pitch step (right). Lines by contour overlap, but lines by pitch step show separation.*

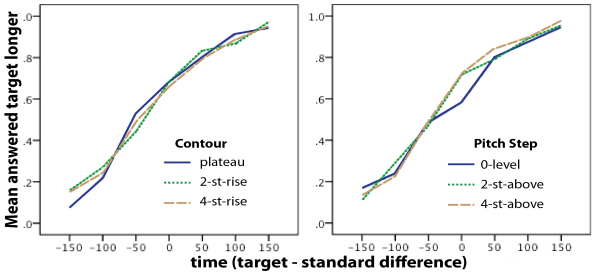

Figure 8: *Experiment 2 results: Mean responses "target longer" by time. Lines by contour (left) overlap. At right, lines by pitch step show some separation at time=0, but otherwise overlap.*

Positive time values indicate a target longer than a standard, and negative that the target is shorter. (For time = 0, target and standard were of identical duration). At left, lines again represent the 3 contours, and at right the 3 pitch steps. The upward diagonal trend of the lines in both graphs shows that subject responses are strongly correlated with the duration, with more responses that the target was longer when the target was indeed objectively longer. The three lines by contour in (figure 8, left) again show virtually no separation, and the 3 lines by pitch step (figure 8, right) only show some suggestion of separation where time = 0.

A mixed model analysis was performed much as in Experiment 1, but with response ("target longer" or "standard longer") as the dependent variable. The result was a model (N = 3360, log-likelihood = -1601) showing significant main effect of time step (target-standard time difference) (Wald Z = 27.47, $p < .0001$). There was no main effect of contour, but also no significant main effect of pitch step. There was, however, a slightly significant interaction between contour and pitch step (Wald Z = 2.43, $p < .05$) only for the 2-st-rise contour with the 4-st-above pitch step.

4. Discussion

The effects of f0 manipulations on grouping perception and duration perception are not identical. The effect of contour (rising pitch vs. plateau) did not strongly influence results in either the grouping perception or the duration perception experiment. Pitch step appears to have influenced responses in both experiments, but potentially in complicated ways.

The complicated interactions between pitch step and contour seen in the results of Experiment 1 are likely a reflection of perceived scaling differences. While pitch step was defined here in terms of pitch distance between the end of *blue* and the following phrase, this likely reflects perceived scaling only for plateau tokens. It is known that for tone glides, perceived pitch is roughly equivalent to a point roughly 2/3 of the way through the glide (Rossi's "2/3 rule," Rossi, 1971 [33]). Estimating perceived pitch thus, tokens where *blue* is either dramatically higher or lower than green will tend to be perceived as B-GP, and where they are similar in pitch there are likely to be more BG-P judgments. Closer pitch across the boundary may influence perceived tonal continuity, and such pitch proximity or similarity of pitch may suggest a weaker boundary. Large pitch changes across a boundary, conversely, create a greater discontinuity, and cue a stronger boundary. Such an observation is in keeping with proposals of prosodic grouping that make reference to gestalt-like principles, such as proposed by Kentner & Féry (2013) [30], and similar to principles proposed for music grouping by Lerdahl & Jackendoff (1983) [34]. It is also worth noting that pitch is recognized as playing a role in connecting phrases into coherent segments in discourses (Wichmann, 2000 [35]; Hansson, 2003 [36]; Hirst, 1993 [37]), but such effects have not been as thoroughly explored in intonational phonology traditions such as AM/ToBI (Beckman & Ayers, 1997 [38]).

In Experiment 2, the lack of effect of pitch contour, seemingly suggests that dynamic pitch does not modulate perceived duration. This may well be due to the orthogonal manipulation of pitch range. When examining the subset of cases where the target and standard durations were equal, more responses that the target was longer can be seen when there is a big pitch jump between target and standard. It is possible that, as shown with the kappa effect, such a pitch jump affects perceived duration of the interceding silent interval. Indeed, it may be the case that subjects are not clearly distinguishing between the durations of the filled intervals vs. the silent intervals. (Note that there is a larger silent interval, 200 *ms* vs. 50 *ms*, in Experiment 2, and this may be reflected in the overall tendency for subjects to hear the first item as longer: 60%, in spite of balanced presentations.) It is possible that at least some of the previously reported effects of dynamic pitch on perceived duration are due to a confound of dynamic pitch introducing pitch step differences across compared tokens. Under certain circumstances dynamic pitch may have an effect, but circumstances may need to be just right, and may be overridden by other effects, such as relative scaling. It is also conceivable that while the psychoacoustic effect of dynamic pitch on perceived duration is real, it may not transfer straightforwardly to speech.

5. Conclusions

These results of these experiments add to our understanding of the effects of pitch on perceived duration, and suggest that pitch factors affect grouping judgments beyond what would be expected from distortions of perceived duration. While pitch factors have been shown to modulate perceived duration, such effects do not account for the degree to which pitch changes affect perceived grouping. Pitch relations across boundaries influence perceived juncture across those boundaries, at times overriding the effects of durational cues. Results support the idea that listeners integrate pitch and timing cues when judging linguistic structure, supporting measures of relative boundary size that combine duration and pitch measures.

Distinguishing Phrase-Final and Phrase-Medial High Tone on Finally Stressed Words in Turkish

Canan Ipek[1], Sun-Ah Jun[2]

[1]Department of Linguistics, University of Southern California, Los Angeles
[2]Department of Linguistics, University of California Los Angeles, Los Angeles
ipek@usc.edu, jun@humnet.ucla.edu

Abstract

The goal of this paper is to investigate the nature of the high tones realized on finally stressed words in Turkish. Following Ipek & Jun's [1] AM model of intonational phonology of Turkish, it was hypothesized that the high tone realized on the last syllable of a phrase (i.e., Intermediate Phrase (ip)) is realized differently from that of a phrase-medial prosodic word (PW), reflecting the prosodic hierarchy. Acoustic data show that an ip-final High tone shows larger f0 rise than a PW-final High tone, and the ip-final syllable is longer than the PW-final syllable. Furthermore, the degree of coarticulation is weaker across an ip boundary than a PW boundary. These findings support the prosodic structure and tonal categories proposed in Ipek & Jun's [1] model of Turkish intonation.

Index Terms: Turkish intonation, pitch accent, Intermediate Phrase, boundary tone

1. Introduction

The intonational contour of a Turkish declarative sentence produced in a neutral context typically consists of a sequence of rising tones [L H], followed by a nuclear accented word in a narrower pitch range, and a low boundary tone at the end of the sentence. The domain of a rising tone is a Prosodic Word (PW) with the L tone on the first syllable of a word and the H tone on its stressed syllable, often the last syllable of the word. The primary goal of this paper is to investigate the nature of high tones on finally-stressed words in Turkish that are either (a) phrase medial, or (b) phrase final. Based on the findings, we aim to support Ipek & Jun's [1] model of the intonational phonology of Turkish being developed in the Autosegmental-metrical (AM) framework [2, 3, 4, 5].

Word-final high tones have been analyzed differently in two previous phonological models of Turkish intonation within the AM framework.. In [6], a high tone on a word-final stressed syllable was analyzed as a pitch accent regardless of whether the word is in the middle or at the end of a Phonological Phrase. On the other hand, [7], following [8],assumes that words with final stress under the traditional analysis [9, 10, 11] are lexically unstressed, and instead the High tone is analyzed as a boundary tone (H-) of a Major Phrase (or Phonological Phrase or Accentual Phrase). Since the Major Phrase included only one prosodic word in [7], it is not clear whether H- is a boundary tone of a prosodic word or of a Major Phrase. It is also not clear how a phrase-medial, word-final High tone would be analyzed in this model.

In Ipek and Jun's [3] intonation model, a High tone on a stressed syllable is analyzed as a H* pitch accent regardless of the location of stress, but when the finally-stressed word is the last word in an Intermdiate Phrase (ip), the prosodic unit above the Prosodic Word, the High tone on the ip-final stressed syllable is assumed to have a dual function. First, it marks prominence on the word (the function of a pitch accent); second, it marks the right edge of an ip (the function of a boundary tone). This tone is therefore given the label H*-.

In the present study, we will examine acoustic data from word-final syllables in the two prosodic conditions, PW-final vs. ip-final. The aim is to examine (a) whether the word-final High tones are realized differently depending on their prosodic condition and (b) whether the degrees of final lengthening and of coarticulation with a following word reflect the word-final syllable's location in the prosodic hierarchy proposed in [1]. Previous studies have shown that, compared with syllables at the edge of lower constituents, syllables at the edge of higher constituents will show higher f0 peaks [2, 12, 13], greater degrees of final lengthening [14, 15, 16, 17], and lesser degrees of trans-boundary segmental coarticulation [18]. We will therefore test the following two hypotheses: (i) There will be a higher f0 peak and more phrase-final lengthening for a word bearing a final H*- than one bearing the H*; (ii) Vowels will undergo less coarticulation across a boundary following the H*- than across a boundary following H*.

2. Experiment

2.1. Method

2.1.1. Stimuli

Five pairs (i.e., ten total) of five-word sentences were designed to examine the acoustic properties of word-final H* and H*-, and the prosodic juncture following them (see Table 1). Every sentence started with a subject noun phrase (NP), and the number of words within the subject NP differed between the two sentences in each pair. One sentence of each pair contained a three-word subject NP (Group 1), and the other contained a two-word subject NP (Group 2), but the target word was always the second word (i.e., word2).

According to [6], word2 in each Group receives a pitch accent (L+H*), but according to [7], word2 in Group 2 receives a H- boundary tone marking a Major Phrase. (The H tone of word2 in Group 1 is not analyzed in [7]). In Ipek and Jun's [1] model, the high tone realized on the final syllable of word2 in Gorup1 is in the middle of an ip (therefore, it would be marked with H*), but the final syllable of the same word in Group2 is the last syllable of an ip (corresponding to a right edge of NP), and so would be marked with H*-.

In addition, in order to measure the degree of vowel coarticulation across the boundary between the second and the

third word in each sentence, the last vowel of the second word was fixed as [a] and the first vowel of the third word was fixed as [i], maximizing the difference in the first (F1) and second formant (F2) values between the vowels.

Table 1. *A list of ten target sentences in the two groups. The second word (in bold) in Group1 is ip-medial, marked with H*, but the same second word in Gorup2 is ip-final, marked with H*-. Below each sentence, an English gloss is given word-by-word, followed by the meaning of the sentence.*

2.1.2. Participants

Data is collected from five native speakers of Turkish (2 males, 3 females) from Istanbul, Turkey, who have been living in America (Los Angeles) for less than five years. Mean age of participants was 33.8 years. None of the participants reported any speech or hearing disorders.

2.1.3. Recording Procedure

The recordings were done in a quiet room, with participants seated in front of a computer screen. A unidirectional USB microphone was placed to the left of the computer, approximately six inches from the speaker's lips. Speakers repeated twenty-five sentences (randomized between ten target and fifteen filler sentences) five times.

2.1.4. Measurements

- Peak f0, Minimum f0, and Magnitude of f0 rise: The f0-peak was measured ten ms before the end of the vowel in the final syllable of the target word (to avoid any effect of microprosody) and the minimum f0 value was measured on the preceding syllable. Each f0 value was converted into semitones and the magnitude of f0 rise was calculated by the difference between the f0 peak and the minimum f0 values.
- Rhyme Duration: Measured the duration between the beginning of the final vowel in the second word and the beginning of the first vowel in the third word. The beginning of the vowel was defined as the point where the second formant energy begins.
- Degree of V-to-V Coarticulation: Measured by the Euclidean distance in the F1 by F2 space between the final vowel of second word (V1) and the first vowel of the third word (V2), i.e., in $V_1C\#V_2$ context, where # represents a prosodic word boundary in Group 1 and an Intermediate Phrase boundary in Group 2.

2.1.5. Statistical Analysis

Statistical analyses were done in R using Linear Mixed-Effects Regression (LMER) package 'lme4' written by [19], with PROSODIC BOUNDARY (prosodic word/intermediate phrase) as the fixed effect, and SUBJECT and SENTENCE as random effects. The simplest and best fitting model for each LMER analysis was derived via model comparison.

In order to obtain *p*-values for the fixed effects, we used *pvals.func* in the 'languageR' package, which computes the relevant *p*-values using Markov chain Monte Carlo sampling (default number of samples=10,000). When the best fitting model involved random slopes, significance for fixed-effect factors was computed using likelihood-ratio test.

2. 2. Results

2.2.1. Peak f0, Minimum f0, and Magnitude of f0-rise

As predicted, the peak f0 values were higher at the Intermediate Phrase boundary (H*-) than at the Prosodic Word boundary (H*), although the difference was not significant (Intercept=13.25, β=0.73, t=1.84, p=0.07). The minimum f0 value was significantly lower before the H*- syllable than before the H* syllable (Intercept= 12.4, β= -0.71, t= -2.95,

p<0.05). Finally, the magnitude of f0 rise at an Intermediate Phrase boundary was significantly larger than that of a Prosodic Word boundary (β=1.435, t=5.925, p<0.05). Figure 1 shows the mean f0 rise in semitone at the end of the second word, i.e., the last syllable of a Prosodic Word (H*) and an Intermediate Phrase (H*-).

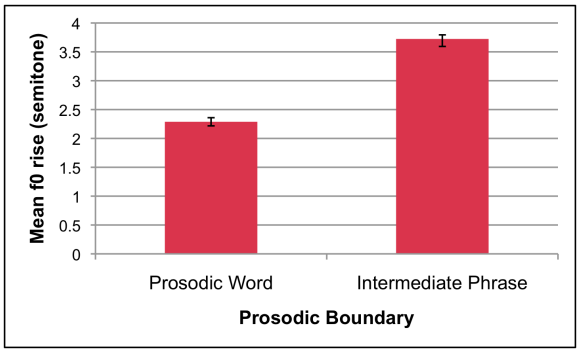

Figure 1: *Magnitude of mean f0 rise at Prosodic Word and Intermediate Phrase boundaries.*

Example pitch tracks of the sentences 1-2 and 2-2 in Table 1 are shown in Figure 2 and 3, respectively. In Figure 2, the second word (*tuzak*) is phrase-medial, thus the f0 peak at the end of the second word receives a pitch accent H*, while the f0 peak of the same word receives H*- in Figure 3 because it marks the end of an Intermediate Phrase.

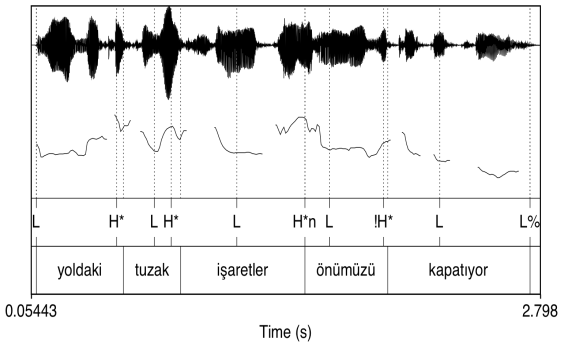

Figure 2: *Sample pitch track of the sentence 1-2 in Table 1, illustrating H* at the end of 2nd word (tuzak), i.e., Prosodic Word boundary.*

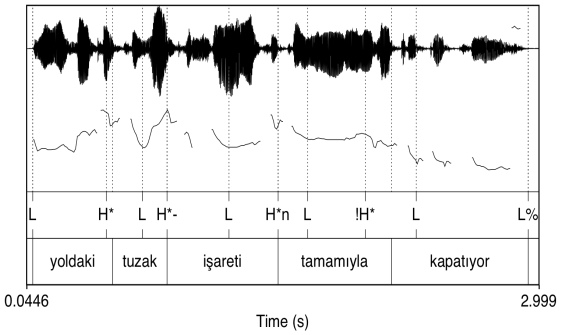

Figure 3: *Sample pitch track of the sentence 2-2 in Table 1, illustrating H*- at the end of 2nd word (tuzak), i.e., Intermediate Phrase boundary.*

2.2.2 Rhyme Duration

Figure 4 shows the mean rhyme duration of the last syllable of the second word at the Prosodic Word and Intermediate Phrase boundaries. As hypothesized, the last syllable of an Intermediate Phrase is longer than that of a Prosodic Word (β=0.067, t=8.38, p < 0.05).

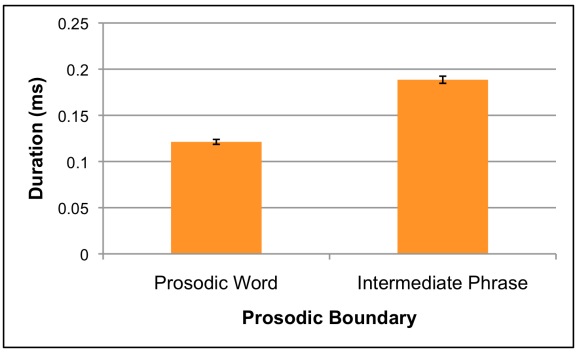

Figure 4: *Rhyme duration of the last syllable at Prosodic Word and Intermediate Phrase boundaries.*

2.3. Degree of Coarticulation

Figure 5 displays the mean Euclidean distance in the F1 by F2 space between each vowel in $V_1C\#V_2$ context. As hypothesized, there is less coarticulation (i.e., larger Euclidean distance) across the Intermediate Phrase boundary than across the Prosodic Word boundary (β=231.1, t=2.145, p<0.05).

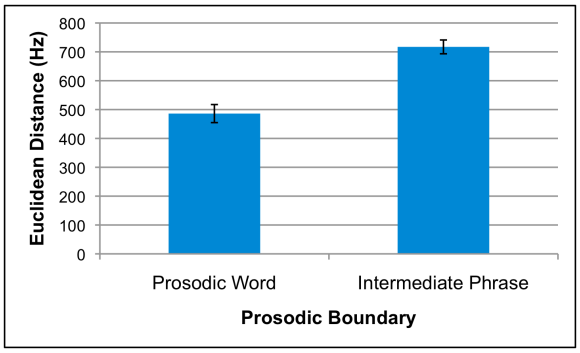

Figure 5: *Euclidean distance across Prosodic Word and Intermediate Phrase boundaries.*

3. Discussion and Conclusion

In this paper, we have shown that the phonetic realization of the high tone on finally-stressed words in Turkish differs depending on its prosodic location. The magnitude of f0 rise is larger at the end of a phrase (Intermediate Phrase/Phonological Phrase/Major Phrase) than in the middle of a phrase. The syllable carrying the high tone is longer when it is the last syllable of an Intermediate Phrase than of a Prosodic Word. Finally, the degree of V-to-V coarticulation is weaker when the two vowels are separated by an Intermediate Phrase boundary than by a Prosodic Word boundary.

The quantitative data found in the experiment therefore support the prosodic structure and tonal categories proposed in Ipek & Jun's model of Turkish intonation. In Ipek & Jun's model, the High tone on the stressed syllable of a prosodic word is labeled as H*, a pitch accent; the High tone realized on the stressed syllable at the end of an ip, however, is labeled as H*-, indicating its function, as both a pitch accent and a boundary tone.

In the experiment reported in the current paper, we only examined finally-stressed words, so an ip-final syllable is always stressed, justifying the H*- symbol. However, as shown in Ipek & Jun [1], the ip-final syllable (or Phonological Phrase/Major Phrase-final syllable in [6, 7]) was still marked by a high tone when the syllable was not stressed. For example, consider Figure 6, where the first two words are non-finally stressed and form a subject NP. Here, each word in the subject NP has a High tone on its stressed syllable (H*) and the second word has an additional High tone on its final syllable, which is also the last syllable of an Intermediate Phrase. Since there is a low f0 target between the two f0 peaks (one over the stressed syllable of the word and the other at the end of the word), and the L tone is closer to the following H tone than the preceding H tone (H*), Ipek & Jun labeled the ip-final f0 rise over an unstressed syllable as LH-. (Note also the shallow falling slope from H* in the first word, interpolating to the initial L boundary tone of the second word in Figure 6). Thus, it is clear that the end of an ip is marked by a high boundary tone regardless of whether the ip-final syllable is stressed or not. However, since the function of the ip-final High tone can differ, the High tone on the ip-final stressed syllable is labeled as H*-, indicating both the prominence marking and the boundary marking functions; the High rising tone on the ip-final unstressed syllable, however, is labeled as LH-, indicating its sole, boundary-marking function.. Further research is needed to investigate whether these tonal categories are perceptually distinct.

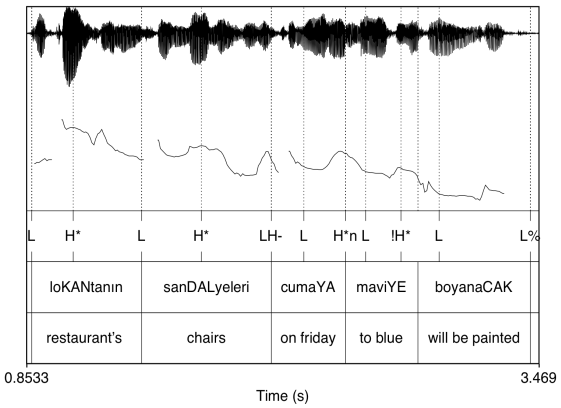

Figure 6: *Sample pitch track of the sentence "Restaurant's chairs will be painted in blue on Friday." The second word (sandalyeleri) is ip-final and is stressed on its second syllable. The second f0 rise on this word, labeled LH-, marks the right edge of ip.*

The interaction of accent and boundary tone in perception of whispered speech

Abstract

We investigated how the perception of Dutch whispered boundary tones depends on the presence of an accent in the utterance-final word, i.e. the boundary tone landing site. Listeners performed near ceiling in normal speech, whereas the same listeners' performance dropped about 30% in whisper, while processing speed decreased in whisper compared to normal speech. Accent position furthermore influenced boundary tone perception. Initial-stress words showed a question bias that affected recognition of that speech act when accent and boundary tone did not coincide. On final-stress words, in which boundary tone and accent coincided, statements and questions were identified equally well.

Index Terms: boundary tone, nuclear accent, perception, whispered speech

1. Introduction

In whispered speech – where voicing and therefore a fundamental frequency (f0) are absent – listeners still perceive, albeit less reliably than in normal speech, prosodic differences that normally heavily depend on f0 presence. For instance, in whisper listeners recognize questions and statements expressed by different boundary tones (H% versus L%) in cases where prosody, rather than lexico-syntax, codes the crucial information [1-3]. Listeners also discriminate intended pitch height [4], differentiate emotional from neutral speech [5], and identify lexical tones [e.g. 6-8]. Many of these studies, however, assessed perception in single syllables, rather than in multi-syllabic or multi-word phrases, whereas the latter would be more ecologically valid. Multi-syllabic utterances will display some form of ranking as to the relative prominence of those syllables (e.g. imposed by lexical stress).

Though earlier work may indicate that intonation in whisper is perceptible, it does not provide much evidence on the perception of whispered intonation in more complicated linguistic structures. In the present study, we investigated how the perception of Dutch whispered boundary tones depends on characteristics of the tone-bearing word, by using disyllabic minimal stress pairs as boundary tone landing sites. In the case that lexical stress, realized as a nuclear accent, lands in final position, the two tonal events fall on the same syllable. In the case that lexical stress lands in initial position, the tonal events fall on adjacent syllables.

For Dutch, as found in studies on normal speech, the most reliable acoustic correlate of lexical stress in sentence context is relative syllable duration [9, 10]. Perceptually, duration also is a reliable cues to stress [11], but for the perception of prominence, f0 is taken to be the primary cue in Dutch [12], as well as in English [13]. In the absence of f0, expressing intonational contrasts in whispered speech seems to be necessarily more intertwined with segmental characteristics than in the case of normal speech. For instance, in whisper formants are not only used to code vowel identity, but also seem to contribute to expressing differences in height [e.g. 14, 15]. Moreover, if different intonational events land on the same syllable, the restricted resources in whisper may be burdened even further.

To our knowledge, one earlier study has addressed the interaction of accent and boundary tones in whispered speech [1], but in a descriptive manner only. In that investigation, Hungarian listeners classified disyllabic minimal stress pairs that were produced either as question or as statement into one of four categories: two lexical stress positions by two boundary tones. A confusion matrix of classification responses showed that boundary tones were identified above chance level, that declaratives were identified correctly more often than interrogatives, and that accent positions were confused less than boundary tones. In addition, there was confusion across accent positions and boundary tones. For instance, ten percent of final-stress declaratives were identified as initial-stress interrogatives, and such across-tonal event responses seem to support the claim that, in whisper, accents and boundary tones may interact in perception. The same type of utterances was classified without errors in normal speech.

To better understand prosody perception in whispered speech communication, the interaction of accent position and boundary tone perception in Dutch was studied in whispered compared to normal speech. A within-subjects design was used that also included reaction time measurements. We predict that listeners perform better when tonal events do not coincide on the same syllable.

2. Method

Perception of the speech act, i.e. interrogative versus declarative, as expressed through the boundary tone (H% versus L%, respectively) was determined in a classification task with reaction time measurements. Boundary tones were produced on disyllabic nouns with lexical stress, realized as a nuclear accent, in either initial or final position. In the latter case, boundary tone and lexical stress coincide on the same syllable (prosodic clash); in the former case lexical stress falls on the syllable preceding the one carrying the boundary tone (no clash). Minimal stress pairs were used, so that segmental structure would be comparable. To verify that the boundary tone does not alter its bearer's interpretation, perception of the items' stress positions was measured using the same task.

2.1. Materials

Four Dutch minimal stress pairs were used: (1) *'ca·non/ka'non*, /kanɔn/, 'canon/cannon', (2) *'Ser·visch/ser'vies*, /sɛrvɪs/, 'Serbian/crockery set', (3) *'Pla·to/pla'teau*, /plato/, 'Plato; plateau', and (4) *'voor·naam/voor'naam*, /vornam/, 'first name/dignified'. Target words were recorded in a neutral

carrier sentence *Hij zei…* 'He said…', which orthographically ended in either a full stop (to elicit L%) or a question mark (to elicit H%), and which forced the nuclear accent onto the target word, thus establishing the prosodic crowding contrast.

Twelve (self-reported) normal-hearing, Dutch native speakers (6 female) participated in 20-minute recording sessions (informed consent was obtained), and were paid a small amount for their efforts. For each speaker, a different listener was present to judge the recordings. This speaker-listener set-up was intended to prompt the speaker to use listener-directed rather than read speech.

Speakers received written instructions, and completed a short practice session, using different minimal pairs than during the actual recording, for both normal and whispered speech. The order of the speech modes was counterbalanced across speakers. Recordings were made using an Edirol R-44 portable recorder and Røde NTG-2 condenser microphone with 'dead cat' windscreen at 44.1 kHz, 24 bits in a sound-treated booth in the phonetics laboratory of Leiden University. Affirmative and interrogative targets were presented to the speaker one by one and in written form on a computer screen, in a pseudo-random order. The listener was seated outside the booth in a silent classroom, wearing Sennheiser HD 414 SL headphones, and used a keyboard to classify each of the speaker's utterances as affirmative or interrogative. Before the next target was presented, the speaker got feedback about the listener's understanding of the previous one. By keeping the listener outside the booth, and invisible to the speaker, the only cues the speaker could provide were auditory. Two repetitions per utterance were recorded and saved as separate wave files, resulting in 32 files per speaker.

The listeners who were present during the recordings labeled the boundary tones in normal speech correctly in 94% of the cases and in whisper, in 68% of the cases. All speaker-listener pairs were different. Using a 6-point Likert scale (1 = very difficult, 6 = very easy) speakers rated the difficulty of their task for both speech modes. According to a Wilcoxon signed ranks test for paired samples, the task was judged more difficult in whisper (median=3.0) than in normal speech (median = 4.5), $Z = -2.5$, $p = .013$. In neither speech mode was the task judged as particularly easy.

Per lexical item, one instance was annotated manually, and that annotation was used to automatically annotate all other instances of the same item using a dynamic time warping procedure in PRAAT [16]. These annotations were manually checked, and corrected if necessary. Target words were cut from the carrier sentences, and intensity was normalized by setting recordings within a speaker and speech mode to 60 dB (rms = 0.020), which corresponded to the minimum intensity of whispered items after scaling peaks to the maximum intensity range (using PRAAT's 'Scale peaks…'). There were 192 stimuli per speech mode: 8 items (4 initial, 4 final stress) × 2 speech acts (question, statement) × 12 speakers.

2.2. Participants and procedure

Twenty-four, right-handed Dutch native listeners (17 females), aged 19-57 (mean = 22 years), were hearing-screened to have normal hearing at octave frequencies between 0.125 and 8 kHz (informed consent obtained). Each of the 192 items per speech mode was presented once to each listener in a blocked design over tasks. Half of the subjects heard the first half of the materials in the Speech Act classification task, and the second half in the Lexical Stress Position classification task. The other half of the subjects listened to the complementary stimulus sets in each task. The set of materials was halved by including only one boundary tone realization, either H% or L%, per speaker and per target word in each half. Subjects received a small fee for participation in the 45-minute session.

Subjects were seated in a sound-treated booth wearing Sennheiser HD 414 SL headphones. After general instructions in written form, more detailed instructions were presented on a computer screen. Response options were shown on screen, while listeners were asked to press one of two response buttons on a keyboard using their index fingers. During speech act classification listeners indicated whether the target sounded like a question or a statement. During lexical stress position classification listeners indicated whether the initial or the final syllable was more prominent. Both tasks were presented once with normal speech materials, and once with whispered speech, resulting in four subsequent tests. Speech modes, response keys and task orders were counterbalanced across subjects. To allow for within-subjects analyses including the factor speech mode (normal vs. whisper), corresponding whispered and normal speech items from the same speaker were presented to the same subject in the same task.

3. Analysis and results

Percent correct responses was computed for both subtasks, i.e. boundary tone (BT) and lexical stress (LS) classification, and transformed to rationalized arcsine units (RAU) [17]. Reaction times (RTs) were measured from target word onset. RTs under 500 ms and over two standard deviations beyond the mean, computed per listener-per speech mode, were excluded (BT: 2.4% of the data; LS: 4.2% of the data). RTs were transformed to their inverse (1/RT) for analysis. Both RAU scores and inverse RTs were subjected to repeated measures ANOVAs with within-subjects factors Speech Mode (normal, whisper), Speech Act (interrogative, declarative), Lexical Stress Position (initial, final) and Minimal Pair (4). If sphericity was violated, Huynh-Feldt correction was applied.

3.1. Boundary tone classification

Significant effects are presented in Table 1. Figure 1a shows that in whisper, boundary tone classification was significantly poorer than in normal speech (61 vs. 94%, respectively), but above chance level [binomial test: $N = 2304$, $p = ½$, $Z = 11.1$, $p < .001$]. Across speech modes, declaratives were classified correctly more often than interrogatives. The interaction of speech mode by speech act showed that in whisper, the difference in correct responses to declaratives versus interrogatives was larger than in normal speech (whisper: 71 vs. 52%; normal speech: 96 vs. 93%, respectively).

Across speech modes, stimuli with final stress yielded similar scores for the two speech acts, but stimuli with initial stress received more correct responses on declaratives than interrogatives. This interaction was found within both speech modes [normal speech: $F(1,23) = 53.2$, $p < .001$; whisper: $F(1,23) = 31.7$, $p < .001$]. Absolute differences were largest in whisper (see Fig. 1a), where for words with initial stress, declaratives were classified correctly well above chance level at 80%, whereas interrogatives were classified below chance level at 41% [$N = 576$, $p = ½$, $Z = -4.2$, $p < .001$]. On final-stress words, scores were 62.5 and 62.3%, respectively. Trends were comparable between minimal stress pairs, and followed the two main effects. Only for the *Plato/plateau* pair, did

speech mode and speech act interact, showing a larger performance difference between the interrogatives and declaratives across speech modes.

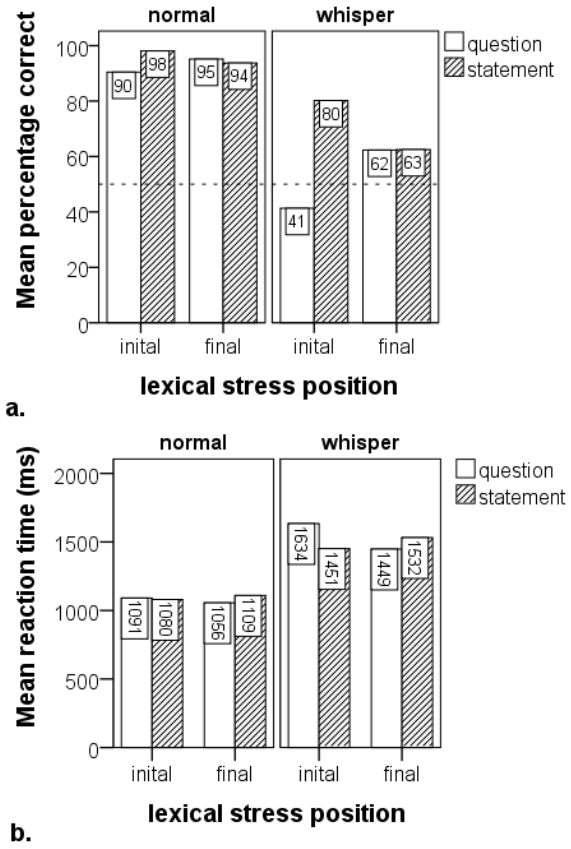

Figure 1: *BT task results, per speech mode, speech act and stress position. a) Mean percentage correct (chance level = 50%). b) Mean reaction time (ms).*

Reaction time results (see Fig. 1b) showed that listeners were faster in normal speech than in whispered speech (1084 and 1502 ms, respectively), faster on words with final stress than with initial stress (1244 and 1255 ms, respectively), and RTs also varied with minimal pair. The effect of stress position, following the main effect, was only significant within whispered speech [$F(1,18) = 7.9$, $p = .012$], as reflected by a marginally significant speech mode by stress position interaction [$F(1,18) = 4.4$, $p = .051$].

Across speech modes, declaratives were responded to equally fast in words with initial and final stress, but interrogatives were responded to faster in final-stress words. This speech act by stress position interaction was found in similar ways in both speech modes [whisper: $F(1,18) = 17.6$, $p = .001$, normal speech: $F(1,23) = 16.5$, $p < .001$]. Across minimal pairs, RTs were longer in whispered than in normal speech, but not exactly to the same extent. Across speech modes, responses to the different minimal pairs followed the main effect of faster responses to words with final stress, but for the *voornaam* pair the trend was in the opposite direction with faster responses to initial-stressed words. The four-way interaction showed that the differences in response times by lexical stress position were mainly caused by differences measured in whisper.

Table 1. *Significant effects and interactions of the RM ANOVAs on BT classification and reaction time data.*

Classification		
Speech mode	$F(1,23) = 403.5$	$p < .001$
Speech act	$F(1,23) = 26.3$	$p < .001$
Minimal pair	$F(3,69) = 3.7$	$p = .016$
Speech mode × speech act	$F(1,23) = 20.2$	$p < .001$
Speech act × stress position	$F(1,23) = 47.8$	$p < .001$
Sp. mode × sp. act × stress pos.	$F(1,23) = 14.8$	$p = .001$
Sp. mode × sp. act × min. pair	$F(3,69) = 5.4$	$p = .002$
Reaction times		
Speech mode	$F(1,18) = 129.1$	$p < .001$
Stress position	$F(1,18) = 6.9$	$p = .017$
Minimal pair	$F(3,54) = 8.9$	$p < .001$
Speech act × stress position	$F(1,18) = 29.6$	$p < .001$
Speech mode × minimal pair	$F(3,54) = 3.6$	$p = .020$
Stress position × minimal pair	$F(3,54) = 3.1$	$p = .033$
Sp. mode × sp. act × min. pair	$F(3,54) = 3.0$	$p = .039$
Sp. mode × sp. act × stress pos.× min. pair	$F(3,54) = 3.0$	$p = .041$

3.2. Lexical stress position classification

Table 2 lists the significant effects for both lexical stress position classification and reaction times. The absence of a speech mode main effect shows that identification of lexical stress position in whisper went as well as in normal speech (89 and 91%, respectively). Across speech modes, there was some variation in mean classification scores per minimal pair, but this difference remained under 4% between the lowest and highest mean scores per pair. Words pronounced as declaratives received more correct responses for initial stress, whereas the correctness of responses to words pronounced as interrogatives was comparable for both stress positions. This trend was observed in both speech modes, but the speech act by stress position interaction was only significant in whisper [$F(1,23) = 18.0$, $p < .001$], not normal speech ($p = .069$).

Table 2. *Significant effects and interactions of the RM ANOVAs on LS classification and reaction time data.*

Classification		
Minimal pair	$F(3,69) = 3.6$	$p = .018$
Speech act × stress position	$F(1,23) = 12.7$	$p = .002$
Reaction times		
Speech act	$F(1,23) = 31.1$	$p < .001$
Stress position	$F(1,23) = 14.4$	$p = .001$
Minimal pair	$F(3,69) = 4.7$	$p = .005$
Speech mode × stress position	$F(1,23) = 19.0$	$p < .001$
Speech act × stress position	$F(1,23) = 11.1$	$p = .003$
Speech act × minimal pair	$F(3,69) = 4.8$	$p = .004$
Sp. act × stress pos.× min. pair	$F(3,69) = 4.0$	$p = .011$

The absence of a speech mode main effect in the RTs indicated that listeners were as fast at identifying lexical stress position in whispered as in normal speech (1304 and 1336 ms, respectively). Across speech modes, responses were faster to declaratives (1279 ms) than to interrogatives (1344 ms), especially for words with initial stress. Responses were faster to final-stress (1289 ms) than to initial-stress (1352 ms) words, but the latter effect did not assume significance for normal speech ($p = .318$), only for whisper [$F(1,23) = 31.2$, $p < .001$].

There was variation in the response times to different words, with fastest responses to *ka'non* (1279 ms) and slowest responses to *'servisch* (1399 ms). The trend for responses to declaratives to be faster than to interrogatives was present in all minimal pairs, but the size of the difference varied between them. Finally, the speech act by stress position interaction was observed in three out of four minimal pairs; for *Plato/plateau*, however, responses to either speech act were equally fast.

4. Discussion

It was expected that in whisper – given the more restricted means of conveying intonation – listeners would have more difficulty correctly identifying boundary tones, and especially when coinciding with lexical stress position. Though the general performance decrease was obtained as expected, the main effect of stress position was not found. Reaction times reflected that processing of final-stress words was in fact somewhat faster, which may hint at easier processing; this effect became significant for whispered stimuli only.

Listener performance showed comparable means around 60% correct on whispered words with initial and final stress; across stress positions, performance was better on declaratives than on interrogatives. This in general suggests that cues to interrogativity were less clear in whisper, which was also found in [1]. But as Fig. 1 shows, performance varied with the stimulus' stress position, especially in whisper. On whispered words with initial stress, where boundary tone and accent do not coincide, performance was much better on declaratives than on interrogatives. Effectively, at 40% correct, questions were not recognized as such on words with initial stress. Moreover, RTs were generally longer for this type of stimulus. For whispered words with final stress, performance was comparable between the speech acts. These results suggest that only on whispered stimuli in which accent and boundary tone coincided on the same (i.e. final) syllable (clash condition), were listeners able to reliably identify the boundary tone.

As performance on interrogatives pronounced on initial-stress words was, in fact, below chance level, we looked for potential response biases in the data. Chi square analyses per speech mode per lexical stress position revealed that in both speech modes, listeners gave a majority of 'interrogative' responses to words with initial stress, whereas equal numbers of either response category were expected (normal speech: 543 out of 1008 'interrogative' responses, $\chi^2(1) = 6.0$, $p = .014$; whisper: 711 out of 1008 'interrogative' responses, $\chi^2(1) = 170$, $p < .001$). In normal conversational speech, statements occur (much) more often than questions [e.g. 18]. As speech perception generally reflects differences in the token frequencies of categories, we expect listeners to respond with the statement category unless there is clear evidence to the contrary. This was not what listeners did. Possibly, listeners interpreted the accent in initial position as prominence in a more general sense that was then associated with an interrogative reading of the utterance as a whole. Alternatively, first-syllable prominence may have been interpreted as a direct cue to a potentially upcoming question, which was not overruled by evidence provided in the relatively weak final syllable. [19] showed that the size of an object accent influenced listener expectations about whether an utterance was a statement or a question: larger object accents triggered stronger question expectation. In the present study, the accent on the first syllable may have similarly signaled a potentially upcoming question, especially when f0 was absent.

For words with lexical stress on the same (i.e. final) syllable as the boundary tone, whispering speakers were able to convey the speech act. In comparison with other studies on boundary tone identification in whisper [2, 3], the task seems to have been relatively more difficult in the present study. The difference may be due to higher demands placed on processing by the two intonational events in close proximity. On the one hand, this is taken to reflect that more complicated linguistic structures, as in the present study, may moderate earlier results on the processing of prosody in whisper (see also [1]). On the other hand, the exclusive use of minimal pairs in the present study may have made listeners aware of the lexical contrast in addition to the speech act difference, also during the boundary tone task, which in turn may have influenced performance.

There was a large difference in the mean reaction times to whispered versus phonated boundary tones. This cannot be explained by the difference in stimulus duration between the speech modes, as this difference was only on the order of 100 ms (693 vs. 583 ms means for whispered and normal speech items, respectively), whereas the reaction time difference was on the order of 400 ms. The slower responses in whisper therefore seem to mainly reflect an increase in processing time due to a difference in cues to boundary tones between the speech modes, including the absence/presence of f0.

Over the same set of stimuli, listeners classified lexical stress position with high accuracy and with similar reaction times in the two speech modes. These results are consistent with the finding that lexical stress position is most reliably realized by durational differences [10], which also form a main cue for listeners [11]. A planned acoustic analysis of the data is expected to reflect the presence of durational information. Moreover, we take the high listener scores to indicate that lexical meaning was generally not influenced by boundary tone realization, in either speech mode.

Words with initial stress pronounced as declaratives were more often identified correctly with respect to stress position than their counterparts with final stress, whereas no difference was found when the same words had been pronounced as interrogatives. Mainly in whisper, responses to interrogatives were around 60 ms faster on words with final stress than on words with initial stress, whereas the average durational difference between the words types was very small (~10 ms). This hints at a small processing benefit for the former type of words, which may be explained by a smaller demand on short term memory for items with final stress.

In sum, depending on the listening task, the same stimuli were responded to very differently. Whispered speech was as clear as normal speech with respect to lexical stress position. For boundary tone perception, however, listeners performed near ceiling in normal speech, whereas the same listeners' performance dropped about 30% in whisper, while processing speed decreased significantly. Accent position furthermore influenced boundary tone perception. Initial-stress words showed a question bias that affected recognition of that speech act. On final-stress words, in which boundary tone and accent coincided, the speech acts were identified comparably.

Abstract

This paper presents a study of the links between punctuation and automatically detected prosodic structures, as observed on large speech corpora that were manually annotated during French speech transcription evaluation campaigns. These corpora contain more than 3 million words and almost 350 thousands punctuation marks. The detection of the prosodic boundaries and of the prosodic structures is based on an automatic approach that integrates little linguistic knowledge and mainly uses the amplitude and the direction of the F0 slopes as described in [1], as well as phone durations. The paper first analyzes the occurrences of the punctuation marks with respect to various sub-corpora, which also highlights the variability among annotators. Then, we focus on analyzing prosodic parameters with respect to the punctuation marks, followed or not by a pause, and on analyzing the links between the automatically detected prosodic structures and the manually annotated punctuation marks.

Index Terms: prosodic structure, speech, punctuation

1. Introduction

Speech is structured by prosodic means to allow the listener to access to lexical units and therefore to the meaning conveyed by the speech signal. For optimal results, most of the automatic speech processing techniques (automatic translation, information retrieval…) need to recover the speech prosodic structuring. This corresponds to adding punctuation marks to the raw streams of words supplied by automatic speech transcription systems. Though orthographic conventions used to capture the speech prosody cannot reflect all the various linguistic and extra-linguistic meanings of the speech prosody, however, they allow to mark its most elementary linguistic functions such as the modality and the finality of a sentence through full stops, exclamation marks, question marks… and through commas the intention of the speaker after a deep prosodic boundary (prosodic group inserted closer to the root than to the leaves in the prosodic tree, cf. Figure 1) to continue to develop the same sentence.

The pattern of the prosodic parameters (mainly F0 movement and syllable duration lengthening) depends on the type of the prosodic boundary. A continuation (major – deeper boundary; or minor – shallower boundary) is indicated by the slope of the F0 movement whose direction can be rising or falling. The end of a declarative sentence is indicated by a falling F0 movement [2],[1] although other (flat or rising) movements are also observed in French spontaneous speech [3]. The modality of the sentence is expressed by the direction and the steepness of the F0 movement: polar (yes-no) questions in French are marked only by a sharply rising F0 slope while an order is marked by a sharply falling F0 slope.

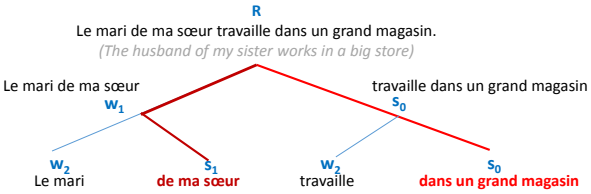

Figure 1: *Metric tree with the deepest prosodic boundaries at nodes s_1 and s_0 (little cohesion to the right)*

In French the syllable duration is closely related to the prosodic boundaries: the duration of a syllable on a continuation prosodic boundary is significantly lengthened compared to the duration of syllables on non-prosodic boundaries. Moreover, the syllable duration, although lengthened on sentence final position, is however shorter than on clause final (major or minor continuation) position [4].

The automatic detection of the prosodic structure used in this study, is based on a theoretical description of prosodic trees; the framework was first developed for prepared speech [1] and later adapted for semi-spontaneous speech [5]. The approach was recently revisited and applied on various types of speech material, including spontaneous speech [6].

In this study, the location of the manually set punctuation marks is compared with prosodic units detected by the automatic approach described in [6]. This comparison allows us observing whether human annotators were or were not influenced by the prosodic parameter values considered as pertinent for the automatic segmentation and also if there is coherence between the location of the punctuation marks and the depth of the prosodic boundaries estimated from their prosodic parameters.

The paper is organized as follows. Section 2 presents the speech corpora used as well as some global statistics about the punctuation marks observed in the manually transcribed data. Section 3 summarizes the process used to obtain automatically the prosodic structures of the speech data. Then, Section 4 analyzes the relations between the punctuation marks and the prosodic parameters, the prosodic groups and the prosodic structures.

2. Speech corpora and punctuation

Several French speech corpora have been used in this study. They come from the recent ESTER2 [7] and ETAPE [8] speech transcription evaluation campaigns, and from the EPAC project [9],[10]. The ESTER2 data are French broadcast news collected from various radio channels; thus mainly prepared speech, plus some interviews. The EPAC data are mainly spontaneous speech, recorded during the ESTER1 campaign, and correspond to shows from three French radios [9]. The ETAPE data corresponds to debates collected from radio and TV channels, and is mainly spontaneous speech. The training part of the ESTER2 and ETAPE data, plus the transcribed part of the EPAC corpus correspond to a total of almost 300 hours of signal and 4 million running words. The development and test parts of the corpora have been left aside for further experiments.

The values of F0 in semitones and of the energy are computed every 10 ms from the speech signal using the ETSI/AURORA [11] acoustic analysis. The phonetic transcription of the text, with pronunciation variants, is obtained using the BDLEX [12] lexicon and an automatic grapheme-to-phoneme transcription system [13] which is applied for words absent from the lexicon. The forced text-speech alignment is carried out with the Sphinx tools [14]. This provides the speech segmentation into phonemes and words, which is then used to compute the sound durations, as well as to obtain the location and the duration of the pauses. As the speech signal quality is rather good, it can be assumed that the segmentation is obtained out without major problems. After the forced alignment step, short pauses of less than 100 ms occurring before a plosive or a fricative are removed. Finally, end of speech events, as well as last word before a speaker change, falls in the columns "plus pause" in the following tables.

Punctuation was present in most of the manual transcription files, which correspond to more than 3 million words (lexical and grammatical words). Table 1 exhibits some global statistics for each of the three corpora. There is on average one punctuation symbol every 8 to 10 words (every 8.3 words for EPAC, every 9.8 words for ETAPE).

Table 1. *Size of the speech corpora used, and number of words and punctuation symbols with respect to position (followed or not by a pause).*

	Files	Words			Punctuation symbols		
		count	plus pause	no pause	count	plus pause	no pause
ESTER	292	2.01 M	18.2%	81.8%	225 k	66.7%	33.3%
EPAC	106	0.92 M	18.5%	81.5%	94 k	50.9%	49.1%
ETAPE	44	0.24 M	20.8%	79.2%	29 k	61.9%	38.1%

With respect to pauses, the three corpora have a similar behavior, on average a pause is observed after every 5 words (about 20% of the words are followed by a pause). However there are more differences for what concern manually set punctuation symbols. About one third of the punctuation symbols are not followed by a pause for the ESTER and ETAPE corpora, whereas this is almost one punctuation symbol out of two which is not followed by a pause in the EPAC corpus. This exhibits a rather large variation in punctuation annotation which is due to annotators as the high frequency of punctuation symbols not followed by a pause in the EPAC corpus does not match neither with the annotations on ESTER (similar radios) nor with the annotations on ETAPE (also mainly spontaneous speech).

Table 2. *Analysis of the various punctuation marks in the three speech corpora.*

	dot	excl.	inter.	3 dots	semi col.	two dots	comma
ESTER	32.9%	1.8%	2.3%	0.8%	1.3%	2.6%	58.3%
EPAC	23.0%	1.6%	4.2%	0.0%	5.9%	5.5%	59.8%
ETAPE	32.0%	2.0%	5.1%	0.5%	0.2%	2.3%	57.9%

Table 2 presents the distribution of the various punctuation marks in the 3 corpora. The frequency of the comma is rather similar between the 3 corpora. However, other punctuation symbols on EPAC exhibit a different behavior, especially with respect to semi-column and two dots marks which are much more used by the annotators of the EPAC corpus than by the annotators of the ESTER and ETAPE corpus.

3. Automatic detection of prosodic structures

As mentioned before, the approach used for the automatic detection of prosodic structures is based mainly on prosodic parameter values and little linguistic knowledge. The process starts by an initial segmentation of the text (i.e., the sequence of words corresponding to the speech signal) into potentially stressed prosodic units. This is carried out by grouping grammatical words with lexical words. Prosodic parameters are then considered only on the vowels of the last syllables of the potentially stressed groups. Two main parameters, the F0 slope and the normalized duration of the vowels in final positions (other than the schwa vowel in final position when the word is plurisyllabic) are used to detect prosodic boundaries. The duration threshold that separates stressed vowels from unstressed vowels was determined from the analysis of the distribution of the duration of vowels in unstressed positions (only syllables other than last syllables of the lexical units were considered for this estimation) and in stressed positions (only syllables followed by a pause were considered for this estimation). A similar approach was applied for determining the threshold that separates the values of the slopes of F0 on prosodic and non-prosodic boundaries. A third parameter, the variation of the F0 value (obtained as the difference in F0 between the current vowel and the previous one not separated from the current vowel by a pause) is also calculated for the last vowel in the prosodic groups. If this variation of the F0 value is higher than 5 semi-tones then a prosodic boundary is set on this syllable.

The automatic approach also evaluates the depth of the prosodic boundaries. A prosodic boundary which is marked by a steep F0 slope (higher than the glissando threshold for speech) and a long vowel duration, or a very long vowel duration and a more moderate F0 slope (higher than the glissando threshold for vowels), receives the symbolic annotation C0. To capture smaller variations of the prosodic parameters, symbolic annotation ranging from C1 (deeper prosodic boundary) to C5 (shallower prosodic boundary) are used. To avoid a too fine-grained prosodic segmentation, prosodic boundaries whose symbolic annotation is C3 and whose length is less than 2 syllables, are neutralized and attached to the following prosodic group. Also, when the prosodic group exceeds 10 syllables, an intermediate prosodic boundary is searched around the middle part of the group

using this time lower threshold values for vowel duration and F0 slope detection. When an appropriate split is found, the prosodic group is cut into 2 groups; otherwise the group regardless of its length is maintained as one single prosodic group. The symbolic annotations (C0, C1, ...) are used to construct prosodic trees for each breath group (speech signal preceeded and followed by a long pause). In the prosodic tree construction, a prosodic group is attached to the next prosodic group if the next group has a lower symbolic depth (i.e. if the next group is closer to the root of the prosodic tree).

4. Prosodic structure and punctuation

This section is dedicated to analyzing in details, on the ESTER training data, the punctuation marks with respect to the prosodic parameters, the prosodic groups and the prosodic structures that were automatically obtained. Besides Table 3, most of the analyzed items are presented as normalized frequency histograms; that means that the figures show the distribution of some parameters (e.g., pause duration, F0 slope …) with respect to the presence or absence of punctuation symbols at the end of prosodic groups. To keep the figures simple, only the dot and the comma punctuation symbols are considered, plus the "*no punctuation*" case, corresponding to end of prosodic groups that are not associated to any punctuation symbol. Moreover, two histograms are drawn in each case, whether a pause follows or not.

4.1. Punctuation and prosodic groups

The first analysis concerns the position of the punctuation marks with respect to the automatically obtained prosodic groups. Table 3 shows that most of the punctuation marks that are followed by a pause (column *plus pause*) match with the end of automatically detected prosodic groups. Moreover, almost two thirds of the punctuation marks that are not followed by a pause also match with the end of prosodic groups. Table 3 shows that, overall, less than 14% of the punctuation marks fall inside the automatically detected prosodic groups. For these cases, if we left aside the few cases were the detection of the prosodic groups is not correct, the annotator's decision was probably influenced more by semantic or syntactic information not marked by prosodic parameters.

Table 3. *Analysis of the various punctuation marks with respect to position (any place or end of automatically detected prosodic groups).*

ESTER		Any place		End prosodic group	
		plus pause	no pause	plus pause	no pause
dot	74154	89.0%	11.0%	89.0%	7.3%
excl.	4026	89.1%	10.9%	88.1%	5.9%
inter.	5163	86.6%	13.4%	86.6%	8.6%
3 dots	1742	84.3%	15.7%	83.5%	9.3%
semi-col.	3018	81.3%	18.7%	80.1%	12.4%
two dots	5969	65.8%	34.2%	63.3%	22.6%
comma	131280	52.1%	47.9%	50.3%	29.7%
Total	*225352*	*66.7%*	*33.3%*	*65.5%*	*20.8%*

For what concerns the length of the prosodic groups, Figure 2 shows that prosodic groups reduced to a single word are almost never followed by a punctuation mark. Prosodic groups followed by a punctuation mark are longer than those not associated to any punctuation mark. Also, the distributions of the length of the prosodic groups followed by a dot or by a comma are very similar. Moreover, the distribution of the length of the prosodic groups is not significantly different whether the prosodic groups are followed by a pause or not.

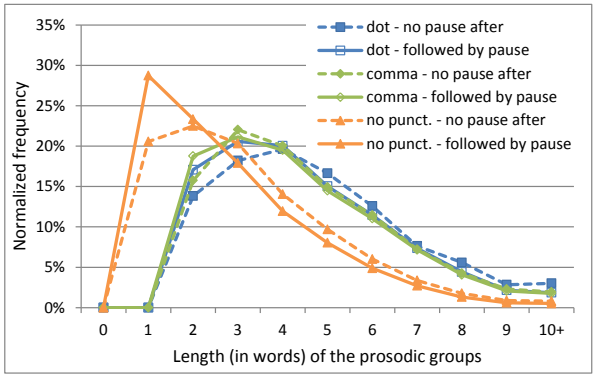

Figure 2: *Normalized frequency histograms of the length of the prosodic groups*

Figure 3 presents the distributions of the pause durations when observed after a prosodic group. When there is no punctuation associated to the prosodic group, the duration of the following pause is most of the time smaller than 200 ms. When a punctuation mark is associated to the prosodic group, the duration of the following pause if typically between 300 ms and 500 ms. Overall, the duration of the pause following a prosodic group tends to be longer for prosodic groups associated to dots than for prosodic groups associated to commas, which are themselves longer than for prosodic groups that are not associated to any punctuation mark.

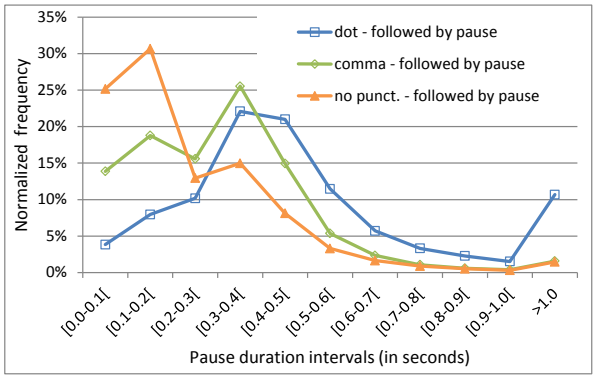

Figure 3: *Normalized frequency histograms of the duration of the pauses after prosodic groups.*

4.2. Punctuation and prosodic parameters

The first prosodic parameter considered here is associated to the global F0 slope, that is the longest F0 slope that ends in the last syllable of the prosodic group. Figure 4 presents the normalized histograms of the absolute variation of F0 (delta F0) between the beginning and the end of the global slope. The delta F0 (Figure 4) and the F0 slope (not represented here) are slightly higher for prosodic groups associated to the dot and comma punctuation marks than for prosodic groups not associated to any punctuation mark. That means that this

parameter is not perceived as pertinent by human annotators for the decision of the punctuation marks.

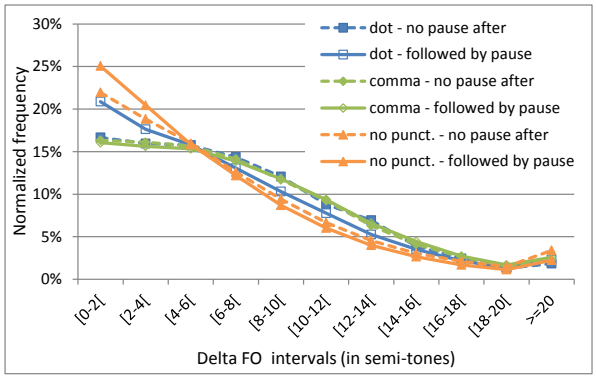

Figure 4: *Normalized frequency histograms of the delta F0 absolute values of the global slope ending in each prosodic group.*

The analysis of the last F0 value on the prosodic groups with respect to the associated punctuation mark is reported in Figure 5. The F0 value was first normalized according to the speaker F0 range, and thus expressed as a percentage of the F0 speaker range (0.0 meaning the lowest F0 value, 1.0 meaning the highest F0 values for the given speaker). It appears from the figure that the highest last F0 values are frequently associated to the comma punctuation mark, intermediate last F0 values are generally not associated to any punctuation mark, whereas dots are associated either to low last F0 values when the prosodic group is followed by a pause or to high last F0 values when there is no following pause.

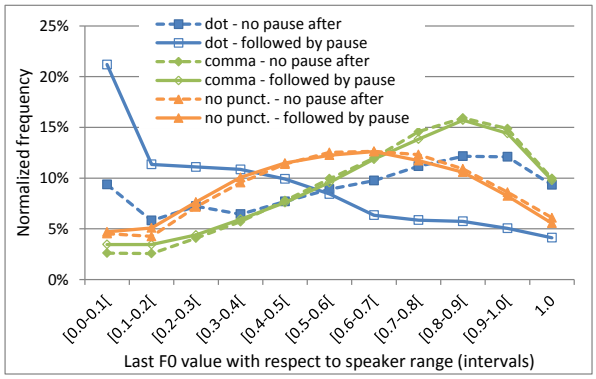

Figure 5: *Normalized frequency histograms of the F0 values at the end of each prosodic group (F0 value expressed as a ratio of the F0 speaker range).*

4.3. Punctuation and prosodic structure

Figure 6 illustrates the relation between the punctuation marks and the level of the prosodic group in the prosodic structures detected automatically. The figure shows that when there is no following pause, the dot and comma are almost always associated to prosodic groups of level 0, i.e., the prosodic group with the deepest boundary in the considered speech segment. However, many prosodic groups of level 0 are also associated to the no punctuation case. When there is no following pause, dot and comma punctuation marks are frequently associated to prosodic groups of level 1. Higher level prosodic groups (level 2 or more) are more frequently observed for the no punctuation case.

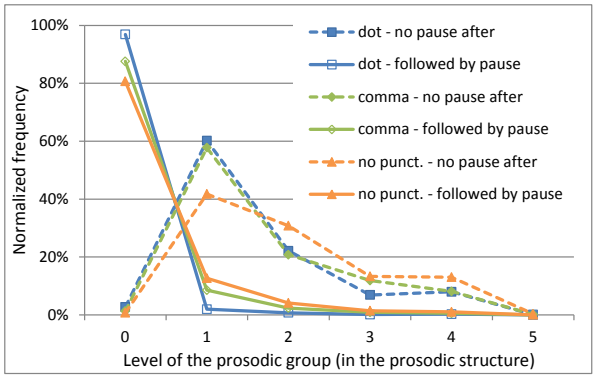

Figure 6: *Normalized frequency histograms of the level of the prosodic group (level in the associated prosodic structure).*

A more detailed analysis shows that for the no punctuation case and for the prosodic groups of level 1, there is a tendency to relate the punctuation symbol to the level of the following prosodic group: a dot if the following group is of level 2 or more, a comma if the following group is also of level 1, and no punctuation if the following group is of level 0.

5. Conclusions

This paper has analyzed the links between the punctuation marks and the prosodic parameters and prosodic structures of the speech data. The analysis was conducted on French speech corpora that were manually transcribed and annotated for speech transcription evaluation campaigns. Several hundred hours of signal were considered. A first statistical analysis of the punctuation marks on several sub corpora showed that the annotation of the punctuation bears a rather large variability due to human annotators.

The prosodic structures of the speech data were obtained automatically through an approach that integrates little linguistic knowledge; the approach mainly relies on the amplitude of the F0 slopes, as well as on phone durations. Most of the manually set punctuation marks match with the end of automatically detected prosodic groups (few punctuation marks fall inside automatically detected prosodic groups).

Prosodic groups, prosodic parameters and prosodic structures were also analyzed with respect to the presence or absence of punctuation marks, whether they are followed or not by a pause. Two punctuation marks were particularly studied: dot and comma. Parameters were analyzed through normalized frequency histograms revealing different behaviors for dot, comma and no punctuation case occurrences.

However, the distribution of the parameters still largely overlap, and each of the prosodic parameters cannot be used alone to decide on the punctuation (if any) that should be associated to the end of a prosodic group. Further studies will investigate the application of automatic classifiers that could handle simultaneously all the parameters for deciding on the presence and on the type of punctuation mark at the end of a prosodic groups.

Perception of Peak Placement in Tashlhiyt Berber

Timo B. Roettger[1], Rachid Ridouane[2] & Martine Grice[1]

Abstract

Previous production studies on Tashlhiyt Berber have demonstrated that questions and statements have similar intonation contours, i.e., a final rise to a F0 peak and subsequent fall. The contours tended to differ in overall pitch register and peak location: questions (a) revealed a stronger tendency to be realized with the F0 peak on the final syllable than statements and (b) even within the same syllable, peaks were often aligned later in questions than in statements. The peak location, however, was reported to vary strongly both within and across speakers, interpreted as free alternation of tonal association. Given this high degree of variation, the question arises as to how relevant this variation is for communication. The present perception study shows that both pitch register (low vs. high) and tonal placement (peak on penultimate vs. final syllable) affect listeners' judgments on sentence modality as well as reaction times. Whereas peak alignment within the syllable (early vs. late) did not affect judgments, it did have a marginal effect on reaction times. By demonstrating their perceptual impact, this study confirms that the patterns found in production are communicatively relevant.

Index Terms: Tashlhiyt Berber, intonation, tonal association, tonal alignment, pitch register

1. Introduction

Berber is an Afro-Asiatic language spoken across large parts of North Africa. Tashlhiyt Berber, the variety investigated here, is one of three major Berber varieties in Morocco.

Recent studies on Tashlhiyt have shown that the intonation of this language involves a high degree of variation both within and across speakers [1,2,3,4]. In particular, it was shown that in polar questions and contrastive statements pitch peaks consistently co-occur with available sonorant nuclei [3,4]. The authors accounted for this placement in terms of a phonological association. More specifically, the tone is analysed as an edge tone, H, of a prosodically defined phrase with a secondary association to a tone bearing unit, a syllable with a sonorant nucleus. However, there was considerable variation with regard to which sonorant nucleus the peak co-occurs with. In fact, speakers showed a certain degree of free alternation: Consider the examples in Figure 1 which demonstrate this apparent free alternation. The same speaker produced the sentence /inːa tugl/ (*'He said 'she held''*), embedded in the same context, with an intonational peak on the final syllable (Top) or on the penultimate syllable (Bottom). Nonetheless, this alternation was not found to be entirely free. Even though there was a strong trend to realize the H on the final syllable in both types of utterances, there were more occurrences of H on the final syllable in questions than in statements. Impressionistically the peak placement goes hand in hand with some degree of segmental prominence, i.e., the syllable the peak co-occurs with is longer and louder than it would be without a peak (compare /u/ and /l/ in /tugl/ of Figure 1 with and without an intonational peak)

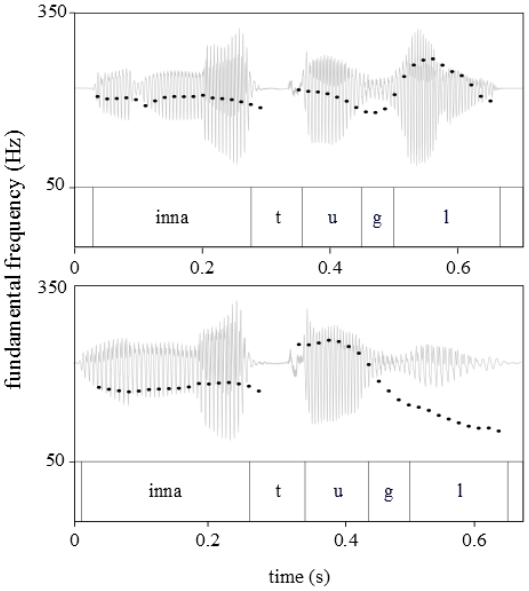

Figure 1: *Waveform and F0 contours of statements /inːa tugl/ (3ms-say 3fs-held) 'He said 'she held'' produced by the same speaker in the same context. Top: Peak placed on final syllable; Bottom: peak placed on penultimate syllable.*

Moreover, this discrete asymmetry, interpreted as phonological association of the H tone, was reflected in more gradual phonetic detail, i.e., the phonetic alignment within the syllable [cf. 4]. Peaks in questions were aligned later in the syllable than in statements. This tendency appeared to be highly speaker dependent. In addition to these differences in peak placement, questions differed from statements in terms of pitch register. Questions were produced with a higher baseline and a concomitant steeper rise to the pitch peak than statements.

The discussed different preferences in questions and statements have to be considered as functionally motivated to distinguish sentence modality. The remaining variability, however, might reflect the redundant nature of peak location in Tashlhiyt. Polar questions are marked by an initial preverb /is/. This morphosyntactic marker could already be sufficient for indicating sentence modality. Tonal cues might thus be redundant to some degree. However, there is also an echo question in this language (inːa tugl? '*He said* '*she held*'*?*'). This type of question is morphosyntactically identical to statements, and differs from statements by intonation only. The present paper reports on a perception study which investigates the contribution of tonal cues to the discriminability of the contrast between statements and echo questions.

On an alternative account, the observed variability could be due to the sample tested in previous studies. The production data of [3,4] was based on Tashlhiyt speakers that have lived in

Paris for a significant amount of time, which might have had an influence on their productions. Thus, the present study attempts to validate the obtained patterns in production (based on speakers living in France) by testing these contours perceptually with Tashlhiyt speakers living in Morocco.

2. The present study

To summarize, polar questions and statements in Tashlhiyt have been mainly shown to differ according to following dimensions:

(a) Questions are more likely to have the peak on the final syllable than statements.
(b) Peaks in questions are aligned later within the syllable than peaks in statements.
(c) Questions reveal a greater pitch register than statements.

The present study investigates the impact of those three factors on the perception of sentence modality.

2.1 Methodology

2.1.1 Speech material

We used stimuli with a resynthesized F0 contour in order to control for pitch register and peak placement. As base stimuli we used four short phrases /inːa baba/, /inːa bibi/, /inːa dimaː/, and /inːa ʁila/ '*3ms-say* ('*father*, *turkey*, *always*, *now*')' produced by a trained native speaker of Tashlhiyt. For each phrase, the speaker produced two contours corresponding to two different tonal associations of the high tone as displayed in Figure 2, resulting in two sets of stimuli. One set (PU) contained a rise to an F0 peak on the prefinal syllable (Figure 2 bottom) and the other set (F) contained the rise and peak on the final syllable (Figure 2 top). As mentioned above, tonal association was accompanied by segmental prominence, i.e., the syllable the peak was co-occurring with was longer and louder (cf. Figure 1-2).

Both sets were resynthesized using PSOLA in Praat [5]. F0 was manipulated resulting in two different pitch register conditions: The *low* register condition started with a baseline of 130 Hz the *high* register condition started 4 semitones higher (~164 Hz).

Generally, F0 was manipulated to start rising at the offset of /inːa/ towards two different F0 maximum locations for each set: In the *early* peak condition F0 reached its maximum at 1/3 of the vowel (penult in set PU and final in set F), in the late peak condition F0 reached its maximum at 2/3 of the vowel. The maximum F0 value was 4 semitones higher than the baseline (~164 Hz and ~206 Hz respectively). After reaching its maximum, F0 fell towards the baseline located at the end of the target word. These manipulations resulted in 32 stimuli (4 target words * 2 tonal associations (penultima vs. final) * 2 peak alignments (early vs. late) * 2 pitch registers (low vs. high)) (cf. Figure 3).

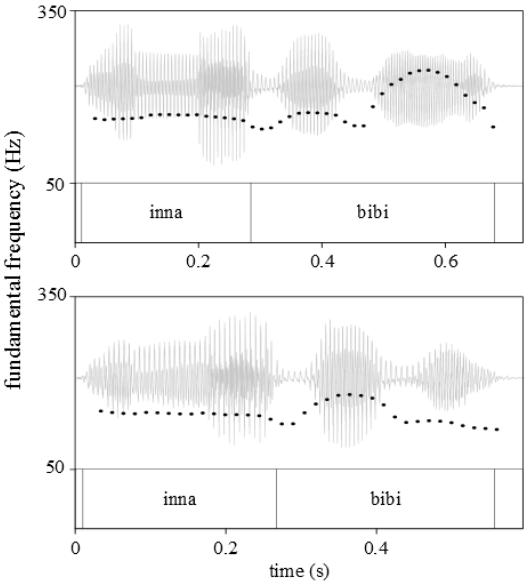

Figure 2: *Waveform and F0 contours of base stimulus productions /inːa bibi/ (3ms-say turkey) 'He said 'turkey'' as an echo question with a peak on the final syllable (Top) and as a statement with a peak on the penultimate syllable (Bottom).*

2.1.2 Participants and procedure

Eight native speakers of Tashlhiyt Berber (average age = 21; 4 men; 4 women) participated in our experiment. All live in Agadir, Morocco, and speak at least Moroccan Arabic and to a lesser extent French. Participants were seated in front of a computer screen in a quiet room at the Ibn Zohr University in Agadir. Participants were told that they were going to listen to a robot which does well in speaking Tashlhiyt, however, struggles with producing the difference between statements and questions.

The experiment was controlled using Superlab [6]. At the beginning of each trial, a fixation stimulus consisting of a '+'

was presented in the centre of the screen for 1500 ms. Following this, the stimulus was presented auditorily. Simultaneously two sentences appeared on the right and left side of the screen. Participants had to press a left or right button on the computer keyboard. On one side the statement was displayed in Latin script in blue (e.g. inna baba !), on the other side the question was displayed in red (e.g. inna baba ?). The position of question vs. statement was kept constant within participants, but was counterbalanced across participants. After response delivery, a blank screen appeared for 500 ms.

2.1.3 Analyses

All data were analyzed with generalized linear mixed models, using R [7] and the package *lme4* [8]. To analyze responses categorically, we used mixed logistic regression models with "RATING" (question or statement) as the dependent measure. As fixed effects we included TONAL ASSOCIATION (PU vs. F), PEAK ALIGNMENT (early vs. late), PITCH REGISTER (low vs. high), in addition to TARGET WORD and mean-centered REPETITION. To analyze reaction times (RTs, measured from the offset of the audio stimulus), we used models with Gaussian error distribution with RTs as dependent variable. As fixed effects we included the two-way interactions of RATING and TONAL ASSOCIATION, RATING and PEAK ALIGNMENT, and RATING and PITCH REGISTER, in addition to TARGET WORD and mean-centered REPETITION. For both analyses, we included a term for random intercepts for speakers as well as correlated random slopes for the fixed effects TONAL ASSOCIATION, PEAK ALIGNMENT and PITCH REGISTER (and RATING). For both dependent variables, we tested whether the inclusion of any of the fixed effects did improve the models prediction significantly via likelihood ratio tests.

3. Results and Discussion

Rating: Figure 4 depicts the rating results according to the factors TONAL ASSOCIATION, PEAK ALIGNMENT and PITCH REGISTER. Overall, participants rated the stimuli to correspond to questions in 43% of the cases. There was a significant effect of TONAL ASSOCIATION ($\chi^2(1)=8.66$, $p=0.003$) such that items with the peak on the final syllable were significantly more often rated as a question than statements (61% vs. 25%). There was a significant effect of PITCH REGISTER ($\chi^2(1)=9.14$, $p=0.003$), as well, such that items with a high pitch register were significantly more often rated as a question (58% vs. 28%). PEAK ALIGNMENT did not have a significant effect on responses. Early peaks were rated to correspond to questions comparably as often as late peaks (44% vs. 41%) ($\chi^2(1)= 1.18$, $p=0.28$). As can be seen in Figure 4, there was no apparent interaction of TONAL ASSOCIATION and PITCH REGISTER. Those effects rather add up, with a final peak in a high register being the most preferred question type, and a prefinal peak in a low register being the least preferred question type. However, there appears to be no clear cut. Even the least preferred intonational pattern for questions (low register and peak on PU) shows a considerable amount of question ratings (14%).

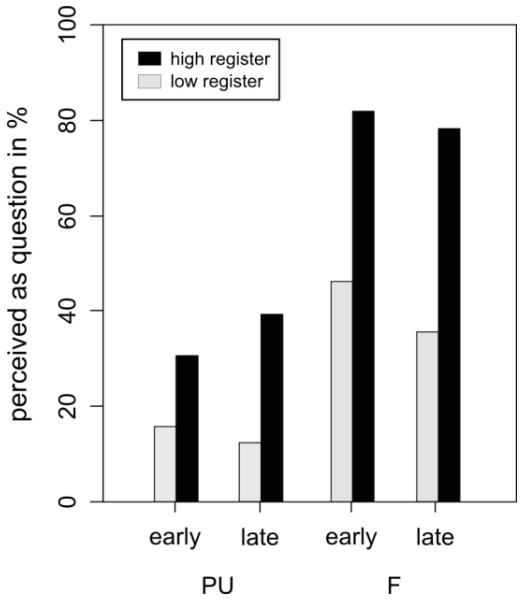

Figure 4: *Ratings as a function of tonal association (PU vs. F), peak alignment (early vs. late) and pitch register (low vs. high).*

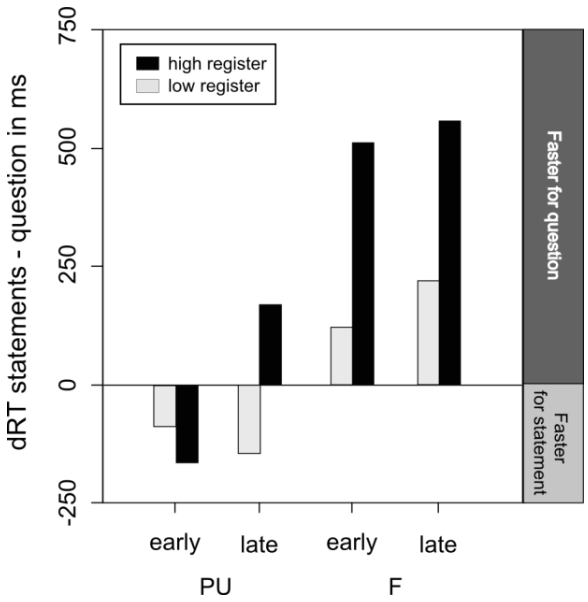

Figure 5: *Differences in response latency between statement and question as a function of tonal association (PU vs. F), peak alignment (early vs. late) and pitch register (low vs. high). Positive values indicate faster responses for questions; negative values indicate faster responses for statements. dRT = 0 indicates no RT difference between statement and question rating.*

RTs: Figure 5 depicts the RT results according to the factors TONAL ASSOCIATION, PEAK ALIGNMENT and PITCH REGISTER. There was a significant interaction of RATING and TONAL ASSOCIATION ($\chi^2(1)=13.49$, $p=0.002$) such that items with the peak on the final syllable were responded to faster when rated as a question (307 ms), while items with the peak on the

penultimate syllable were responded to faster when rated as a statement (123 ms). There was a significant interaction of rating and pitch register ($\chi^2(1)=19.72$, $p<0.0001$), as well, such that there was a greater response latency advantage for questions when stimuli were in a high register (305 ms) as opposed to low register (47 ms). Thus the RT analyses reflect the general finding that both a higher pitch register and a peak on the final syllable are preferred properties of questions. Despite the absence of an effect of PEAK ALIGNMENT on RATING, we find a marginally significant interaction of RATING and PEAK ALIGNMENT for RTs ($\chi^2(1)=2.86$, $p=0.09$), such that there was a greater response latency advantage for questions when stimuli had late peaks (191 ms) as opposed to early peaks (91 ms) (cf. Figure 5).

To sum up, we were able to identify two main factors influencing the perception of the distinction between statements and questions. First, contours with H tones associated to the final syllable are perceived more frequently and faster as questions than H tones associated to the penultimate syllable. However, even contours with a peak on the penultimate syllable appear to be acceptable for questions. Second, contours in a high pitch register are perceived more frequently and faster as questions than contours in a low register. The evidence for peak alignment within each syllable is somewhat weaker. While there was no significant rating asymmetry between early and late peaks, response latencies indicate that late peaks are processed faster when rated as a question (marginally significant). These findings are comparable to results from production, in which [3,4] found some degree of free alternation of tonal association of H tones in polar questions and statements, although questions had a stronger tendency to be realized with a high tone on the final syllable than statements. They further report on later peaks in questions in terms of where the peak is located within the syllable it co-occurs with. Finally, based on impressionistic observations, they report on higher pitch register in questions.

4. General Discussion

The most important contribution of the present study is that Tashlhiyt speakers not only exhibit free alternation of H tone association in production, but are also tolerant with regard to peak placement in perception. For example in questions, there is a probabilistic trend for the peak to be placed on the final syllable, nonetheless, speakers not only produce peaks on the penultimate syllable but also accept those as questions in perception.

We conclude that this variability in locating the tone is free alternation of tonal association. While there have been reports on free alternation of word prominence for Indonesian [9], free alternation in higher prosodic domains are so far unattested. Even though such an alternation of tonal association has not been reported yet, there is some degree of alternation in a number of languages, depending on the properties of syllables at or near the phrase edge. For instance, in Standard Greek, there is secondary association to a lexical stressed syllable if there is one available, otherwise the edge tone is associated with the final syllable [10,11].

We have also observed a preference to place the peak as far to the right as possible. The general preference for late peaks in questions (in terms of both association and alignment), i.e., a rise in pitch, is common across languages [12]. Moreover, several studies showed that speakers use pitch peak alignment to disambiguate sentence types. For example, [13] showed that peak alignment plays a role in disambiguating Hungarian statements and polar questions, whereby an early pitch peak (in the accented vowel) is associated with declaratives and a late peak with interrogatives (see also [14], for Neapolitan Italian; [15], for Swedish; and [16], for Russian). As mentioned above, pitch peaks in Tashlhiyt questions have been observed to exhibit a concomitant steeper rise than in statements. Thus, in production, peak alignment differences could be an artifact of reaching a higher peak. It is well known that a higher peak can perceptually have the same effect as peak delay [14,15,17]. The present study indicate that Tashlhiyt listeners might be sensitive to peak delay irrespective of peak height (although only for RTs).

The remaining variability found in both production and perception, might reflect the redundant nature of peak location in Tashlhiyt. Global pitch cues such as pitch register could already be sufficient for marking sentence modality. The actual peak location phrase finally is thus one of a number of cues and redundant to some degree.

It is important to stress, that while earlier reports on Tashlhiyt intonation [1,3,4] were based on Tashlhiyt speakers living in Paris. The present study recruited subjects that have lived in Morocco for all their lives. We were thus able to confirm the observed patterns in production making it unlikely that they are merely due to interference. Thus, this study not only reveals information about the perception of tonal cues in Tashlhiyt for the first time, it is also a first validation of obtained patterns in production.

5. Acknowledgements

We would like to thank all members of the faculty of Amazigh studies and the dean of the humanities Ahmed Sabir from the Ibn Zohr University in Agadir for their support. We are grateful for all subjects that patiently participated in this experiment. We also thank three anonymous reviewers for their valuable comments. This research was funded by the Volkswagen Stiftung (Project: *Tonal Placement - the Interaction of Qualitative and Quantitative Factors*: *ToPIQQ*).

The meaning of French "implication" contour in conversation

Cristel Portes [1], *Uwe Reyle* [1, 2]

Abstract

French intonational contours inventory have a rising-falling tune which presents very interesting semantic properties. It has been called "intonation d'implication" by Delattre [1] suggesting that the contour triggers an implicit meaning, i.e. an implicature in Gricean terms. Besides, the "implication" contour have been claimed to convey various attitudinal meanings from obviousness to exasperation, and also to mark contrastive focus. The aim of the present paper is to give a unified account of these seemingly differing semantic descriptions of the "implication" contour in French, using a dynamic semantic framework, namely Discourse Representation Theory (DRT). We claim that the main semantic component of the "implication" contour is to convey a contradiction (or a contrast). We first present our DRT-theoretical approach, and then apply it to occurrences of the "implication" contour in a corpus of conversational dialogue.

Index Terms: intonation, intonational meaning, "implication" contour, semantics, Discourse Representation Theory, dialogue, conversation, French

1. Introduction

The rising-falling contour called "intonation d'implication" (implication contour) by Delattre [1] is one of the tunes in French that has been attributed a whole range of different kinds of meaning. Delattre himself proposed that the meaning of the contour is to link the meaning of the actual utterance to an implicit content which must be recovered from the context: it may convey various meanings such as obviousness, exasperation or, on the contrary, politeness. Another role attributed to French "implication" is related to a high degree of expressivity or emphasis. For instance Rossi called it "expressème" ([2], [3]) and Di Cristo & Hirst [4] spoke about "emphase contrastive" (contrastive emphasis). This latter proposal refers to another meaning that has been attributed to the contour, i.e. contrast. A related idea expressed in more semantic terms is found in Mertens' and in Ladd's more recent proposals ([5], [6]) where the contour is said to convey speaker commitment. These approaches give very detailed and rich accounts of the phonetics and phonological aspects of the "implication contour" in French. However, its semantic aspects are mostly presented in broad attitudinal terms, which do not account for the dialogical dimension of its meaning.

On the other hand, the semantic literature gives more and more attention to both dialogue and intonation. For instance, working in a semantic framework developed by Ginzburg [7], Beyssade & Marandin [8] proposed that intonational meaning relies crucially on the attribution of attitudes to the addressee. For Gunlogson [9], rising intonation in declarative questions expresses the speaker commitment to a proposition but, at the same time, marks it as contingent on ratification by the addressee. Very recently, Groenendijk & Roelofsen [10] have proposed an "inquisitive" semantic framework where assertions bear inquisitive contents that are inviting responses from other participants. Using this framework, Westera [11] claimed that final rises in English signal that a conversational maxim is violated. And Portes & Reyle [12] followed Krifka's proposal [13] to interpret speech acts by development of spaces of commitments assigned to the discourse participants, in order to explain the meaning of four contours of French inventory.

Convoking both phonological and semantic literature, the present paper aims at showing that French "implication" contour conveys a complex meaning whose different dimensions can be accounted for in a dynamic semantic approach modeling dialogue. After a brief exposal on the phonology of the contour in section 2, section 3 develops a semantic account of its meaning using Discourse Representation Theory (DRT). Then, section 4 verifies the reliability of the proposed unified meaning in a corpus of conversational data, before section 5 concludes.

2. The phonology and phonetics of French "implication" contour

The "implication" contour is not the only rising-falling movement of French intonational inventory. It is sometimes (but must not be) mixed up with a rise-fall the high f0 target of which is localized on the *penultimate* syllable of the accentual phrase (AP: the basic constituent of French phrasing), while it occurs on the *final* (full) syllable for the "implication" contour. The present section gives a brief account of what must be known about the phonology and phonetics of the contour under investigation here.

The clearest account of the phonological contrast and the phonetic implementation of the "implication" rise-fall has been given by Post ([14], [15]). Phonologically, she distinguished this contour from the fall from penultimate contour by attributing two different pitch accents to them. Hence, the former is coded LH*L% with a monotonal H* pitch accent while the latter is coded LH+H*L% with a bitonal H+H* pitch accent.

Phonetically, the "implication" contour LH*L% is said to be implemented with a global difference in temporal alignment compared to the rise LH*H%, the H target of which also occurs on the last syllable of the AP. The alignment of LH*L% is earlier both for its initial L target and for its H* target as shown in Figure 1 and 2 below. This regular phonetic difference has been confirmed by quantitative measures in a large corpus study on naturally occurring data carried out by Portes [16].

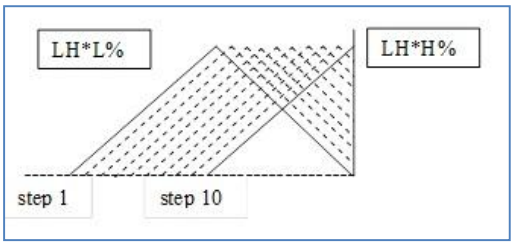

Figure 1: *Design of the ten step alignment continuum between the "implication" contour LH*L% and the rising contour LH*H% used by Post in a categorical perception experiment. The temporal alignment of both the first L and the H* targets are delayed from step 1 to 10.*

Another important aspect of the "implication" contour is that it can occur at the end of an intonational phrase (IP) but also at the end of an intermediate phrase (ip). In this case the final low boundary tone L% may be preceded by a low phrasal tone L- triggered by a narrow focus occurring on a non final constituent, as proposed by Jun & Fougeron [17]. This L- phrasal tone spreads until the end of the IP up to the L%, triggering deaccentuation on the material following the narrow focus constituent, at least when it is marked as background information by the speaker. Figure 2 depicts a corpus example of such a use of the "implication" contour borrowed from Bigi and colleagues [18].

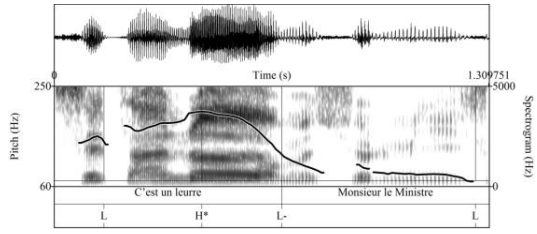

Figure 2: *A corpus example of an ip-final "implication" contour resulting in a LH*L-L%. The background part of the utterance, which is also syntactically right detached, is deaccented through the spreading of the phrasal tone L-. The text is "C'est un leurre, Monsieur le Ministre" (This is an illusion, Minister).*

3. A DRT account of the meaning of the French "implication" contour

We now come back to the meaning of the "implication" contour. In the semantics of French intonation proposed by Beyssade and Marandin [8], this tune belongs to a group of "non falling contours" which are appropriate in what they call a "defective" context (following Stalnaker [19]), namely a context where the assumed beliefs of speaker and addressee are not compatible. More recently, Portes and Beyssade [20] proposed a compositional account of the meaning of French intonation where the "implication" contour is said to convey disagreement. The data in (1) confirm this claim. The contours are depicted with the following codes: F for the simple fall and IRF for the "implication" rise-fall.

(1) a. L1: *Dans cette ville, il n'y a de restaurants que pour les carnivores.* F

In this town, there are restaurants only for carnivores.

b. L2: *Non, il y a un restaurant végétarien* F

No, there is a vegetarian restaurant.

c. L2: *Il y a un restaurant végétarien* IRF

There is a vegetarian restaurant.

Consider the declarative in (1b). Its content q contradicts the assertion p made by L1 in (1a) (with a falling contour). It has been stressed by several authors (cf. Lascarides and Asher [21]) that disagreement should be made explicit, whereas undenied commitments persist in dialogue. For that reason, L2 explicitly rejects p by the preceding "no" in case she wants to use the simple fall F, as in (1b). But (1c) shows that L2 has other means to mark the rejection, and hence to react negatively on the expectation to add p to the common ground (CG), namely by her use of the "implication" contour IRF. This shows that the use of the "implication" contour in (1c) conveys the rejection of p just as the explicit "no" does in (1b).

Conversely, the "implication" contour IRF is not appropriate in (2b) below contrary to the simple fall F. This is because, in this case, there is no contradiction between p (the content of (2a) which is equivalent of that of (1a)) and r, the content of (2b).

(2) a. L1: *Dans cette ville, il n'y a de restaurants que pour les carnivores.* F

In this town, there are restaurants only for carnivores.

b. L2: *Il n'y a pas de restaurant végétarien* F but #IRF

There is no vegetarian restaurant.

Examples (1) and (2) suggest that the "implication" contour expresses a *contradiction*, or more generally a *contrast*. We claim that the implication contour *presupposes*[1] such a contrast and that the different meanings of the contour can be explained on the basis of how this presupposition is resolved in the context of the dialogue. The main ingredients of the explanation are:

(i) Following [22] we assume that the defining criterion for "contrast" is the awareness of a manageable set of alternatives; the set of alternatives is given by the context.

(ii) Implicit Questions under Discussion (QUDs) are present at any stage of the discourse ([22], [23], [7]).

(iii) The interpretation of the implication contour presupposes a contrast, i.e. a set of alternatives to be identified with a contextually given QUD. The particular meaning of the contour then follows from the information that has brought about this QUD at the first place.

To make this more precise, consider (1). L1's statement involves the focus-sensitive operator "il n'y a que" (only). In the framework of an alternative semantics for focus ([24]) such an operator requires a set of alternatives, e.g. "What kinds of restaurants are there in Aix", which can be considered as the QUD to which L1 tries to give an answer by his asserting (1a). The meaning of "il n'y a que" implies that the QUD is fully answered, i.e. all alternatives except p are

[1] A presupposition is a condition associated with a sentence or utterance which must be fulfilled in the context in which the utterance occurs (or the sentence is used) in order that this sentence or utterance succeeds in determining a well-defined proposition.

excluded. If we assume that there are three types of restaurants, non-vegetarians (p), vegetarians (q) and vegans (r), that are relevant in the discussion of L1 and L2, we have before L1's uttering (1a) the QUD = {p,q,r}. With his utterance (1a), L1 proposes a complete answer to L2, i.e. a fully resolved QUD = {p}, as shown in the final line of the following diagram.

utterance	presupposition	QUD
		{p, q, r}
p (= (1.a))		
		{p}

According to our assumption the implication contour on (1c) triggers the presupposition that there must be a contrast, given by a contextually relevant set of alternatives to q. In the context of (1) we may assume that the alternatives are {p,q,r} again. But if we look at the utterance (1c) in isolation, this contrast is underspecified. The only thing we know is, that there are alternatives to q, i.e. the contrast has the form {q}∪C, where C is a non-empty, contextually determined set of alternatives to q. In our example (1), C will be identified with {p,r}. As each assertion requires acknowledgment of the hearer, L2 has to signal disagreement with (1a) if she wants to object. Suppose she agreed and uttered (1c) with the "implication" contour nevertheless. Then the presupposition that there is a QUD = {q}∪C cannot be resolved, because the current QUD consists of the singleton set {p} only, but the presupposition requires a non-singleton set containing q. This explains why uttering (1c) with a fall F (L*L%) is not appropriate. In case L2 doesn't agree with (1a), she may signal her objection with a pure "no", as in (1b). The effect of the rejection is that the original QUD remains active. We take the felicitousness of (1c) with the implication contour as another possibility to express disagreement with (1a). So, once (1a) is rejected by the implication contour, the original QUD is still accessible and the presupposition triggered by the contour can be resolved to {p,q,r}. At the same time, L2 claims to resolve the QUD by his assertion of ¬p[1].

...	...	...
q (= (1.c))	{q}∪C	{p, q, r}
	C = {p,r}	{q}

The dialogue (3), taken from the CID-corpus, has the same structure as (1). The situation and the interpretation of the implication contour is, however, different, because YM's assertion only partially settles the original QUD, i.e. the implicit question of "what there is, that they have at their windows".

(3) YM : *il y a il y a pas de volets quoi*

There are there are no shutters

AG : *ah oui ils y ont des rideaux* IRF *hein*

Ah yes they have curtains havn't they

Let us assume, that there are shutters (p), curtains (q), or nothing at all (r) at the windows, i.e. the implicit question that YM answers with his assertion is QUD = {p,q,r}. Then his utterance only partially resolves this issue, YM only excludes possibility p and leaves the remaining options for further discussion.

utterance	presupposition	QUD
		{p, q, r}
¬p (= YM)		
		{q, r}
q (= AG)	{q}∪C	
	C = {r}	{q}

AG accepts YM's proposal by his *ah oui*. Nevertheless he uses the "implication" contour for his utterance of *ils ont des rideaux*. But this time the presupposition of the contour can be resolved, because the original QUD is not restricted to a singleton, but to {q, r}. AG's assertion is not contradictory to YM's assertion. It tries to settle the original QUD raised but not completely resolved by YM. And this is why – to the extend of AG accepting YM as authority wrt. the original QUD – AG's assertion is understood as a confirmation request.

Our claim is that even cases of confirmation request, information retrieval, exclamation or politeness can be argued to be derived from the general unified meaning we proposed. The politeness effect in (4) is easy to explain on the basis of our contrast-based analysis.

(4) Context: the speaker, while opening a door, says to the hearer:

Après-vous IRF, *cher Monsieur* (deaccented)

After you, Sir

The speaker asserts that he will go after the hearer (p) and, by mean of the contour, contrasts his assertion with the proposition q to go first. Politeness follows as conventional implicature (suggesting that the speaker would never q, i.e. go first). But note, that q need not be uttered (or even thought) by the hearer.

4. A corpus based evaluation

In order to evaluate our semantic proposal of the meaning of the "implication" contour on conversational data, we carried out an analysis of all the occurrences of the contour in a one hour dialogue extracted from the CID corpus [26]. In this corpus, two male speakers, AG and YM, well-knowing each other, were gathered in an anechoic room and fitted out with individual microphones in order to be recorded on separated

[1] In [25], we gave a formal analysis of the meaning of the implication contour that corresponds to the rejection and contradiction case of (1). We assumed that the use of the contour in an utterance of p triggers a presupposition that is more specified than the one we assume in this paper, because the contradiction that explains this particular meaning of the contour is already built in the presupposition itself. This implies that the contour is considered ambiguous between the particular meaning we investigated and the other meanings described in the literature. This paper starts from the assumption that the implication contour is not ambiguous, but underspecified and receives its final meaning by specification in context.

tracks. They were requested to talk freely about unusual events that have happened to them.

Thanks to the hearing and visual inspection of the sound tracks using Praat [27] carried out by the first author of the present paper, 167 occurrences of the "implication" contour were found. 62 were produced by speaker AG and 105 by speaker YM.

We classified the occurrences into 12 different types of situations depending on different uses of the contour. Table 1 below shows the number of occurrences for each type of situation by speaker. The lines in italic correspond to uses for which the meaning is clearly *defective* (i.e. involves a *contradiction* or a *contrast*), what we have described as the crucial dimension of the contour's meaning.

Type of situation	**AG**	**YM**
Contradiction	*3*	*12*
Correction	*7*	
Auto-correction	*5*	*6*
Disagreement, protest	*2*	*9*
contrast	*16*	*33*
paradox	*2*	*3*
"Je sais pas" (I don't know)	*1*	*7*
Adressee's incredulity	*10*	
Confirmation request	4	3
Information retrieval	1	3
Exclamation (emphasis)	3+1	8+9
obviousness	7	12
TOTAL	**62**	**105**

Table 1. *Number of occurrences of the "implication" rise-fall for each type of situation by speaker.*

These contradictory/contrastive items can be said to confirm the meaning proposed in section 2 above, especially by involving a contradiction between a proposition p and its negation ¬p, even if it is sometimes indirectly, i.e. p is not the actual content of the utterance, or by involving a contrast between two incompatible referents or situations. Table 2 gives the proportions of the contradictory/contrastive occurrences versus the other occurrences by speaker. It shows that for both speakers, 70% of the occurrences of the "implication" contour are used in situations and with meanings that confirm our semantic proposal.

Type of situation	**AG**	**YM**
defective	74%	67%
others	26%	33%

Table 2. *Proportions of the defective occurrences of the "implication" rise-fall versus the other occurrences by speaker.*

Here are some examples extracted from the dialogue under study that will make the claim more explicit.

(5) AG : *non* IRF *ça se voyait peut-être je me rappelle plus trop mais je crois pas que ça se voyait* IRF

No perhaps it was visible I don't remember well but I don't think it was visible

Example (5) illustrates a direct contradiction where the speaker AG explicitly negates his addressee's proposition.

(6) AG: *c'est des châtaignes* IRF *ben bien sûr* IRF *ouais il y a que ça* IRF *qui est comestible*

That's chestnut of course yeah only this is good to eat

In (6), the first contour contrasts with anybody's (except the speaker's) potential assumption that it's not des *chataîgnes*, but des *marrons*, the second expresses obviousness (as shown by the words), and the third reinforces the contrast already expressed by the first. Here, the disagreement is not with the addressee, but with a general opinion. The contour on *bien sûr* (of course), shows that even the obviousness use indeed refers to a potential or actual disagreement.

The case of the expression *Je sais pas* (I don't know) is more difficult to explain but also very regular in the corpus. It is used idiomatically with the "implication" contour, once by AG but 7 times by YM, in order to refute in advance the implicit request by the addressee of certified information due to Grice's cooperation principle [28]. Hence, these systematically implicate "I should know" (i.e. ¬p). Example (7) illustrates this case.

(7) *et c'était des glaces y avait je sais pas* IRF quinze litres de glace

And that was ice cream there were I don't' know fifteen liters of ice cream

Even cases of confirmation request, information retrieval and exclamation can be argued to be derived from the general unified meaning we proposed. Confirmation requests involve an issue {p, ¬p} and a commitment of the speaker towards p. Information retrieval examples refer to the presence versus absence of the relevant information. Finally, exclamative or emphatic items rhetorically refer to the incredibility of the information. In all three cases, a potential alternative ¬p is implicated.

5. Conclusion

In this paper, a unified and detailed meaning is proposed for French "implication" contour. This meaning centrally relies on an underspecified presupposition of contrast. The interpretative task of justifying this presupposition in context explains why the contour appears disguised in different kinds of meanings, labeled by other authors as obviousness, exasperation, politeness, emphasis, confirmation request, information retrieval, etc. This unified meaning reliably explains most of the uses of the contour in a spontaneous dialogue extracted from the CID corpus. These results give important support to two important theoretical issues: i) meaning (and especially intonational meaning) contains "inquisitive" components ([8], [10]), and ii) Gussenhoven's "linguistic normalcy" view, that intonational contours have meaning on their own [29].

Abstract

In this paper we present some experiments on multiclass ToBI pitch accent classification. The system is based on the fusion of pairwise classifiers, which are specialized in the distinction of pairs of prosodic labels. Several machine learning techniques, including neural networks, decision trees and support vector machines, are combined in different ways in order to find the best overall combination. Variations of pairwise classifiers are introduced in order to take into account the influence of the samples of the remaining classes during the training of the binary classifiers. The use of these techniques allowed us to improve the results, both the overall classification accuracy and the balance across the different ToBI pitch accent classes.

Index Terms: automatic prosodic labeling, ToBI, classifier combination, pairwise classifiers

1. Introduction

Automatic multiclass pitch accent classification remains a challenging problem in computational prosody. There is a high perceptual similarity between some ToBI labels and some classes are more difficult to identify than others. On the other hand, some prosodic events are more frequent than others, which causes the corpora used in experiments to be clearly imbalanced, and, therefore, the classification performance is negatively affected.

In our previous work we reported a classification strategy based on pairwise classifiers which provided good performance [1]. Pairwise classifiers are specialized in the distinction of the prosodic labels in pairs. Basically, the multiclass classification problem is divided into a set of binary classification subproblems. The distinction of classes in pairs is an easier problem than the distinction between multiple classes and the combination of binary decisions provides improved classification results [2, 3].

In this paper we evaluate two variations of the pairwise strategy: *training with remaining classes* and *correcting classifiers* (to be described in sections 3.3.1 and 3.3.2 respectively). These variations try to avoid the problem that a binary classifier trained to distinguish between two particular classes l and m, might provide unreliable estimations for instances which belong neither to class l nor to class m. We experimented with the fusion of different configurations of the pairwise classifiers based on these variations and on different types of classifiers: neural networks, decision trees and support vector machines. Different types of classifiers appear to behave differently when they attempt to discriminate different classes and their outputs can be complementary.

The use of these machine learning techniques for prosody recognition allowed us to improve the results in multiclass pitch accent classification. As a conclusion, it is difficult to improve at the same time the total classification accuracy and the accuracy rate of each individual class. Thus, we selected two different configurations of the final system: one which improves the total classification accuracy and one which provides more balanced rates among all the prosodic classes.

The structure of the paper is as follows. First, we review the state of the art on automatic prosodic labeling. Then, the classification procedure and the experimental setup are described. Finally, we analyze the results and present some conclusions.

2. State of the art

Automatic detection and classification of ToBI events have been performed using different machine learning techniques: decision trees [1, 4, 5, 6, 7, 8, 9], Markov models [4, 10, 11], maximum entropy models [12], neural networks [1, 7, 8, 13, 14], GMM [13, 15, 16, 17], n-grams [10, 13, 18], Bayesian networks [19], conditional random fields [7, 8] and support vector machines [7, 8, 9, 14]. In most of those works, a combination of these techniques was used.

A common finding of previous work is that accuracy rates are highly dependent on the task: the identification of boundary tones and breaks is easier than the identification of pitch accents. Besides, the results were significantly better in prosodic event detection than in classification. The most efficient classifiers use morpho-syntactic features in conjunction with prosodic acoustic features (F0, intensity and duration) and their temporal evolution. Accuracy rates over 90% are reported in the detection of pitch accents [8]. Nevertheless, accuracy rates in classification are lower, 70.8% in [1], showing a high dependence on the number of classes and speakers, as shown in table 1. Although results can be improved by reducing the number of classes, we decided to keep the original set of classes in this work, since they convey linguistic meaning as defined in the standard [20], which should be preserved.

3. Classification method

In this section we describe the classification procedure used in the experiments, which is an evolution of the system presented in [1]. First we describe the strategy of multiple classifier combination and the base classifiers used in the experiments. Then, two variations of pairwise classification are explained. Finally, we present the experimental setup.

3.1. Multiple classifier combination

The pairwise coupled approach basically divides a given multiclass classification problem into a number of binary classification subproblems, whose results must be combined to obtain the final classification result [2, 3]. According to this approach, let us refer by $\hat{P}(l|x,\lambda^k_{l,m})$ to an estimation of the probability $P(y = l|x, \quad y = l \vee m)$, where l and m are two different prosodic labels; x is the input of the classifier (in our case, the prosodic features); y is the class label; and $\lambda^k_{l,m}$ is a pairwise classifier of type k that is trained to separate classes l and m (neural network, $k = 1$; decision tree, $k = 2$; support vector machine, $k = 3$).

From these estimators, we build $\hat{P}(l|x,\lambda^k)$, which is obtained with classifiers of type k by:

$$\hat{P}(l|x,\lambda^k) = \prod_{\substack{m=1..C \\ l\neq m}} \hat{P}(l|x,\lambda^k_{l,m}) \quad (1)$$

where C is the number of classes, or prosodic labels.

Then, the results of K different types of classifiers are combined, so that the final estimation of $P(l|x)$, $\hat{P}(l|x)$, is computed as follows:

$$\hat{P}(l|x) = \prod_{k=1..K} \hat{P}(l|x,\lambda^k) \quad (2)$$

For each classifier type, there are as many classifiers as there are combinations of pairs of C classes: $\frac{C\cdot(C-1)}{2}$. Each classifier, $\lambda^k_{l,m}$, provides the posterior probability estimates $\hat{P}(l|x,\lambda^k_{l,m})$ and $\hat{P}(m|x,\lambda^k_{l,m})$.

Since the labeling of a given word depends on the context in which the word has been uttered, we introduce language model dependence. Experiments reported in [4, 13, 23] showed an improvement in results when a model of the sequence of labels was used. A detailed description of the process can be found in [1, 4, 13]. To search for the most likely prosodic label sequence, we applied the Viterbi algorithm [24]. The SRILM toolkit was used to build trigram prosodic language models [25], with Katz backoff for smoothing. The training data was used to build these models.

3.2. Base classifiers

We used three different types of classifiers in this work: decision trees (DT), neural networks (NN) and support vector machines (SVM). The reason for using different types of classifiers is that different classifiers behave differently on the discrimination of prosodic labels [1, 26].

A multilayer perceptron (MLP) was used, trained by means of the standard Error Backpropagation learning algorithm. Nonlinear sigmoid units were used in the hidden and output layers. A single hidden layer was used and a total of 100 training epochs. In the output layer we used as many units as classes, one per each class to classify. The POS feature was transformed into quantitative values by using a binary coding of the 33 values, using 6 bits. Normalization techniques were applied, using Z-Norm normalization across the same speaker.

The Weka toolkit [27] was used to build C4.5 decision trees (J48 in Weka). Different values for the confidence threshold for pruning have been tested, although the best results were obtained with the default value (0.25). The minimum number of instances per leaf was also set to the default value (2). This classifier was trained with qualitative POS features and unnormalized data. To obtain better class probability estimates, we turned off pruning, turned off *collapsing* and calculated class probabilities with the Laplace correction, as described in [28].

We used the Weka machine learning toolkit [27] implementation of the support vector machines. We tested different kernels and selected the polynomial kernel. To obtain probability estimates, logistic regression models were used at the output of the support vector machine. This classifier was trained with qualitative POS features and unnormalized data.

3.3. Variations of pairwise classification

In the canonical pairwise classification scheme, each pairwise classifier is trained to distinguish between two particular classes l and m. Then, only samples of this two classes are used in the learning stage. In the classification stage, each individual pairwise classifier, $\lambda^k_{l,m}$, is coupled with the others in order to get the final output for each test sample x. Given that x can belong to any class, the input of a particular classifier can belong to its target classes (l or m) or not. In this last case, the problem, observed in our work and in the literature [2, 29], is that the

Table 2: *Accuracy of the base classifiers (DT: Decision Tree; NN: Neural Network; SVM: Support Vector Machine; RC: training with Remaining Classes; CC: Correcting Classifiers).*

	DT	DT-RC	DT-CC	NN	NN-RC	NN-CC	SVM	SVM-RC	SVM-CC

Total	66.2%	70.7%	71.2%	68.1%	67.9%	71.2%	63.5%	67.9%	68.6%

classifier might provide an unreliable output. Moreover, this unreliable output could be a high value, which might cause the instance to be incorrectly assigned to class l or to class m.

In order to cope with the described problem, we propose the use of two techniques: training with remaining classes (RC) and correcting classifiers (CC). Therefore, for each classifier type, we have three different classifier configurations: original pairwise classifiers, training with remaining classes and correcting classifiers.

3.3.1. Training with remaining classes

During the training phase, each classifier $\lambda^k_{l,m}$, is trained with examples of three classes: l, m and $\neg lm$ (this last is composed by the training examples of the rest of classes).

In the case of NN, the output layer is composed by two cells, $\{O_1, O_2\}$, assigning each cell at a certain target class, e.g., O_1 to l and O_2 to m. In the standard training method, the desired outputs are fixed to $\{1.0,0.0\}$ for l class samples and $\{0.0,1.0\}$ for m class samples. In the test stage, the input, x, is assigned to the class with the corresponding higher output, i.e, if the higher is O_1 x is assigned to l and if the higher is O_2 x is assigned to m. In the *training with remaining classes* method, the desired outputs in the learning stage are fixed at: $\{1.0,0.0\}$ for the l class training examples, $\{0.0,1.0\}$ for the m class training examples and $\{0.5,0.5\}$ for the $\neg lm$ class training examples. That is, the MLP is trained to provide high outputs when the input belongs only to the l or m classes.

In the case of DT and SVM, a similar method is applied. We extended the binary pairwise classifiers and built classifiers that can distinguish between three classes: l, m and $\neg lm$. Thereby, the probability estimates $\hat{P}(l|x, \lambda^k_{l,m})$ and $\hat{P}(m|x, \lambda^k_{l,m})$ provide high values only when the input belongs to classes l or m.

3.3.2. Correcting classifiers

For each pairwise classifier $\lambda^k_{l,m}$, separating class l from class m, an additional classifier is trained, $\phi^k_{l,m}$, separating classes l and m from all the other classes [29]. This additional classifier generates $\hat{Q}(lm|x, \phi^k_{l,m})$, an estimation that sample x belongs to either class l or class m, and can be included in equation (1), which becomes:

$$\hat{P}(l|x, \lambda^k) = \prod_{\substack{m=1..C \\ l \neq m}} \hat{P}(l|x, \lambda^k_{l,m}) \hat{Q}(lm|x, \phi^k_{l,m}) \quad (3)$$

The drawback of this technique is the cost of training $\frac{C \cdot (C-1)}{2}$ additional classifiers for each classifier type.

3.4. Experimental setup

We used the Boston University Radio News Corpus (BURNC) [30]. The experiments were performed using the word as the reference unit. All utterances in the corpus with ToBI labels from all the speakers were used. Pitch accents considered in this paper (and the number of samples of each) were: *H** (7,587), *L+H** (2,383), *!H** (2,144), *H+!H** (586), *L+!H** (638), *L** (517), *L*+H* (44) and *none* (13,868). We used oversampling in order to reduce the negative impact of imbalanced data on the final result [1, 9, 26]. Ten-fold cross-validation was applied in all the experiments.

We used similar features to the ones used in other experiments [13]. *Frequency features*: within-word F0 range, difference between maximum and average within-word F0, difference between average and minimum within-word F0, difference between within-word F0 average and utterance average F0. *Energy features*: within-word energy range, difference between maximum and average within-word energy, difference between average and minimum within-word energy. *Vowel nucleus duration*: we used the maximum normalized vowel nucleus duration from all of the vowels of the word. *Part of speech*: we used the POS tags that come with the BURNC corpus, which were automatically obtained and were hand-corrected [31].

In order to model the temporal evolution of the pitch contour along the unit of reference, we included additional features: Tilt and Bézier parameters. *Tilt* is probably the most widely applied technique for parameterizing the pitch contours [32]. Tilt has been explicitly used in the state of the art of prosodic event detection [9, 18]. *Bézier stylization* is based on the approximation of the pitch contours with Bézier functions [33]. The minimum square fitting approximation technique is used to represent the shape of the F0 contour along a given reference unit. In this work, we use 4 control points of the spline as parameters.

The use of context features can improve the classification results [1, 9, 21, 22, 34]. We decided to select the features to model the context using the Correlation-based Feature Selection (CFS) algorithm [35]. Without the use of context, for each word, we use 18 features. The CFS algorithm selected 8 features to be used as context features. We used 2 previous words and 2 following words as context [1].

Table 3: *Accuracy of the fusion of classifiers, with and without applying the Viterbi algorithm.*

4. Experimental results

Table 2 shows the classification results of the base classifiers, before the fusion. The total accuracy of the different classifiers ranges from 63.5% for the SVM classifier to 71.2% for the DT-CC and NN-CC classifiers. The strategies RC and CC improve the results of their baseline counterparts: for instance, DT improves from 66.2% to 70.7% and 71.2% respectively.

Another important result in table 2 is that some classifiers are more effective in the identification of a given class than others. This justifies the improvements achieved with the classifier fusion strategy. For example, the SVM classifier is the most efficient in identifying class *L**, with a rate of 45.5%. For this class, DT classifiers only obtain 18.6% at most.

Table 3 shows the results of the fusion of classifiers, with and without applying the Viterbi algorithm. A first conclusion from these results is that the fusion improves the results achieved with the base classifiers. The best global results are achieved when the Viterbi algorithm is used, because it allows to search for the most likely prosodic label sequence, instead of considering the accents in isolation. However, this global improvement is mainly due to the improvement of classes *H** and *none* (the most frequent ones), as shown in table 4.

As we are interested in multiclass classification, higher classification rates in each of the classes are also important. Table 4 compares two alternative combinations with the baseline of our previous work. In the third column, the classifier DT-CC+NN-CC+SVM+Vit provides higher total accuracy rate, but is clearly specialized in the *H** and *none* classes, with accuracies of 78.0% and 91.8% respectively. In the second column, the classifier DT+NN-RC+SVM provides a better balance in accuracy across the different pitch accent classes. This classifier obtains the highest rates of all configurations for classes *L+H**, *!H**, *H+!H**, *L+!H** and *L**. These classes proved to be very difficult to recognize.

Table 4: *Rate of ToBI labels for different combinations of classifiers. We show the combination which provides more balanced results among classes and the combination which provides higher accuracy rate (to select the most balanced configuration we calculated the geometric mean of the classification rate of all classes except class L*+H. DT: Decision Tree; NN: Neural Network; SVM: Support Vector Machine; RC: training with Remaining Classes; CC: Correcting Classifiers; Vit: Viterbi).*

	Previous work [1]		More Balanced		Higher rate	
H*	72.5%	DT+NN+Vit	66.8%	DT+NN-RC+SVM	78.0%	DT-CC+NN-CC+SVM+Vit
L+H*	25.3%		37.3%		25.9%	
!H*	35.2%		46.9%		36.5%	
H+!H*	12.1%		25.3%		10.4%	
L+!H*	6.0%		11.4%		2.2%	
L*	11.4%		32.1%		9.1%	
L*+H	0.0%		0.0%		0.0%	
none	91.0%		88.4%		91.8%	
Total	**70.8%**		**70.7%**		**72.6%**	

Table 4 also shows that with the experiments reported in this paper we have outperformed the results of our previous work [1].

5. Conclusions

We have presented a system for the multiclass classification of ToBI pitch accents, which is based on classification by pairwise coupling and is an extension of our previous work [1]. A classifier for each pair of classes is built and the final label is assigned combining all the pairwise predictions. Several machine learning techniques are used to build the base classifiers: neural networks, decision trees and support vector machines.

We have described two different techniques in order to incorporate the samples of the other classes during the training of the pairwise classifiers: training with remaining classes and correcting classifiers. The use of both techniques provided us with various different configurations of the base classifiers, which seemed to be complementary. The combination of these configurations allowed us to improve our previous results [1]. Some combinations improve the overall classification accuracy: the classifier DT-CC+NN-CC+SVM+Vit improves the total rate from 70.8% to 72.6%. Other combinations provide more balanced accuracies among the different pitch accent classes: the classifier DT+NN-RC+SVM doubles the identification rate (or close to double the rate) of the classes *L**, *L+!H** and *H+!H**.

Production-Comprehension (A)symmetry: Individual Differences in the Acquisition of Prosodic Focus-marking

Aoju Chen

Utrecht University & Max Planck Institute for Psycholinguistics

aoju.chen@uu.nl

Abstract

Previous work based on different groups of children has shown that four- to five-year-old children are similar to adults in both producing and comprehending the focus-to-accentuation mapping in Dutch, contra the alleged production-precedes-comprehension asymmetry in earlier studies. In the current study, we addressed the question of whether there are individual differences in the production-comprehension (a)symmetricity. To this end, we examined the use of prosody in focus marking in production and the processing of focus-related prosody in online language comprehension in the same group of 4- to 5-year-olds. We have found that the relationship between comprehension and production can be rather diverse at an individual level. This result suggests some degree of independence in learning to use prosody to mark focus in production and learning to process focus-related prosodic information in online language comprehension, and implies influences of other linguistic and non-linguistic factors on the production-comprehension (a)symmetricity.

Index Terms: prosody, focus, comprehension-production asymmetry, individual differences, first language acquisition

1. Introduction

A common pattern in language acquisition is that comprehension precedes production [1, 2]. There are however aspects of language which are characterised by production-precedes-comprehension asymmetries [2]. The acquisition of sentence-level prosody (or: intonation) is a case in point. A most widely discussed phenomenon is the mapping between accentuation and focus. Focus refers to the predication on a topic and typically contains new information to the hearer [3, 4]. In many languages, there is a strong association between focus and accentuation. Specifically, speakers tend to accent the focused constituent and deaccent the unfocused constituents, especially if they are post-focal [5]. Listeners take this into account in online language comprehension such that appropriate focus-to-accentuation mapping speeds up comprehension and inappropriate focus-to-accentuation mapping slows down comprehension [6]. Further, listeners use this mapping to anticipate the upcoming referent in online reference resolution [7]. Adult-like competence in prosodic focus-marking thus entails that children not only can place accentuation to encode focus but also efficiently exploit the focus-to-accentuation mapping in language comprehension. The literature on the acquisition of the focus-to-accentuation mapping over the past two decades has been dominated by the claim that children can use accentuation to mark focus before they can interpret or efficiently use the focus-to-accentuation in comprehension [8].

Recently [9] has pointed out that the alleged asymmetry in the acquisition of the focus-to-accentuation mapping could arise from asymmetries in the test materials used in the production and comprehension studies. More specifically, the test materials in the comprehension studies were usually syntactically more complex and semantically more demanding than the materials used in the production studies. Consequently, what children were supposed to comprehend went beyond the simple focus-to-accentuation mapping in SVO or SV sentences, e.g. the use of accentuation to disambiguate pronouns, accentuation as a cue to contrastive focus in sentences with the focus particle 'only'. [9] examined 4- to 5-year-olds' and adults' production and online comprehension of the focus-to-accentuation mapping in Dutch SVO sentences and found that the 4- to 5-year-olds were similar to the adults in both production and comprehension and the differences between them were of a gradient nature (i.e. more frequent use of accentuation in post-focus constituents and slower reaction times in the children). This is the first evidence suggesting that there is no asymmetry in the acquisition of prosodic focus-marking when the syntactic complexity is controlled for in production and comprehension.

However, prosodic focus-marking is more than the use of accentuation. Accent type also plays a role in focus-marking [10]. For example, in Dutch the preferred accent type to mark focus is H*L in both contrastive and non-contrastive focus [11]. When the same accent type occurs, speakers vary the phonetic realisation of the accent for the purpose of focus marking [12, 13]. Four- to five-year-old Dutch-speaking children are adult-like in choice of accent type in sentence-initial position but not in sentence-final position in SVO sentences [11]. Further, they cannot use phonetic realisation for focus-marking purposes until the age of 8 [12]. Together with the differences in the frequency of accentuation and deaccentuation between children and adults, these differences may have perceptual consequences. It can thus be very useful to examine children's use of prosody in focus-marking through adults' evaluation of children's production.

More importantly, the children in [9]'s production experiment were not the same children as the ones in her comprehension experiment, although they were similar in age and recruited from the same schools. Individual differences in children's intonational skills have been reported for both production and comprehension tasks in earlier work [9, 14]. Can we reduplicate [9]'s results if we examine both production and comprehension in the same group of children? Further, if at the group level, children's production is similar to their comprehension, relative to adults' production and comprehension, does it then mean that production and comprehension go in tandem in every child? In other words, are there individual differences in the production-comprehension symmetricity?

To address the aforementioned questions, we investigated the use of prosody to mark focus in production and the processing of focus-related prosodic information in a single group of Dutch 4- to 5-year-olds. Production data were obtained from the children in a semi-spontaneous setting. Sentence produced by the children were subsequently

evaluated for the appropriateness of the prosody in the corresponding context by trained raters. Comprehension was examined using the same method as in [9]. The focus conditions at issue were narrow focus on the subject NP and narrow focus on the object NP.

2. The production study

The production study consisted of a production experiment and an evaluation experiment. In the production experiment, SVO sentences were elicited in different focus conditions. In the evaluation experiment, trained raters evaluated the appropriateness of the prosody in the participants' sentences.

2.1. The production experiment

2.1.1. Data elicitation

The picture-matching game used in [9] was adapted for the current purpose. The game was played in experimenter-participant dyads. The participant's task was to help the experimenter to find the matching picture for each of her pictures by answering her questions. The conversation between the experimenter and the participant was primarily composed of short question-answer dialogues. The participant had direct access to the information that the experimenter needed and could respond directly to the experimenter's queries. This was achieved by providing the participant with his own set of pictures, each of which depicted a complete event including an agent, a patient and an action. Prior to the game, each participant completed a picture-naming task, in which he named each animal, personage, object and action present in the game and got corrected if he misnamed an entity or used a non-target form. The entities in the pictures were thus referentially given to the participant at the start of the game, rendering the use of a definite article in reference in the game appropriate.

In the game, the experimenter showed the participant one picture a time, drew the participant's attention to the picture, briefly described it (e.g. Look! The girl. There is also the pan. It seems that the girl cooks something.), and then asked the participant a question about the picture (e.g. What does the girl cook?). The participant took a picture from his own set of pictures, which were pre-arranged in an order corresponding to the order of the experimenter's pictures, and tried to identify the information requested by the experimenter. When the participant looked away from his picture, the experimenter repeated her question. The participant then answered the question in an SVO sentence (e.g. The girl cooks the carrot.).

Fifteen question-answer dialogues were embedded in the game to elicit fifteen SVO sentences in five focus conditions: narrow focus in sentence-initial position (NF-i), responding to who-questions and narrow focus in sentence-final position (NF-f), responding to what-questions, in addition to narrow focus in sentence-medial position (NF-m), responding to what-does-X-do-with-Y questions, contrastive focus in sentence-medial position (CF-m), correcting the experimenter's statement about the action, broad focus over the whole sentence (BF), responding to what-happens questions. The target SVO sentences were unique combinations of 3 verbs, 3 object-nouns and 6 subject-nouns. All words were highly familiar words to Dutch 4-year-olds. Each verb and object noun occurred once in each focus condition but never appeared with the same subject noun twice in the game.

2.1.2. Participants

Seventy-five 4- and 5-year-olds (age range: 4;1 to 5;11) participated in the production study. The children were all from monolingual Dutch-speaking families and were recruited from four primary schools in Utrecht Province. Nine adult female native speakers of Dutch took part in the experiment as controls. All participants had normal hearing and speaking ability. Three children did not finish the game. Each session was audio-recorded at a sampling rate of 44.l kHz with 16 bits resolution and video-recorded.

2.1.3. Data annotation

For each participant, the recording was first orthographically annotated in Praat [15]. Second, full-sentence responses were selected as usable responses if they were not plagued by any of the following factors: self-correction, use of pronouns, use of non-target words, detectable hesitation-induced silences, responding to a non-target question, elided responses, overlap with the experimenter's speech, and poor recording quality. Third, the usable full-sentence responses and the corresponding questions or statements were selected and extracted as individual .wav files.

2.2. The evaluation experiment

The usable full-sentence responses and corresponding questions or statements were combined into context-response dialogues with a 1000-ms interval between the question and the response in each dialogue. Subsequently, three intonationally-trained native speakers of Dutch listened to the dialogues and evaluated each response on how well its prosody fitted in the context on a five-point Equal Appearing Interval scale, with 1 standing for 'does not fit' for and 5 standing for 'fits perfectly'. In total, 105 dialogues from 42 children and 25 dialogues from 9 adults in the NF-i condition and 92 dialogues from 36 children and 25 dialogues from 9 adults in the NF-f condition were subjected to evaluation, together with the dialogues from the other focus conditions. The production of 32 of the children was evaluated in both the NF-i and NF-f conditions. To minimise variation in the scores due to comparisons between speakers, the dialogues were presented to the raters per speaker and the experiment was conducted in four 20- to 30-minute sessions. The raters could listen to each dialogue maximally three times before finalising the score. Inter-rater reliability analysis showed that there was a high inter-rater agreement (Cronbach's Alpha = .793; Interclass correlation coefficient = .774)

2.3. Results

Mixed modelling was used to examine the difference in the scores between the children and the adults in each focus condition. The fixed factor was 'age-group' (children vs. adults). The random factors included 'sentence' and 'participant'. The dependent variable was the mean score of the raters. In each analysis on the effect of 'age-group', two models were built, one with only the random factors, and one with both the random factors and the fixed factor. The two models were then compared to each other in an ANOVA test. A statistically significant difference between these two models indicated a main effect of the fixed factor. The p-values reported here were the p-values of the ANOVA tests. Our models showed that the fixed factor 'age-group' had a main effect on the scores in the NF-i condition but not in the NF-f condition. The difference between the children (mean: 2.56) and the adults (mean: 3.65) was thus statistically significant in the NF-f condition ($p < .001$), indicating that the children were not adult-like in their use of prosody in sentences with a focal subject. The differences between the children (mean score: 3.45) and the adults (mean score: 3.22) in the NF-i condition was not statistically significant, indicating that the children could use prosody as appropriately as the adults did in sentences with a focal object.

Taking results from [11, 12] into account, these results suggest that the adult listeners found accenting the post-focus object NPs, acceptable, as found by [16, 17]. But they found the children's failure to exploit phonetic realisation to

distinguish focus from non-focus in the NF-i condition less acceptable.

3. The comprehension study

The reaction-time experiment used in [9] was conducted on the four- to five-year-olds who took part in the production study about two weeks after the production experiment. We only describe the most essential details of the RT experiment here and refer the reader to [9] for further information.

3.1. The RT experiment

The experiment was presented to the children as a game. The children were told that in the game a boy was going to look at a number of pictures with his three pets, a parrot, a chicken, and a duck. The boy wanted to know whether his pets knew the pictures well and which of the pets knew the pictures best. To find this out, the boy showed one picture a time to one of his pets and asked the pet a question about the picture. The children could hear the conversations between the boy and the pets via a headphone set and see each picture on a computer screen together with the boy and his pets. The children were asked to listen to the dialogues between the boy and his pets carefully and judge whether the pets have given correct answers to the boy's questions or not. If they thought a pet gave a correct answer, they should press the green button of the pushbutton box. If they thought that the pet's answer was incorrect for some reason, they should press the red button.

Four lists of 24 experimental dialogues were created from 24 source answer–sentences together with the accompanying pictures. The answer sentences were lexically identical but appeared in different focus conditions (NF-i and NF-f) and prosody conditions in different lists. The prosody of the answer sentences was appropriate in half of the dialogues and inappropriate in the other half of the dialogues. In addition, 20 fillers were included. The answers in the experimental dialogues were all semantically correct but the answers in the fillers contained either a lexical error or a pronunciation error. The questions of the dialogues were recorded by a male speaker of Dutch and the answers by a female speaker of Dutch at a sampling rate of 44.l kHz with 16 bits resolution in the recording studio of the Max Planck Institute for Psycholinguistics. Prosodic analysis on the answer sentences confirmed that the prosody was as intended in both the appropriate and inappropriate prosody conditions. The answer sentences were similar in length across focus conditions and prosody conditions.

The children did the experiment individually in a quite room at their schools. The experiment was conducted by means of the Zep Experimental Control Application [18]. An approximately equal number of children were assigned to each of the list. The exact stimulus list a child got was however randomly decided. Each session lasted about 20 minutes starting with a practice session. In the practice session, the children were familiarised with the task and trained to use the push-button box properly.

The timeline of a trial was as follows: A target picture together with the picture of the boy and one of his pets appeared on the screen. At the same time, the boy said *Kijk* 'look' as an attention getter. 800 ms later, he named an entity in the picture. The 800-ms delay was built in to allow the participants to take a proper look at the picture. 1200 ms after the naming, the boy asked the question. 2200 ms after the end of the question, the pet answered the question. At the end of the answer sentence, a timer with 1 ms accuracy was activated and a picture of the push-button box appeared on the screen.

The RT was recorded from the end of the answer sentence until a button was pressed and the correct–incorrect judgment was automatically recorded. The children were instructed to press the button as quickly as they could, but not before the end of the answer sentence. A timeout device was set at 4 s after the end of a sentence.

Seventy-one out of the 75 children completed the experiment. Two measures were taken from each child, i.e. the 'correct–incorrect' judgement and the RT.

3.2. Statistical analysis and results

The children judged the answers on the experimental trials to be correct in nearly all cases, as expected. The reaction times obtained from the children whose production was evaluated in the NF-i condition and the reaction times obtained from the children whose production was evaluated in the NF-f condition were included for further analysis. The reaction times were log-transformed. Mixed-effect modelling was used to assess the effect of two fixed factors, 'prosody' (appropriate vs. inappropriate) and 'focus condition' (NF-i vs. NF-f) and their interaction on the log-transformed reaction times. Two random factors were included, 'participant' and 'list'. The models were built as described in section 2.2. Our models revealed a main effect the fixed factor 'focus' ($p<.0001$) and a significant interaction between 'focus' and intonation' ($p<.0001$). The main effect of 'focus condition' was such that object focus triggered a longer mean RT than subject focus. This was related to the fact that one had to wait till the end of the sentence in the NF-f condition to form his judgement [9]. The effect of the interaction between 'prosody' and 'focus condition' was such that inappropriate prosody triggered a longer mean RT than appropriate prosody in the NF-f condition but a shorter mean RT in the NF-i condition. This showed that the children were similar to adults in their processing of the focus-prosody interface only when focus was sentence-final.

4. Production and Comprehension

The discussion above centred on the general patterns that have emerged in the children as a group in production on the one hand and in comprehension on the other hand. The results revealed a production-comprehension symmetry whereby the children's production went in tandem with their comprehension. In this section, we address the question of whether there are individual differences in the production-comprehension symmetricity. We focus on the data from the children who were both evaluated for their production and completed the reaction experiment (40 in the NF-i condition and 36 in the NF-f condition; 32 of the children appeared in both conditions; mean age: 5;3).

To quantify individual differences in the production-comprehension interface, two kinds of scores were obtained for each child: 'production scores' that could reflect a child's ability to use prosody in different focus conditions in production; 'comprehension scores' that could reflect how a child processed inappropriate prosody compared to appropriate prosody in different focus conditions. Regarding the production scores, a score was computed for each child in each focus condition by first calculating the mean score of the raters for each response and then averaging the mean scores of all available responses in each focus condition. Regarding the comprehension scores, a score was computed for each child by calculating the ratio between the mean log-transformed reaction time in the inappropriate-prosody condition and that in the appropriate-prosody condition in each focus condition. If the child responded faster in the appropriate-prosody condition than in the inappropriate-prosody condition, the child should have a comprehension score bigger than 1.

We examined the correlation between the production scores and comprehension scores by conducting a Spearman's

correlation coefficient test in each focus condition. The Spearman's correlation coefficient was .113 in the NF-i condition and .034 in the NF-f condition. The significance of the correlation coefficient was .481 and .845 respectively. The results suggested that there was no significant relationship between production and comprehension.

Interestingly, examining the production and comprehension scores in each child, we observed notable individual differences among the children. Assuming that a comprehension score higher than 1 meant successful processing of the focus-prosody interface and a production score higher than 3 indicated relatively accurate use of prosody in focus marking, there appeared to be four sub-groups in the children regardless of the focus condition: (1) poor production, poor comprehension; (2) good production, good comprehension; (3) poor production, good comprehension; (4) good production, poor comprehension, as shown in Figure 1. Such notable individual differences account for the insignificant correlation coefficients in the correlation tests.

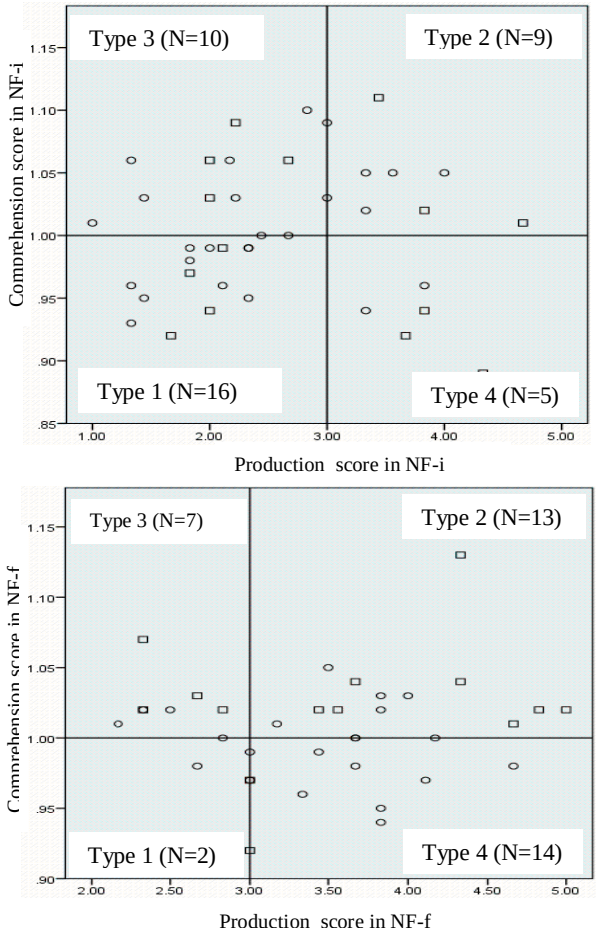

Figure 1. Children's production and comprehension scores (40 in the NF-i condition, 36 in the NF-f condition). Circle: female; square: male

5. Discussion and conclusions

In the current study, we have taken into account the use of multiple prosodic cues in focus marking and examined production and comprehension in a single group of Dutch 4- to 5-year-olds. The children were perceived to be able to mark focus prosodically like adults when focus was in sentence-final position, but not when focus was in sentence-initial position. This asymmetry in the children's production ability was in line with the results based on phonological and phonetic analysis on children's prosody [11, 12] and the tendency to accent given information in adult Dutch [15,16]. By evaluating the overall use of prosody in focus marking, we have obtained a more accurate picture of children's prosodic focus-marking in production. Our results however differed from the results reported in [9] regarding comprehension. The 4- to 5-year-olds in this study differed from their age-matched peers and adults in [9], who responded faster in the appropriate-prosody condition regardless of focus conditions. At first sight, these results may look perplexing. However, these results can be well explained by the children's own production. The children were adult-like in how they processed the focus-prosody interface in the NF-f condition but not in the NF-i condition. Interestingly, their use of prosody was judged to be as appropriate as the adults' use of prosody in the NF-f condition but not so in the NF-i condition (section 2.3). Thus, the children had difficulty with the focus-prosody interface in the NF-i condition in both production and comprehension. Our results thus show at a more fine-grained level that production and comprehension are symmetrical when we treat children as a homogenous group.

The picture is quite different regarding the relationship between production and comprehension in each child. There was not just one type of relationship between production and comprehension present in the data. Zooming in on the production and comprehension scores of each child, we have identified four kinds of relationships between production and comprehension: (1) poor production, poor comprehension; (2) good production, good comprehension; (3) poor production, good production; (4) good production, poor comprehension. These results suggest some degree of independence in learning to use prosody to mark focus in production and learning to process focus-related prosodic information in online language comprehension. Having the representation of the focus-prosody interface does not guarantee success in the actual production at the age of 4 or 5. Conversely, being able to use prosody accurately in focus marking does not entail the ability to integrate focus-related prosodic information into online language comprehension at this age. Possibly, the children who did well in both production and comprehension differed from those who did poor in both or did well in either production or comprehension in other aspects of language development and/or in other areas developmentally. Future research is needed to have a better understanding of the causes for the striking individual differences in the production-comprehension (a)symmetricity.

Abstract

While speech synthesis research is now focussing on the generation of various speaking styles or emotions, very few studies have considered the possibility of including phonetic variations according to the communicative situation of the targeted speech (sports commentaries, TV news, etc.). This paper proposes a phonetic analysis of large French corpora to assess the influence exerted by three situational 'traits': read/spontaneous, media/non-media and expressive/non-expressive. It shows that some variations, like elision, tend to be more frequent in spontaneous and non-media speech, conversely to liaisons which appear more often in read and media speech. Interestingly, no phonetic variation draws a clearcut distinction between expressive and non-expressive speech. Finally, a prosodic analysis indicates that the phonetic variations are not directly correlated with the rhythmic features of their corresponding situational 'trait'.
Index Terms: Phonetics, Rhythm, Speaking Style, Speech Synthesis

1. Introduction

Text-To-Speech (TTS) synthesis has reached in the last decades a fairly good level of quality and intelligibility for the generation of neutral read speech. The interest has now shifted to the production of speech corresponding to various speaking styles and emotions. Most studies focussing on this topic have considered modifications at the prosodic and voice quality levels only (see [1, 2]). Surprisingly, potential phonetic modifications of the sentence to synthesize are generally discarded. One rare exception is presented in [3], which modifies the pronunciation of final schwas according to the communicative situation (radio news, conversation, etc.).

This concern is particularly relevant in French, where words are characterized by a high amount of phonetic variants. Schwa elisions and liaisons are the most frequent phonetic modifications. The first consists in the optional pronunciation of a schwa vowel in the middle or at the end of a word (e.g. *petite* pronounced [ptit]). The second relates to latent consonant at the end of a word which can be pronounced when followed by a vowel or a mute h (e.g. *les enfants* pronounced [le͡zɑ̃fɑ̃]). Many linguistic studies have analyzed the modalities of appearance of these phenomena (see [4] and [5] for liaisons, [6] and [7] for epenthetic schwa, [8] and [9] for elisions). They show that the realization of the different variants can be explained by many factors: morpho-syntax [10], speech rate [11, 8, 5], word frequency [4, 5], word probability [12], degree of articulation [13], origin of the speaker [9, 14], age of the speaker [9], etc. Few linguistic analyses, however, have studied the influence exerted on phonetic variations by the communicative situation (TV news, political speech, text reading, etc.), also sometimes referred to as the 'phonogenre' [15, 16]. Yet, the potential interaction between both levels is widely acknowledged [8, 17] and was shown to be very influential for prosody [3, 17, 16]. Only the phonetic differences between read and spontaneous speech have aroused great interest [6, 4, 18].

Most speech synthesizers integrate basic phonetic variations. However, they are trained to produce a phonetic transcription corresponding to standard read speech. For optional variations, the most likely variant is generally produced, independently of the communicative situation. While research is now targeting the generation of expressive [1, 2] and media-related speech (e.g. sports commentaries [19]), the need for a broad study of the influence of these situational 'traits' (as further defined) on phonetics is striking.

Our study proposes an analysis of the influence exerted by the communicative situation on the phonetic realization. Because they cannot be easily ranked on a single scale, the various communicative situations are defined according to three binary 'traits': media/non-media, expressive/non-expressive and read/spontaneous. They will be referred to as 'situational traits' in the remainder of this paper. The main objective of the study is to offer an insightful description of the phonetic features of each 'trait' to outline what should be considered when synthesizing a certain communicative situation.

Our analysis has the advantage of relying on a very large corpus in French of about 300 minutes from 32 speakers and 10 communicative situations (sports commentaries, TV news, political speech, etc.). The study of the phonetic realization is based on a strategy making use of natural language processing (NLP) techniques. In a second stage, rhythm is considered as it was shown to be one of the prosodic correlates of phonetic variations [11, 5]. The potential correlation between phonetic and rhythmic features is then evaluated.

The paper is organized as follows. Section 2 presents the corpus and its annotation. The methodology exploited to carry out our study is detailed in Section 3. The main analysis, both phonetic and rhythmic, of the corpus is described and discussed in Section 4. Finally, Section 5 concludes the paper and discusses further works.

2. Corpus design

Our corpus is an extended version of C-PROM [20] including additional sub-corpora exploited for speech synthesis. A special focus is made on sports commentaries [21] which have also been added to the corpus. The phonetization of the speech files was done automatically and further corrected manually. The entire corpus was then automatically phonetically aligned

with EasyAlign [22] and Train&Align [23].

The corpus consists of 300 minutes from 32 French-speaking speakers (French, Belgian and Swiss) and ten sub-corpora corresponding to different communicative situations (interview, political speech, etc.). Each situation contains 2 to 7 speakers and is defined according to three binary situational 'traits': media, read and expressive. Expressive is here defined as an audible emotive implication of the speaker (e.g. excitation, anger, happiness, etc.), be it acted or not. It should be noted that this 'trait' gathers different kinds of expressivity. Emotion valence, for example, can be positive (e.g. happy) or negative (e.g. sad). This could lead to averaged effects in our analysis, and hinder the interpretation of the role played by the various aspects of expressivity.

A summary of the different sub-corpora is shown in Table 1. The situational 'traits' being continuums, some corpora were not classified (NC) if their nature regarding a dimension was ambiguous. The continuum between read and spontaneous speech, for example, goes through 'prepared', which could be assigned to conferences. Because text to speech corpora were not broadcast as such, but could be used for public announcements, they were not classified for the media 'trait'. For interviews, only the parts of the interviewee were kept. The number of speakers per 'trait' is rather balanced and ranges from 13 to 17 with an average length of about 2 hours of speech per trait.

Table 1: *Distribution of the sub-corpora according to the three studied situational 'traits' (TTS corpora were recorded for speech synthesis purposes).*

Communicative situation	Read	Media	Expressive
Sports commentaries	-	+	+
Conference	NC	NC	-
Political discourse	+	+	NC
Interview	-	+	+
Itinerary explanations	-	-	-
TV news	+	+	NC
Expressive speech TTS	+	NC	+
Neutral speech TTS	+	NC	-
Neutral reading	+	-	-
Narration	-	-	+

3. Methodology

For the phonetic analysis, we developed a specific methodology integrating NLP techniques. For each sub-corpus, the orthographic transcription was exploited to produce its automatic phonetization with the NLP tool ELite [24] designed for TTS purposes. It produced a 'standard' phonetization of the text, corresponding to neutral read speech. This transcription was then automatically aligned with the phonetic transcription really pronounced by the speaker (and which was manually checked).

This alignment relies on a slightly modified version of Levenshtein's edit distance [25]. Several adaptations were made:

- Each phoneme is represented by only one character,
- Some phonemes substitutions are not penalized (ø→œ, e → ɛ, etc.) as they might result from a subjective perception of the annotator,
- Insertions and deletions of silences are not penalized.

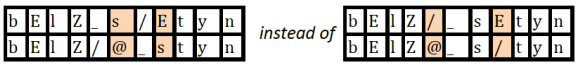
To retrieve the alignment, the matrix obtained by the algorithm is backtracked. Finally, all modifications are stored according to their type (insertion, deletion or substitution).

To avoid potential phonetization errors of the NLP, all sound files containing numbers (written as ciphers) were deleted. Proper names being very frequent in sports commentaries, their deletion would have resulted in a highly reduced sub-corpus. For that reason, we decided to consider only modifications of phonemes not belonging to proper names or to syllables just before and after a proper name.

A first analysis of the alignment highlighted recurrent errors made by the algorithm when two modifications occurred in a small phonetic context. This led to some refinements:

- The deletion and insertion of schwas being more frequent, they were favored and assigned a reduced cost.
- The cost was also reduced for substitution of [i] by [j], which is rather frequent.

This avoided alignments such as:



The main advantage of using NLP-produced phonetization is that it allows for an easy comparison of the pronunciation of the corpus with a so-called 'standard' pronunciation. The latter already considers most mandatory phonetic variations such as liaisons or elisions dictated by the linguistic context. It provides a more precise analysis than a comparison with a phonetized dictionary (see e.g. [4]) while being fully automatic.

Throughout this study, the statistical significance of the results is calculated via unilateral t-tests or Wilcoxon tests depending on the normality of the variable distribution. Correlations are evaluated using Spearman's coefficient.

4. Phonetic and prosodic analysis

4.1. Analysis of the phonetic variations

In this section, we first consider the overall proportion of phonetic variations for each situational 'trait' (4.1.1). We then focus on the analysis of four phonetic variations that were qualitatively assessed to be the most frequent in our corpus: schwa elision (4.1.2), epenthetic schwa (4.1.3), final consonant elisions (4.1.4) and liaisons (4.1.5).

4.1.1. Overall proportion of phonetic changes

Phonetic variations are analyzed by comparing the NLP-produced standard phonetization with the real pronunciation by the speaker. The overall proportion of phonetic changes is computed as the total amount of modifications (deletions, insertions or substitutions) divided by the maximal number of characters, i.e. the number of characters of the longest of both strings.

Table 2 shows significant differences in the amount of phonetic changes for both media and read dimensions (with respectively p=0.043 and p=1.2e-05). This indicates that spontaneous and non-media speech differ rather strongly from what produces a generic NLP. Conversely, read speech corpora exploited for speech synthesis display, on average, only 1.31% of phonetic changes. This finding partly implies that, while the NLP produces suitable phonetizations for neutral read speech, it requires non-negligible modifications to produce non-media

or spontaneous speech. Finally it is worth noting that no significant differences are found along the 'expressive' dimension. This might be due to the heterogeneity of this 'trait', which notably gathers emotions with different valences.

The next sections investigate typical phonetic phenomena for each 'trait'.

4.1.2. Schwa elision

Schwa elision is one of the most intricate phonetic variations in French. It relates to schwas which can be pronounced or not at the middle or the end of a word. Our analysis excludes final schwas which may rather be linked to liaisons and are further investigated in the next subsection. The percentage of elided schwa is here computed as the number of schwa deletions, inside words, divided by the total amount of schwas inside words. Figure 1 shows the significant role played by the distinctions spontaneous/read and media/non-media (with respectively p=0.005 and p=1.7e-04). It shows that more schwas are elided in spontaneous speech, corroborating earlier studies [4, 9, 6]. An interesting finding is that more schwas are also elided in non-media speech. This may be explained by the fact that media speech tends to belong to a higher level of language which has been said to be correlated with lower elision rates [26]. As in [8], we observe rather high inter-speaker variability.

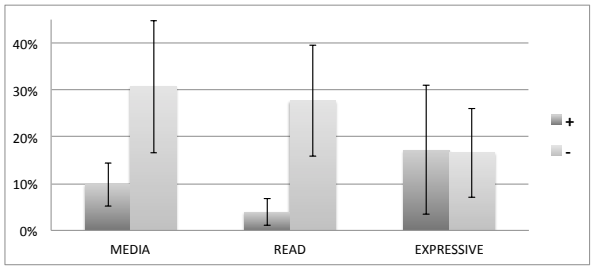


Figure 1: *Percentage of elided schwas in middle word position, together with their 95% confidence intervals.*

4.1.3. Epenthetic schwa

The epenthetic schwa is seen as the insertion of a final schwa on a word ending or not in -e (e.g. *match* pronounced [matʃə]) [6, 27, 28]. Candea [7] shows that its frequency has increased in the last decades and that it can occur independently of the phonetic or rhythmic context. While it was previously seen as a sign of informality, the sociolinguistic aspect is now fading out.

Our analysis focussed only on epenthetic schwas in words with no final -e. Interestingly, this variation is significantly more frequent in media compared to non-media speech, as shown in Figure 2 (p=0.013). This goes in line with [3] which assessed a higher rate of ending schwa pronunciations (all words considered) in radio news and political speech compared to conversational speech. This rate is also significantly higher in spontaneous and expressive speech (p=0.019 and p=0.008), most likely due to their high frequency in sports commentaries. High inter-speaker variability is however observed. While they are often studied on Parisian French, no difference was witnessed in our corpus between French, Belgian and Swiss speakers.

4.1.4. Final consonant elisions

When analyzing the alignment of both predicted and real phonetizations, we observed that the 'il' pronoun (meaning 'he' or 'it') is often pronounced [i], with elision of the final 'l'. This phenomenon occurring quasi-exclusively in front of phonetic consonants, we analyzed its appearance in that specific context (see Table 2). Only sub-corpora containing at least 3 occurrences of the pronoun in that context were kept. Both media and read 'traits' are significant, with higher elision rates in spontaneous and non-media speech (respectively p=6.1529e-05 and p=0.002) which goes in line with results obtained for the elision of schwa in Section 4.1.2.

Another type of consonant elision regards the elision of the final liquid when preceded by an obstruent (e.g. 'peut-être" pronounced [pøtɛt]) [29]. A first qualitative analysis shows that this phonetic variation highly depends on the phonetic context. The liquid is nearly always pronounced when followed by a vowel. Conversely, it may be dropped when followed by a consonant. Our analysis was carried out in this latter phonetic context only, on corpora containing at least 4 occurrences of such phonetic context. Table 2 shows that, here again, spontaneous and non-media corpora display significantly more elisions of the liquid than read and non-expressive speech (with respectively p=1.1e-05 and p=0.04).

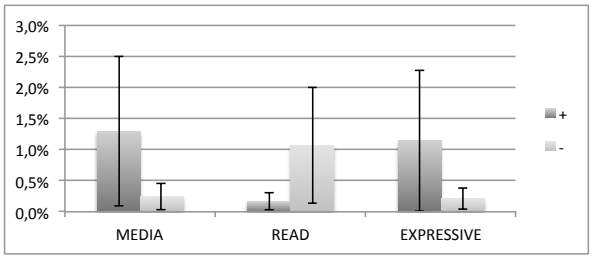

Figure 2: *Percentage of words, not ending in -e, pronounced with a final schwa, together with their 95% confidence intervals.*

4.1.5. Liaisons

We defined potential liaisons contexts as words ending in a French liaison consonant /t, n, z, R, p/ and followed by a vowel, as in [4, 5, 10]. It should be noted that these potential liaisons do not refer to so-called 'optional liaisons', all liaisons being considered, be they mandatory, facultative or prohibited. Table 2 shows that read speech displays a significantly higher rate of liaisons (p=4.6396e-05) which confirms findings in [4, 5, 18]. Interestingly, media speech also shows more liaisons, even if the difference is not significant. This might be due to the fact that media and read speech tend to be more formal, 'sustained' speech being more inclined to high liaison rates [30, 26].

4.2. Prosody: Any correlations between phonetic and rhythmic features?

Rhythm, and speaking rate in particular, has been shown to be correlated with schwa elisions, more elisions appearing in fast speech [11]. This section analyzes various rhythmic features to assess their correspondence with the situational 'traits' and evaluate their correlation with the aforementioned phonetic variations. It focusses on three rhythmic measures: the articulation rate, the mean duration of inter-pausal units (IPU) and the proportion of prominent syllables.

The analysis of the *articulation rate*[1] highlights significant

[1] We focus here on the articulation rate, i.e. the speaking rate (num-

Table 2: *Summary of the phonetic changes for the three situational 'trait' dimensions.*

	All changes		Elision of [l] in 'il"		Elision of liquid in obstruent+liquid		Liaisons	
Situational 'trait'	+	-	+	-	+	-	+	-
Read	1.78%	4.25%	8.33%	76.56%	3.65%	50.34%	59.33%	42.15%
Media	2.93%	4.11%	51.87%	96.67%	18.53%	49.99%	54.52%	44.77%
Expressive	3.57%	2.92%	52.53%	34.72%	33.54%	21.74%	44.53%	50.27%

differences for the read 'trait' only, with lower speaking rates in spontaneous speech (p=0.019). This can be explained by the presence of lengthened syllables, due to hesitations. As in [17], we also observe a significantly lower percentage of articulation for spontaneous speech (p=0.049). Conversely to existing studies (e.g. [11]), however, no significant correlation is found between speaking rate and schwa elision ($|Rho| < 0.09$), or any other phonetic variation. We have shown, on the contrary, that elisions are more frequent in spontaneous speech which displays a lower articulation rate. This difference might be due to the fact that most existing studies focus on one specific task (e.g. text reading) in which only speaking rate is modified to observe the frequency of elisions. In our corpus, too many factors are influencing the speaking rate, e.g. hesitations, communicative situation, speaker idiosyncrasies, etc.

The mean duration of IPU turns out to be significantly longer in spontaneous speech compared to read speech (p=0.04). This seems to indicate that spontaneous speech displays less but longer silences. A possible explanation is that short pauses are rarely silent in spontaneous speech and rather tend to be filled by disfluency markers. Finally, the *percentage of prominent syllables* is assessed with Prosoprom [31], an automatic algorithm for detecting prominent syllables on an acoustic basis. Only the media dimension seems to be influential for that measure, media speech containing more prominent syllables (see Figure 3). This distinction also stands out when looking at initial stresses only, media displaying 19.1% of prominent initial syllables against 16.4% in non-media speech. This confirms findings in [15]. However, the inter-speaker variability is rather high which makes this difference not significant (p=0.07).

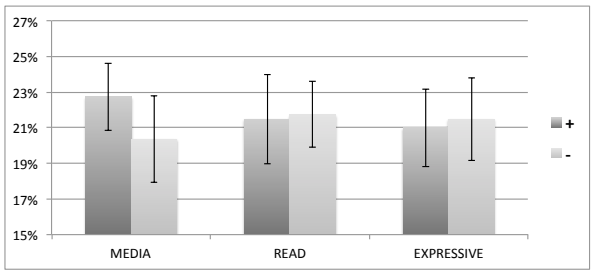

Figure 3: *Percentage of prominent syllables, together with their 95% confidence intervals.*

IPU duration is moderately correlated with schwa elisions and 'l' elisions of the 'il' pronoun (respectively Rho=0.59 and Rho=0.43). This may imply that more elisions are realized when longer sections of speech are uttered without pauses. This, however, does not hold for liquid elisions after obstruents. Interestingly, no correlation can be found between the percentage of prominences and phonetic variations.

ber of syllables per second) with silences excluded, the sub-corpora displaying different silence densities.

On the whole, correlations between rhythmic and phonetic variations are rather weak. This seems to indicate that phonetic variation is more directly dependent on the situational 'trait' itself than on the rhythmic features of the 'trait'. It should be noted that, as for phonetic variation, the expressive 'trait' is not characterized by any specific rhythmic feature.

5. Conclusion and perspectives

While speech synthesis of various speaking styles and emotions is now the focus of much research, very few studies consider potential phonetic variations according to the communicative situation (expressive, spontaneous, etc.). This paper proposed a phonetic analysis of a large corpus in French to assess the influence played by three situational 'traits': read/spontaneous, media/non-media and expressive/non-expressive. It first showed that spontaneous and non-media speech exhibit a significantly higher percentage of phonetic variations compared to standard read speech as produced by a conventional NLP for TTS. Regarding the various phenomena, we showed that spontaneous speech is characterized by a higher elision rate and less liaisons, which confirms results of earlier studies. Media speech usually follows the same phonetic tendencies as read speech, which may be due to the overall higher level of language compared to spontaneous and non-media speech. However, it displays much more epenthetic schwas, which seems to be particularly characteristic of sports commentaries. Interestingly, the expressive 'trait' is not associated with any specific phonetic feature. The diversity of the corpora in that 'trait' (e.g. emotions with different valences) should be further investigated to evaluate the role played by the different aspects of expressivity.

Rhythm was analyzed in a second stage and showed higher speaking rates and shorter inter-pausal units for read speech. Higher proportions of prominences were observed for media speech. Here again, no specific rhythmic feature was associated with the expressive 'trait'. Finally, low levels of correlation were found between the rhythmic parameters and the phonetic variations, except for a moderate correlation between the duration of the inter-pausal unit and some types of elisions. This implies that phonetic variations depend primarily on the situational 'trait' (read/spontaneous and media/non-media) and not on the rhythmic features of that 'trait'.

Further studies will focus on the perceptive analysis of those phonetic changes to assess whether they only constitute possible variants or if they influence the credibility of the message. Required phonetic variations will then be integrated in HMM-based synthesis according to the targeted communicative situation.

Differences between the acoustic typology of autonomy-supportive and controlling sentences

Abstract

The current study was first to describe distinct patterns of prosody that discriminate motivationally laden speech. To do this we applied self-determination theory, a widely used motivational framework. Participants in the US and UK were asked to read out loud either autonomy-supportive sentences (that support choice and volition) or controlling (pressuring and coercive) sentences. Data analyses were conducted using a conservative hierarchical linear modeling approach to account for nesting of sentences within individuals. Across both countries and controlling for gender, autonomy-supportive sentences were read using lower pitch, less intensity, and a slower speech rate than were controlling sentences. Multiple regression analyses showed links between these patterns of prosody for each participant and his or her current level of motivation, providing additional validity to results. Findings inform both the motivation and prosody literatures and offer a first description of how different kinds of motivational speech may sound.

Index Terms: autonomy-support, controlled motivation, motivational prosody, social prosody, prosodic contour, sentence prosody

1. Introduction

Motivational language is a significant aspect of daily interactions across relationships; it is a fundamental component of people's influence on, and responses to, others. People regularly attempt to shape the behavior of others with motivationally laden language. A child may be told to "go and tidy your room" and while the verbal message plays an important role in shaping behavior, there is reason to believe that prosody is also critical; for example, listening to a calm but firm tone of voice saying "go and tidy your room now" will have greater impact on children's behavior than listening to the same words spoken in a shaky, low tone of voice.

Human communications are often intended to drive and shape others' behaviors, and in these cases motivational elements are imbued in language. The theoretical framework provided by self-determination theory (SDT) argues that two types of qualitatively different messages can drive behavior. Autonomy-supportive statements, such as "you may [do this] if you choose" improve relationships and well-being by supporting perceived choice and volition in the listener. In contrast, controlling statements such as "you must [do this]" are experienced as pressuring or coercive and can undermine well-being [1], but they may also be more effective for achieving desired behaviors in the short-term. The motivational qualities of an interaction have numerous impacts on the personal, relational, and behavioral outcomes of that interaction. Autonomy-supportive versus controlling environments have been shown to shape defiant behaviors [2], encourage interpersonal closeness [3], increase well-being [4], lead to more responsible decision-making [5], and shape successful or unsuccessful performance on important tasks [6], among other outcomes. Furthermore, these motivational communications are relevant in political communications, parent-child relationships, sports and exercise, education, the workplace, and healthcare [7], and as such this fundamental work on motivational communications can be extended across the gamut of human interactions.

Although social psychology has a long tradition of exploring how individuals deliver and understand motivationally laden ideas expressed through specific verbal messages (i.e. words), and research emerging from SDT has examined the words used in both types of messages [8], there is no research to date on how prosody distinguishes these qualities of motivation. Attention to vocal attributes of utterances is crucial in everyday life, particularly in situations when semantic cues are missing (e.g. "time to leave", can be said in either a controlling or autonomy supportive way) or when semantics and prosody mismatch. However, the basic semantic analyses commonly used do not capture the important effect prosody has on motivational language processing. Thus, the current study set out to explore the role prosody plays when communicating motivational language. Past research on another function of prosody, namely emotional prosody, has highlighted that the interplay of multiple acoustic parameters such as frequency variables (e.g., mean, range, contour of pitch), voice qualities (e.g., jitter, shimmer, spectral frequencies), intensity (loudness), and speaking rate, are reliably associated with specific emotional states. For instance, angry statements are often expressed with high intensity, high pitch, and fast speaking rate, while sad statements are conveyed with reduced intensity, low pitch, and slow speaking rate [9]. Thus, in spoken communication, listeners can rely on differences in temporal, pitch, and intensity cues to infer how someone feels; presumably, the same is true when individuals hear motivational messages. It is crucial to note that although basic emotions and motivational styles may correlate, for example, someone who is angry may use a controlling tone, the two constructs are conceptually and operationally distinct – someone who is angry may still use autonomy-supportive language. Accordingly, emotions and motivation should show related but distinct prosody patterns, so that understanding basic emotions does not translate to defining motivational prosody patterns. Specifically, we expected that control and autonomous motivational sentences would be defined by distinct acoustic configuration profiles, as reflected in pitch, temporal, and amplitude differences for the two sentence types.

2. Method

2.1. Participants and procedures

Participants were 100 students recruited from a small university in the North-East USA (n = 51) and from a

comparably sized university in the East of England (n = 49). Of these, 39 American and 31 British females took part. Participants were aged 18 to 32 (M = 22 years).

Participants were randomly assigned to an Autonomy-Supportive or Controlling condition (2-way between-subjects design), which determined the motivational content of the sentences to be read out loud. Instructions for this part of the study asked participants to: "*…read a number of sentences out loud… Please read them in a loud and expressive voice, and pronounce clearly. As if you really mean it…*" Sentences were then presented one at a time at the center of a computer screen at a rate of 12 seconds per sentence. Participants first practiced on a set of 10 motivationally neutral sentences, including "join me at the park" and "why don't we meet tomorrow?" Following this, participants were asked to say aloud the sentences specific to their allocated condition multiple times. The first reading of motivational sentences was designed to increase participant immersion in the particular motivational state, though we have focused on data collected during a second reading.

2.2. Materials

2.2.1. Autonomy supportive and controlling sentences

A series of 12 each autonomy-supportive and controlling sentences were selected based on theoretical considerations and previous research in SDT [10]. Examples of these are "you may do this if you choose" and "you're free to do this" (autonomy) and "you have to do it my way" and "you ought to do it" (control). Conditions were matched on the number of words – both sets of sentences ranged from 3 to 9 words.

To describe the acoustic typology of autonomy and controlling speech, the most commonly studied acoustic parameters, pitch and intensity (mean, minimum, maximum and range), were measured in the current study. Speech rate was also measured that reflected duration of reading out a sentence (in sec.) divided by the number of syllables in that sentence (sentences ranged from 3-10 syllables each).

A rating study was conducted to validate sentences. In particular, we aimed to confirm that autonomous sentences were perceived by others to be more supportive of choice, and that controlling ones were perceived by others to be more pressuring. To this end, an independent sample (n = 33) of British participants listened to recordings of both controlling and autonomy-supportive sentences. Sentences were presented in randomized blocks grouped by condition, and order of sentences was randomized within each block (within-subjects design). Following each sentence, participants were asked to report on the extent each sentence was pressuring (for the controlling condition) using a scale of 1 (*not pressuring at all*) to 5 (*very pressuring*) and on the extent speakers provided choice (for the autonomous condition) with a scale of 1 (*does not support choice*) to 5 (*supports choice very much*). Results showed that participants perceived controlling sentences to be more pressuring (M = 3.80) than supportive sentences (M = 2.16), $F(1, 32) = 133.57$, $p < .001$, and less supportive of choice (M = 2.06) than autonomy supportive sentences (M = 3.62), $F(1, 32) = 31.24$, $p < .001$.

Participants also reported on their current levels of controlled motivation after each block of sentences (blocks presented multiple sentences from one condition only). Findings showed exposure to multiple sentences altered motivational states in a way consistent with the framing of the sentence. After hearing controlling sentences participants reported more controlled motivation (M = 3.14) as compared to after hearing autonomy supportive sentences (M = 2.72), $F(1, 32) = 13.73$, $p = .001$.

2.2.2. State motivation

Participants taking part in the main study, i.e. participants who read aloud the different sentences, reported on their state levels of controlled motivation after a prompt delivered at the end of the study: "how much do you feel this way right now?" Three items assessed motivation, namely feeling "pressured", "coerced", and "choiceless". Each was paired with a seven-point scale ranging from 1(not at all) to 7(very much). Internal reliability was acceptable, $\alpha = .81$.

3. Results

3.1. Analytic strategy

Primary analyses were conducted with hierarchical linear modeling (HLM) [11], [12] because individual sentences (defined at level 1) were nested within speakers (defined at level 2). This method recognizes interdependence of sentences collected from the same participant as well as variation between participants and condition. We first conducted unconditional models to assess intraclass correlation (ICC); this analysis provided an estimate of the variability within-speakers (between sentences) and between-speakers and all parameters showed sufficient variability at both levels for conducting full models. Full models predicted major prosody parameters from gender, country of origin, and condition, as well as the interactions between predictors. The order in which we entered variables was determined by conceptual considerations. Level 2 variables were centered on sample means as recommended by Bryk and Raudenbush [11]; no predictors were specified at level 1. Degrees of freedom for these models are based on the number of participants and observations included in specific analyses, accounting for limited missing data (<5%) due to problems with recordings.

3.2. Preliminary findings

3.2.1. Manipulation check

Preliminary univariate analyses of variances (ANOVAs) predicted state levels of controlled motivation from assignment to condition, gender, country, and their interactions. Findings showed no effect of sex or country on state motivation, $F(1, 87) = .14$, $p = .71$, and $F(1, 87) = 1.01$, $p = .32$. However, those in the Autonomy condition reported less controlled motivation (M = 1.80) at the end of the study as compared to those in the Controlling condition (M = 2.49), $F(1, 87) = 6.26$, $p = .02$. There were no interactions between condition, gender, and country, $F(1, 87) < 2.80$, $ps > .10$. This finding confirms the effectiveness of the sentences used in the two conditions as a mean of motivation manipulation, indicating that assignment to condition did effectively shape speakers' motivational profiles.

3.2.2. Mean levels within countries and genders

Table 1 presents findings for mean scores in each of the two countries and for each gender. Since each of these two predictors may be expected to impact the effects of condition

on prosody indicators, both were controlled for in later analyses.

Table 1. *Means for primary variables of interest in both countries tested and for each gender.*

	M USA	*M* UK	*M* Men	*M* Women
Pitch mean	202.50	186.43	148.39	214.38
Pitch min	143.14	143.15	103.12	160.98
Pitch max	336.76	293.66	261.11	338.02
Pitch range	193.62	150.51	158.66	177.04
Intensity mean	69.35	56.62	63.30	62.83
Intensity min	54.34	32.20	40.26	44.47
Intensity max	82.22	70.09	76.45	76.08
Intensity range	27.88	37.89	36.19	31.61
Speech rate	0.20	0.23	0.21	0.22

3.3. Primary findings

Separate hierarchical linear models predicted mean, minimum, maximum, and range pitch and intensity, as well as speech rate per syllable from gender, country, and condition, and from their interactions.

3.3.1. Pitch measurements

Results showed women spoke in a higher pitch than men, b = 64.88, $t(91) = 8.73$, $p < .001$, though there was no difference across countries, $b = 7.34$, $t(91) = 1.20$, $p = .23$. Controlling for the two covariates, condition marginally affected pitch, b = -10.64, $t(91) = -1.90$, $p = .06$, such that those in the Autonomy condition used lower pitch than those in the Control condition (see Table 2 for a summary of findings and effect sizes). Neither gender, $b = 14.73$, $t(89) = 1.10$, $p = .28$, nor country, b = 14.52, $t(89) = 1.22$, $p = .23$, interacted with condition, indicating motivation was expressed in similar ways across subsamples. In separate models, it was found that autonomy-supportive sentences had marginally lower minimum pitch, b = -6.79, $t(91) = -1.86$, $p = .06$, while results for maximum pitch did not show a significant difference, $b = -22.61$, $t(91)$ = -1.49, $p = .14$; as well, range did not differ across conditions, b = -15.81, $t(91) = -1.08$, $p = .28$.

3.3.2. Intensity measurements

Generally, women spoke with lower intensity than did men, b = -2.01, $t(91) = -2.14$, $p = .04$, as did participants from the UK versus the US, $b = 13.02$, $t(91) = 15.84$, $p < .01$. Controlling for these gender and country differences, participants in the Control condition spoke with a louder tone of voice than those in the Autonomy condition, $b = -2.59$, $t(91) = -3.29$, $p = .002$. Condition did not interact with either gender, $b = -1.52$, $t(89)$ = -0.87, $p = .39$, or country, $b = -0.31$, $t(89) = -0.21$, $p = .83$. It was also found that controlling sentences were spoken with a higher maximum intensity, $b = -2.49$, $t(91) = -2.48$, $p = .02$, though there was no effect of condition on minimum intensity, b = -0.20, $t(91)$ = -0.20, p = .84. As well, autonomous sentences had marginally less range in intensity, $b = -2.29$, $t(91) = -1.98$, $p = .05$, controlling for country, $b = -9.12$, $t(91)$ = -8.28, $p < .001$, and gender, $b = -3.83$, $t(91) = -2.79$, p = .007. Condition did not interact with either country, b = 0.91, $t(91) = 0.47$, $p = .64$, or gender, $b = -2.34$, $t(91) = -0.93$, p = .36, in predicting range in intensity.

3.3.3. Speech rate

Results from full HLM models indicated participants from the US spoke at a faster rate, $b = -0.02$, $t(92) = -2.83$, $p = .006$, though no gender differences were apparent, $b = 0.01$, $t(91)$ = 0.93, $p = .36$. Autonomous sentences were spoken at a slower rate, $b = 0.03$, $t(92) = 4.79$, $p < .001$.

Table 2. *Effects of condition for all acoustic indicators: Results from primary HLM models.*

	b	*t*	*d*
Pitch mean	-10.64	-1.90◆	.40
Pitch min	-6.79	-1.86◆	.39
Pitch max	-22.61	-1.49	.31
Pitch range	-15.81	-1.08	.23
Intensity mean	-2.59	-3.29**	.69
Intensity min	-0.20	-0.20	.04
Intensity max	-2.49	-2.48*	.52
Intensity range	-2.29	-1.98*	.42
Speech rate	0.01	1.96*	.41

Note: effect size was computed using formulation for Cohen's *d*. ◆marginal significance, *$p \leq .05$, **$p < .01$.

3.4. State level outcomes of motivational sentences

To link prosody to state levels of motivation at the end of the study, a multiple linear regression analysis was used regressing the reported state levels of controlled motivation from speakers' tone of voice (prosodic profile) in the controlling condition, accounting for covariates. Mean pitch, intensity, and speech rate (reversed) were standardized and averaged to construct a controlling prosody profile; higher scores reflected more expression of a controlling prosodic tone of voice. Results showed use of controlling tones was linked to a more controlling state orientation at the end of the study, β = .24, $t(91) = 2.51$, $p = .01$; furthermore, in a second step of the analysis, this effect did not interact with covariates, βs < +/-.28, $t(89) < 0.59$, $p > .16$. These findings indicated that those who used a more controlling profile were then more likely to report a motivational style consistent with their tone, providing additional support that these profiles reflected an expression of one's motivational state.

3.5. Supporting analyses with exemplar files

Two independent research assistants blind to hypotheses and previous findings were asked to identify audiofiles that sounded natural, as if spoken and not read, and determined that twenty participants spoke in that ideally natural tone of voice. Sentences from this subset of participants were subjected to analyses of variances (ANOVAs) to attempt to replicate findings from the overall sample presented above. As before, analyses controlled for gender and country; findings for condition are presented below.

3.5.1. Pitch

Results of ANOVAs showed that autonomous sentences (M = 178.7) were spoken with lower pitch, $F(1, 246) = 5.52$, p =

.02, than controlled sentences (M = 188.3). Along with a lower mean, autonomous sentences showed lower minimum pitch, $F(1, 246) = 9.97$, $p = .002$ ($M_{autonomy}$ = 124.2 vs. $M_{control}$ = 135.2), as well as a lower maximum pitch, $F(1, 246) = 4.32$, $p = .04$ ($M_{autonomy}$ = 263.8 vs. $M_{control}$ = 297.6). As was the case for full HLM models, condition did not predict range in pitch, $F(1, 246) = 2.02$, $p = .16$ ($M_{autonomy}$ = 139.7 vs. $M_{control}$ = 162.4).

3.5.2. Intensity

Similarly to pitch, autonomous sentences (M = 62.1) were expressed using lower intensity, $F(1, 246) = 5.69$, $p = .02$, than controlled sentences (M = 63.2). Sentences showed higher minimum intensity in the Autonomy condition, $F(1, 246) = 8.55$, $p = .004$ ($M_{autonomy}$ = 44.1 vs. $M_{control}$ = 41.0), and no differences in maximum intensity, $F(1, 246) = 0.90$, $p = .35$ ($M_{autonomy}$ = 77.5 vs. $M_{control}$ = 78.2). In a separate analysis, autonomous sentences had a lower range of intensity, $F(1, 246) = 8.73$, $p = .003$ ($M_{autonomy}$ = 33.4 vs. $M_{control}$ = 37.2).

3.5.3. Speech rate

Finally, autonomous sentences also showed a slower speech rate than did controlled sentences, $F(1, 246) = 7.72$, $p = .006$ ($M_{autonomy}$ = .016 vs. $M_{control}$ = 0.18).

4. Discussion

The present study set out to explore the acoustic-perceptual underpinnings of motivational prosody using an experimental design. In contrast to studies investigating the acoustic profiles underlying emotional prosody (e.g. [9]), we used a large number of untrained speakers to develop an initial acoustic typology of motivational speech. Findings showed that autonomy-supportive messages such as "you're free to do this" were spoken with a lower mean pitch, lower mean intensity and were read more slowly than controlling sentences. These messages were also expressed using a smaller pitch range than controlling sentences. In contrast, latter messages such as "you ought to do it" were expressed with a higher maximum intensity (i.e. louder) than autonomy supportive sentences. The observed differences in pitch, amplitude, and temporal characteristics of our motivationally laden utterances suggest that speakers adopt specific prosodic speech patterns when communicating autonomy-supportive and controlling motivational sentences.

Everyday motivationally laden messages are used to shape listeners' behaviors. For instance, doctors encourage patients to adhere to preferred health and medical procedures, teachers aim to educate and socialize their students, and parents try to energize their children to engage in valued and avoid harmful behaviors. Even in non-vertical relationships between friends, romantic partners, or housemates, motivational messages are shared daily for important tasks (e.g. financial or lifestyle decisions that affect both partners) and small tasks (e.g. cleaning one's room). Previous work has examined which words are used to discriminate different motivations [8], but next to nothing is known about motivational communication beyond words, in the tone of voice used to express these messages. Our findings support the view that perceptually distinct vocal profiles are used to express motivational speech. Moreover, we show that listeners actually perceive auditorially presented autonomous sentences as being more autonomy-supportive or supportive of choice, whereas sentences from the controlling condition were perceived to be more pressuring. This suggests that expressive tones of voice can be formed and used to drive others to action, at least when prosodic and lexical-semantic cues are used concurrently.

Three major acoustic parameters were measured to identify vocal indicators of motivation: pitch, intensity, and speech rate. Interpretations about the direction of effects have to remain speculative at this point, but, arguably, controlling speech requires more 'effort' than autonomy controlled speech given that one is explicitly trying to shape someone else's behavior. Indeed, we find that the amount of energy used to produce controlling sentences is higher than when producing autonomy-supportive messages. Not only is this extra emphasis missing in the latter condition, autonomy-supportive speech is also characterized by slower speech rate, suggesting that the speaker might be less pressured and more flexible in their attempts to influence others' behaviors. In fact, it is well known that physiological modifications of the systems involved in speech production (i.e. respiratory, phonatory, articulatory) systematically alter a speaker's tone, and research in SDT has linked control to more physiological stress [13].

Our aim is that this research is seen as a starting point to outline different prosody patterns as a function of the speaker's motivational state and intention. Future studies can elaborate on this research in a number of ways. For example, this sample was relatively young and sentences read in a tightly controlled lab setting. This research should be replicated with older participants and those imagining themselves in real-life interactions. Furthermore, we tested a number of indicators of prosody, but future studies could further explore the exact prosody typology that characterizes autonomous and controlled motivation by examining a wider range of acoustic parameters. Finally, future studies will have to confirm acoustic profiles for the two different motivational states, independent of the content used to express a message. One way to do this is to use semantically neutral sentences intoned in either motivationally laden state.

5. Conclusions

The current study was aimed at classifying motivational speech patterns to develop an acoustic typology for autonomous and controlled motivations; ultimately, our goal is to advance a richer understanding of the nature of motivational communication. This is important for a number of reasons. First, prosody research has yet to be generalized to the large body of motivational research in SDT that manipulates motivation – the very manipulations used in the field can be modified and constructed systematically to reproduce expressive tones of voice that affect motivation and subsequent behaviors. Second, this research can be applied in analyzing real life recordings when individuals interact, to examine how motivation functions in daily life. Finally, speech inconsistencies and deceptive motivational influences can be studied for the first time once tone of voice is understood and defined as independent from words. More importantly, this research is fundamental to understanding the basic nature of autonomous and controlled motivations and how these can be communicated in tone of voice.

Abstract

Congenital Amusia is a developmental disorder that has a negative influence on pitch perception. While it used to be described as a disorder of musical pitch perception, recent studies indicate that congenital amusics also show deficits in linguistic pitch perception.

This study investigates the perception of linguistic and non-linguistic pitch by ten German amusics and their matched controls. To test the influence of amusia on linguistic pitch perception, the present study parametrically varied pitch differences in steps of one semitone in resynthesized statement-question pairs. In addition, we looked at the influence of stimulus duration, continuity of pitch and direction of pitch change (statement or question). Performance accuracy and reaction times were recorded. Behavioral results show that amusics performed worse than controls over all conditions. The reaction time analysis supports these findings, as amusics were significantly slower across all conditions. Both groups were faster in discriminating statements than questions. Performance accuracy supports these findings, as questions were also harder to discriminate. The present results warrant further investigation of the linguistic factors influencing amusics' perception of intonation.

Index Terms: congenital amusia, pitch, perception disorder

1. Introduction

Congenital amusia is a lifelong disorder defined by difficulties with the perception of tonal differences in music as well as speech. Affected individuals (henceforth: *amusics*) are faced with impairments in the musical domain. Their symptoms can range from an inability to discriminate notes of different pitches, an inability to recognize well-known songs without lyrics or an inability to recognize out of tune singing to an inability to recognize music as such. In the most extreme cases, it causes extreme discomfort and headaches [1-3]. Insufficient exposure to music, a hearing deficiency or brain damage have been excluded as causes [4], while the exact underlying deficit is still unknown. A fine-grained pitch processing deficit has long been assumed as underlying cause [3-6] but has recently been rejected as the sole cause of congenital amusia [7, 8]. Other proposed underlying deficits are a learning disability with respect to statistical learning [9, 10], a working-memory deficit specific to non-verbal sequences [7, 11, 12] or problems with rapid auditory temporal processing [13]. There has been no conclusive evidence for any of these hypotheses and a combination of underlying deficits is now being considered [7].

While it has been proven that congenital amusia negatively affects the musical domain, there has been uncertainty whether it is domain-specific to music or whether it also affects language. It was presumed that language is spared since it employs bigger pitch differences [2, 4, 5] but there is mounting evidence proving that language is also affected [14-17]. Patel et al. ([14]) investigated the pitch perception of English and French speaking amusics with an AX discrimination task using natural statement-question pairs, edited in a way that they differed acoustically in the final region of the intonation contour only. Tonal analogs of these statement-question pairs were also used. They found that 30% of amusics had difficulty discriminating statements from questions and that they performed better for the tonal analogs.

Liu et al. ([15]) also investigated the pitch processing of amusics using an AX discrimination (same-different) task with statement–question pairs, nonsense speech and tonal analogs. As in the study by Patel et al. [14], the stimuli retained the final pitch of naturally produced statements or questions. In this study all amusics performed significantly worse across all three stimuli types. Furthermore, amusics performed better on gliding tones than on natural speech, thereby demonstrating that congenital amusia impairs intonation perception.

The above-mentioned studies thus indicate that the view of congenital amusia as a music-specific disorder has to be reconsidered. Further studies show that amusics have problems distinguishing subtle intonational differences [15], emotional prosody [18], and lexical tones in tonal languages [16, 17, 19, 20]. It is therefore justified to say that congenital amusia is not limited to the musical domain. In light of these findings, further investigations concerning amusics' impairments in language perception are in order.

The present study investigates congenital amusia in speakers of German, a group that has not previously been studied. Our goal is to amass more evidence that congenital amusia does negatively affect language, more specifically, intonation perception, and to investigate possible factors which might influence amusics' perception. This study examines the discrimination of linguistic pitch and two types of tonal analogs by ten amusics and 30 matched controls. In contrast to earlier studies [5, 14, 15], the present study employs a parametric manipulation of small pitch differences from one to seven semitones. Furthermore, it tests the influence of three parameters – the length of stimuli, the continuity of the pitch curve and the direction of pitch change – on amusics' perception. The influence of stimuli length – amusics perform worse for longer stimuli – was shown in studies proposing a memory deficit [11, 12]. The influence of the continuity of the pitch curve was shown to be relevant for amusics in an earlier study [16], and the influence of the direction of pitch change was indicated by a case study [2], the latter showing that the tested amusic only detected rising pitch changes. The present study did not only consider performance accuracy, but also reaction times since amusics have been shown to react more slowly than controls [8, 21, 22].

	Age	Gender	Years of education	MBEA scale	MBEA contour	MBEA interval	MBEA rhythm	MBEA average

2. Method

2.1. Participants

10 amusic participants and 30 matched control participants were included in this study. None had neurological or psychiatric disorders. All were German native speakers with normal hearing (defined as a mean hearing level of 20 dB or less in both ears), which was assessed before the experiment by pure tone audiometry at 250–8000 Hz. All participants were recruited via advertisement and screened with the *Montreal Battery of Evaluation of Amusia* (MBEA; [23]), the main diagnostic tool to assess amusics, which consists of six subtests testing melodic organization (scale, contour and interval subtests), temporal organization (rhythm and meter subtests) and melodic memory (memory subtest). A mean score of 22 (or lower) out of 30 on the first four subtests was used to diagnose amusia in the present study (cf. [13, 15] and [24] for a detailed discussion). In addition, participants also had to answer a questionnaire about their musical background. The control group was matched for age, handedness, gender and years of education (cf. Table 1). Controls were screened with a shortened version of the MBEA, which contained only the scale and the rhythm subtest, to assess their musical abilities. All participants received a small monetary reimbursement for their participation.

2.2. Stimuli

The experiment was conducted in German. A male native speaker read four statement-question pairs (with a mean fundamental frequency 106.6 Hz) that were embedded in a story. These productions were recorded in a sound-attenuated booth with a Sennheiser ME 62 microphone and a Sound Devices MixPre microphone preamplifier/mixer onto a Marantz PMD570 solid-state recorder with a sampling frequency of 44.1 kHz. The two sentences in each pair were lexically identical but differed in the final region in the direction of the intonation contour (cf. [14]), i.e. statements had a falling pitch and echo questions a rising one. The sentences were constructed so that they differed in two further phonetic parameters. The first parameter was the continuity of the pitch curve, i.e. half of the sentences consisted only of voiced sounds, resulting in a continuous pitch contour, while the other half contained voiceless obstruents, yielding a discontinuous pitch contour. The second parameter was length: half the sentences were short (sentences 1 to 4 had 3 to 6 syllables with a mean duration of 1.05 s and a SD of 0.08 s) and the other half long (sentences 5 to 8 had 7 to 10 syllables with a mean duration of 1.59 s and a SD of 0.24 s).

Praat [25] was utilized to extract, stylize and simplify the pitch contour of each target sentence (for details see [24]). The resulting simplified pitch contour was then used to replace the original pitch contour, yielding synthesized stimuli. Seven further pitch contours were created for every target sentence by moving the final pitch region of the stimulus either upwards (for the statements) or downwards (for the questions) in one-semitone steps, thereby yielding a set of eight different stimuli per target sentence (cf. Figure 1) and 64 stimuli in total. The question was manipulated downwards towards a statement, but never reached the pitch level of the recorded statement, and the statement was manipulated upwards. The logarithmic semitone scale was used instead of a linear scale (as e.g. in [5]), thereby making the result more comparable to pitch detection thresholds of amusics in the literature [3, 26].

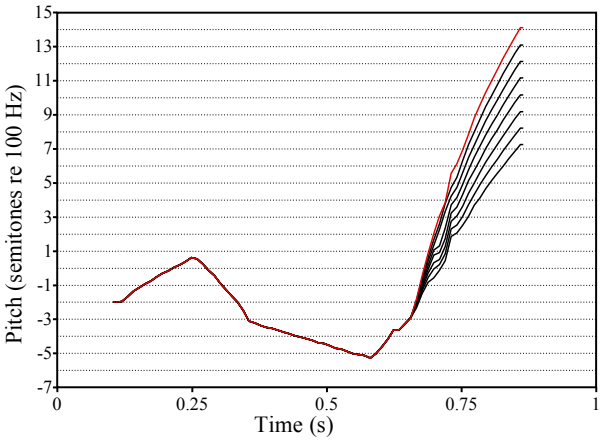

Figure 1. *Pitch contours of stimuli. Original simplified contour in red and seven manipulations in black.*

In addition to the speech stimuli, two types of tonal analogs, consisting of sinusoidal waves and pulse trains respectively, were created, resulting in a total of 192 different stimuli.
The sinusoidal wave analogs (short: sine) were created by converting the synthesized sentences into sinusoidal waves whose frequency exactly followed the sentences' pitch contour (cf. [14, 27]). The pulse train analogs (short: pulses) were created by converting the sine analogs into sequences of pulses, with the distance between pulses inversely proportional to the frequency of the pitch curve (a higher frequency corresponds to a smaller distance). These two types of tonal analogs were chosen since they differ in acoustic complexity. While the sinusoidal waves have a relatively

simple acoustic signal, the pulse trains have a more complex acoustic signal. The three different stimulus types therefore vary in the presence or absence of linguistic material and in acoustic complexity from sine, as the simplest one, to pulses, as the intermediate one, to speech, as the most complex one.
Since an AX discrimination task was used, stimuli had to be paired. Each stimulus with an altered final pitch region (black in Figure 1) was once paired with itself and once with the unaltered version (red in Figure 1), while a separation between the stimuli created from different sentences and between the different stimulus types was maintained (i.e. sine was not mixed with pulse or speech stimuli etc.). This yielded seven 'different' pairs and one 'same' pair per stimulus. For counterbalancing reasons, an equal number of 'same' and 'different' pairs was included in the experiment, i.e. 14 stimuli pairs. In total, 336 experimental stimuli pairs were included, consisting of 8 original sentences (4 statement-question pairs) x 3 different stimulus types (speech stimuli and tonal analogs) x 14 stimuli pairs (7 'same' pairs with unaltered final pitch regions and 7 'different' pairs with altered final pitch regions).
In addition to the 336 experimental trials, nine practice and 12 catch stimuli were created in the same way. Catch trials were 'different' stimuli pairs in which the final pitch region of one stimulus was altered by 24 semitones. These catch trials were included in the experiment to ensure participants paid attention and performed the task correctly. Controls and amusics perceived all catch pairs as different, thus no one had to be excluded on these grounds. Practice trials consisted of the three short, continuous, statement stimuli which were paired either with themselves (resulting in three 'same' stimuli pairs), or with contours that were raised finally by 2.5 and 5.5 semitones (resulting in six 'different" stimuli pairs). These nine practice trials were used in the practice session before the experiment.

2.3. Design and procedure

The 336 stimuli pairs differed in 5 conditions:

- type (voice, sine, pulses),
- length (short, long),
- continuity (continuous, discontinuous),
- direction (question, statement),
- interval (0-7 semitones).

They were used in a same-different discrimination task with a blocked design. The 14 stimuli pairs that shared all conditions were presented within a block in a randomized order. Across blocks, the order was pseudo-randomized so that blocks with more than two conditions in common did not immediately follow each other. The order of blocks was counter-balanced across participants to compensate for fatigue. There were two breaks, one after every eight blocks.

The experimental sessions took place in the phonetics laboratory at the University of Düsseldorf and lasted approximately 60 minutes. Participants were seated in a sound-attenuated booth, and the stimuli were presented over AKG K 601 headphones using Praat on a Windows XP computer. Participants could adjust the volume to a comfortable level. They were asked to listen carefully to each trial and to decide whether the two stimuli were the same or different. They were told to respond as quickly as possible by pressing labeled buttons on the keyboard. Behavioral results and reaction times were recorded with Praat.
Each trial followed the same pattern: A warning signal was followed by one second of silence followed by the stimulus pair with an inter-stimulus interval (ISI) of one second. This ISI was chosen since Williamson et al. [13] pointed out that longer ISIs may interfere with possible pitch memory deficits in amusics, while shorter ISIs might cause problems due to a rapid auditory processing deficit in amusics. The experiment was preceded by a practice session to familiarize participants with the experimental procedure, the different types of stimuli and the semitone intervals. Feedback was provided during the practice session but not during the experiment.

3. Results

Responses were scored as hits when different stimuli pairs were correctly identified as different, and as misses when they were not correctly identified. Conversely, correctly identified same-pairs were scored as correct rejections and as false alarms when they were incorrectly identified.

3.1. Reaction time (RT) analysis

RTs were measured from the offset of the second stimulus of each pair. Outliers, here defined as negative RTs or RTs slower than 3 SD of the group mean, were excluded. In a first step, the mean RTs for controls and amusics over all conditions were compared (cf. Figure 2). The RTs of amusics (M = 1121, SE = 13.2) and controls (M = 946, SE = 4.6) differed significantly ($t(998) = 12.5$, $p < 0.001$) only for hits. This represented a medium-sized effect r = 0.37. RTs are conventionally analyzed for hits only, therefore the following analysis takes only RTs of hits into account.

The next step consists of analyzing the RTs per variation step in semitones. Controls and amusics differed significantly at all semitone steps, except step 1 (Table 2). Next, RTs were submitted to an ANOVA with group (amusic, control) as the between-participant factor and length, continuity, direction and type as within-participant factors. All parameters had significant main effects except for continuity, which failed to reach significance (p = 0.29). Since continuity was also not included in any significant interactions, it was excluded from the statistical analysis in order to increase the power of the analysis. An ANOVA was run again without continuity.

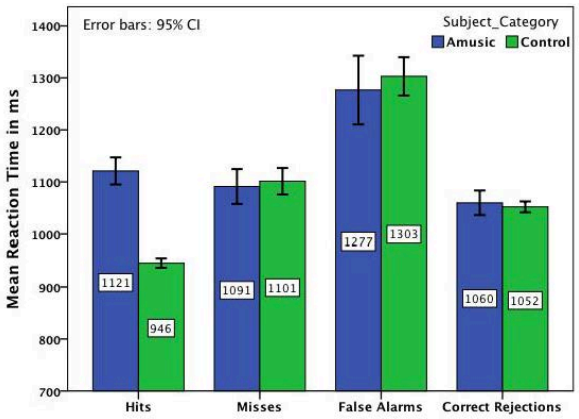

Figure 2. *Mean reaction times of amusics and controls for hits, misses, false alarms and correct rejections.*

A significant main effect was found for group ($F(1, 35)$ = 4.89, p = 0.034), indicating that amusic participants were slower to respond than control participants.

Variation Step	1	2	3	4	5	6	7	average
Amusic								
Mean (in ms)	1215	1208	1115	1079	1142	1109	1090	1121
SD (in ms)	482	384	394	343	377	360	355	374
Control								
Mean (in ms)	1112	1035	982	936	915	901	885	946
SD (in ms)	336	305	320	280	273	268	244	290
t-test								
t	1.414	4.188	3.094	4.442	6.697	6.922	7.070	12.501
p	0.163	**< 0.001**	**0.002**	**< 0.001**	**< 0.001**	**< 0.001**	**< 0.001**	**< 0.001**

Table 2. *Descriptive statistics and results of t-tests comparing amusics' and controls' reaction times across variation steps; SD: standard deviation; t: test statistic of the independent samples t-test; p: probability value; bold face indicates significant results.*

Significant main effects were also found for: Length ($F(1, 35) = 11.70$, $p = 0.002$), indicating that the discrimination of long stimuli ($M = 1008$, $SE = 33.2$) was faster than of short stimuli ($M = 1048$, $SE = 31.7$); direction ($F(1, 35) = 50.81$, $p < 0.001$), indicating that the discrimination of statements ($M = 979$, SE 32.8) was faster than that of questions ($M = 1077$, $SE = 32.6$); and type ($F(2, 70) = 7.82$, $p = 0.001$), indicating that the discrimination of voice stimuli ($M = 997$, $SE = 33.5$) was faster than of pulses ($M = 1028$, $SE = 30.5$) or sine stimuli ($M = 1059$, $SE = 35.3$). This last main effect reflected the significant difference between voice and sine stimuli ($p < 0.001$). There were no significant interactions between group and any of the other parameters. The absence of any significant interactions with group shows that the investigated parameters influenced the reaction times of amusics and controls in the same way, while still maintaining the main effect of group, i.e. that amusics are generally slower. There was a significant interaction between length and direction but since this interaction does not involve a group difference, it is not analyzed further at this point.

3.2. Performance accuracy analysis

The hit rate was calculated by dividing the number of correct responses for different trials by the total number of different trials. Across all conditions, amusics ($M = 0.42$, $SD = 0.20$) and controls ($M = 0.80$, $SD = 0.23$) differed significantly ($t(12) = -3.35$, $p = 0.006$). An analysis using Signal Detection Theory, a psychophysical approach of measuring performance, while taking the individual's ability to discriminate and their response bias into consideration [28], was also conducted. All data were analyzed using a regression analysis. A detailed discussion of this analysis with a subset of the participants can be found in [24]. Due to lack of space, only the results of the hit rate analysis will be reported here briefly. Main effects of group ($p < 0.001$), direction ($p < 0.001$), type ($p < 0.001$) and interval ($p < 0.001$) were found and interactions between group and type ($p < 0.001$) and group and interval ($p < 0.001$) were also found.

4. Discussion

The present study amasses more evidence that congenital amusia negatively influences speech perception by showing that amusics performed behaviorally worse and slower than controls for non-linguistic as well as linguistic stimuli. This supports earlier studies [14-17] claiming that amusia is not limited to the musical domain. While Patel et al. [14] found that only a subset of amusics had an impaired discrimination of linguistic material, in the present study all amusics were impaired (cf. also [15]).

Furthermore different parameters influencing amusics' perception were considered. It was shown that even at a distance of seven semitones, amusics were still impaired in comparison to controls. Their hit rate was not only lower, their reaction times were also significantly slower (see also [8, 21, 22]). Continuity of the stimuli did not significantly influence perception even though amusics performed slower/worse for discontinuous stimuli, supporting the findings by [16] where amusics performed worse for discrete stimuli. Questions, i.e. rising pitch changes, were discriminated slower and worse by amusics and controls. This is in contrast to the findings of [2], where the one tested amusic could only detect rising pitch changes. We hypothesize that statements might have been easier to discriminate since they appear more often than questions in real speech.

There were also dissociations between reaction times and performance accuracy: For length, there was no influence on the performance accuracy, but on RTs: surprisingly, long stimuli were discriminated faster. And while amusic and controls performed faster for linguistic stimuli, controls performed significantly better for non-linguistic stimuli, which was not the case for amusics. Amusics' performance accuracy did not differ for linguistic and non-linguistic stimuli. This supports findings by [16], who also found that the presence or absence of linguistic material did not influence amusics' performance, while controls performed better for non-linguistic material. This dissociation between reaction times and performance accuracy as well as the influence of the pitch change direction need to be investigated further.

5. Conclusions

In the present study, we investigated the pitch perception of amusics. Our goal was to gather further evidence that amusia does indeed affect intonation perception and to gain insight into factors that might have an influence. We found that amusics performed significantly worse across the entire experiment. Their pitch perception was impaired for speech stimuli and tonal analogs even at a distance of seven semitones, which is in line with earlier studies ([14-17]). This further substantiates the hypothesis that congenital amusia is not domain-specific but rather a general perceptual impairment. Concerning possible factors influencing amusics' perception, stimuli length and direction of pitch change were shown to play a role while continuity of stimuli did not. These and other linguistic parameters require further investigation.

Abstract

There are many techniques for modelling properties of speech duration patterns, including models of rhythm as oscillation, partial models of rhythm types as departures from isochrony, models of tempo acceleration and deceleration, and models of duration hierarchies and their relation to hierarchies in word and phrase structure. Except for oscillator modelling, many approaches use data extraction from speech annotations, often with mainly manual methods. We employ computational data-mining for phonetic research, as opposed to phonological research on the one hand or speech technological research on the other, and explore the potential of the computational annotation data-mining paradigm for improving efficiency and scope of analysis. We show consistent variation in syllable duration patterns in selected speech varieties in English, Chinese and Polish, chosen for their known different prosodic typological properties. Results include a possible limen of 50ms for relevant timing patterns. For data-mining we use the *Time Group Analysis* (*TGA*) methodology, directly in the *TGA* online tool and integrated into the *Annotation Pro+TGA* desktop software.

Index Terms: prosody, syllable duration, speech style, register, dialect, annotation mining, English, Chinese, Polish

1. Introduction: domain and methods

Inter-variety differences in speech duration patterning have been studied mainly in the context of prosodic typology and native-foreign pronunciation. The present sociophonetic contribution addresses the issue of intra-language variation in syllable durations at the phonology-phonetics interface, in pilot case studies of different registers or speech styles in the same dialect (English, Polish) and different dialects in the same register (Mandarin) using the computational annotation-mining paradigm [1], [2]. We concentrate on syllable duration patterns in interpausal time groups. Annotation practice in this field has been criticised for lack of a precisely specified empirical basis [3], [4], so pause and syllable annotation criteria require comment.

Pauses are typically defined acoustically with a minimal duration criterion such as 100, 150, or 200 ms ([5], [6], [7], [8], [9], [11], [12], [13], [14], [15], [16]): auditorily by holistic annotator perception (whether actual silence, or associated with final lengthening and other item-final features), or functionally (with syntactic boundary, hesitation). The annotations used here are grounded in a heuristic combination of acoustic, visualised and auditory criteria, with actual acoustic pause lengths sometimes much less than the commonly proposed minimum of 100 ms. Explicit functional criteria were not used, in order to avoid circularity in later studies of the relation between interpausal groups and grammatical constituents. The segmental content of so-called 'filled pauses' was not treated as a pause.

Syllable annotation is based on more language-dependent criteria than for pauses. The initial criterion of word boundary as syllable boundary is relatively straightforward for Mandarin and also for English. For Polish the criterion is more complex (cf. proclitics): a modified *Maximal Onset Principle* was used, with two constraints on onset structure: non-decreasing sonority, and attested actual occurrence as word onset [17]. Word-internally, ambisyllabic consonants were annotated as onsets of the following syllable in English and Polish; the issue does not arise in Mandarin phonotactics. We are not concerned with syllable-internal boundaries.

The literature reveals many techniques for measuring properties of speech duration patterns, including acoustic models of rhythm as oscillation, and annotation mining with partial models of rhythm types as degrees of isochrony, models of acceleration and deceleration, and of duration hierarchies and their relation to word and phrase hierarchies. We focus on annotation mining (cf. Section 2). Section 3 presents the results of the three pilot case studies on English, Mandarin and Polish, and Section 4 contains a summary and conclusion, and outlines future research and applications.

2. Annotation data-mining

We define speech annotation data-mining as the extraction of structured information from speech annotations, and use computational annotation mining tools for efficiency, consistency and handling large corpora: the *Time Group Analysis* (*TGA*) online tool [18] and *TGA* functions integrated into *Annotation Pro* [19], [20]. We apply the tools to reliable statistical distributional analysis of syllable duration relations and patterns, many of these properties being relatively inaccessible to manual approaches, at least for large data sets.

2.1. Annotations

Annotations are in general modelled as two-dimensional constructs structured as parallel symbolic information streams (tiers, layers) of event tags. Event tags are represented as label-interval pairs, where the intervals Δt can be represented in a number of ways: (1) as single time-stamps t for the event start or end with a second time-stamp implicitly provided by an adjacent event tag (ESPS, HTK, BOSS); (2) time information pairs: (a) event beginning and end time-stamps t_1, t_2 (Praat, Transcriber, WaveSurfer, ELAN, Anvil), or (b) event beginning time-stamp t_1 and duration Δt for $\Delta t = t_2 - t_1$ (Annotation Pro [20]). Time-stamps are typically represented (1) as sample numbers (with sample-rate stored in the annotation file metadata for conversion to time values),

(2) as clock time. Rarely, time-stamp triples may be defined for event beginning, centre (or peak) and end (SAM).

The parallel symbolic information streams offer two levels of complexity in annotation data-mining: *intra-stream relations* of sequence and hierarchy in single streams, and *inter-stream relations* of overlap or synchronisation [21], with hierarchy as a special case of overlap. Formal models from graph theory [22], event logic [23], automata theory [24] and interval calculus [25] are available for representing and computing with annotations.

Two kinds of intra-stream information can typically be mined from annotations: (1) distributional properties of label sequences and intervals (cf. Section 3.1); (2) interval duration $I=\Delta t$ and duration difference relations $\Delta I=\Delta\Delta t$ such as interval duration dispersions (or inversely: regularity or isochrony[1]), and interval acceleration and deceleration slopes. We focus on interval duration distributions and duration patterns in interpausal syllable sequences.

2.2. Duration dispersion or isochrony

Measures of duration dispersion (or its inverse, relative isochrony) which have been used for various phonetic units include standard deviation and the models shown in Table 1: *Pairwise Irregularity Measure*, *PIM*; *Pairwise Foot Difference*, *PFD*; *raw* and *normalised Pairwise Variability Index*, *rPVI* and *nPVI*; cf. references and discussion in [1]. *PIM* is a ratio model, *PFD* is a simplified variance model. The *nPVI* is a difference limen model $100*\Delta I/(I/2)$. (rather than the usual $\Delta I/I$, yielding an asymptote of 200 for the *nPVI*, not the usual 1.0), and eliminates rate change effects by comparing neighbours, not all intervals.

Table 1: *Definitions of PIM, PFD, PVI measures.*

$PIM(I_{1,\dots n})$	=	$\sum_{i\neq j}\lvert\log\frac{I_i}{I_j}\rvert$
$PFD(foot_{1\dots n})$	=	$\frac{100\times\sum\lvert MFL-len(foot_i)\rvert}{len(foot_{1\dots n})}$ where MFL = 'mean foot length'
$rPVI(d_{1\dots m})$	=	$\sum_{k=1}^{m-1}\lvert d_k-d_{k+1}\rvert/(m-1)$
$nPVI(d_{1\dots m})$	=	$100\times\sum_{k=1}^{m-1}\lvert\frac{d_k-d_{k+1}}{(d_k+d_{k+1})/2}\rvert/(m-1)$

The models are typically used for specific label types (foot, vocalic and consonantal intervals, syllables), but the formulae are neutral in this respect and may be used for any intervals. The models are not equivalent: Figure 1 shows correlations between the measures for utterances of 5 speakers of Brazilian Portuguese [1]; there is considerable inter-speaker variation in the correlations, and while *corr*(*SD*,*PFD*) is predictably high, *corr*(*PFD*,*nPVI*) and *corr*(*SD*,*nPVI*) are lower, though similar to each other. In general, *PIM* does not relate well to the other measures. The models have been called 'rhythm metrics', but they only fulfil one necessary rhythm condition of *relative* ('*fuzzy*', '*sloppy*') *isochrony*. They fail on the equally necessary condition of *rhythmic alternation*, since the use of absolute (unsigned) values does not distinguish between negative and positive duration changes [1], [2]. The *SD*, *PFD* and *nPVI* measures (though not *PIM*) are still useful models of relative isochrony (regularity, 'smoothness', 'evenness') of intervals, however.

[1] Organisation of an event sequence into equal time intervals; in data transmission engineering (sometimes incorrectly spelled 'isochryny') a particular kind of synchronisation.

Like the formulae, the annotation data-mining approach itself, shown in the pilot case studies in Section 3, is domain-neutral, in that it may be applied to annotations of any segments in speech, to annotations of visual head, hand and postural gesture streams, to both of these combined (or indeed to any comparable empirical time-function). We focus on syllables.

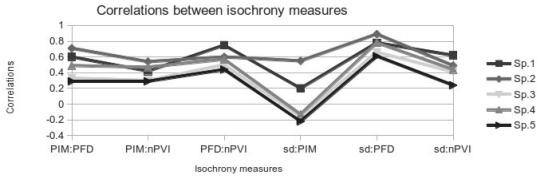

Figure 1: *Correlations between so-called 'rhythm metrics' for 5 speakers of Brazilian Portuguese.*

While the basic manual annotation mining studies noted above have been discredited as rhythm measures and have been conceptually overtaken by oscillator models [26], they have proved their worth as irregularity measures. We go a step further in using computational annotation mining for efficiency, consistency and data quantity, and for processing additional complex empirical parameters.

3. Varietal duration patterns: case studies

Contrary to *nPVI* studies, which ignore speech rate and filter out speech rate change, the case studies on English and Polish speech styles focus on acceleration, deceleration and, for Polish, also speech rate. The Mandarin study investigates relations between duration patterns and grammatical items in Beijing and Hangzhou Mandarin. At this stage, the three studies are designed to show the potential of computational annotation mining techniques with typologically different languages applied to relatively large data sets, rather than to pursue typological studies, because language variety corpora of adequate size are not readily available.

3.1. Case study 1: British English genres

The annotation data for pilot studies of annotation mining techniques with British English are taken from a subset of the Aix-MARSEC [27] database of radio speech, covering a range of sub-genres: *A* (*Commentary*), *B* (*News broadcast*), *C* (*Lecture aimed at general audience*), *D* (*Lecture aimed at restricted audience*), *E* (*Religious broadcast including liturgy*), *F* (*Magazine-style reporting*), *G* (*Fiction*), *H* (*Poetry*), *J* (*Dialogue*), *K* (*Propaganda*) and *M* (*Miscellaneous*). The genres *A*, *B*, *C*, *F* and *K* were included in this study due to their relatively similar discourse types. The Aix-MARSEC repository also contains annotation data-mining tools, but not for parameters investigated here.

Figure 2 shows averages of several metrics for the genre data (values are scaled to permit visualisation in the same graph). Except for genres *F* and *K*, values of the measures are consistently very similar, even though the speakers in each case are different and in some cases several speakers per genre are present in the corpus.

Genres *F* and *K* are outliers with regard to slope. The explanation may lie in a difference in discourse functions: genres *A*, *B*, *C* and *D* are typically formal read-aloud or rehearsed genres, while *F* is associated with more spontaneous speech, and *K*, whether read or not, would be expected to contain persuasion oriented rhetorical prosodic

features, including syllable lengthenings. Higher positive slope values mean increasing average duration, i.e. speech rate deceleration in interpausal units, contrasting with more constant speech rate in the read-aloud genres. Slope may thus be a useful discourse type marker, along with other prosodic parameters which were not represented in the annotations.

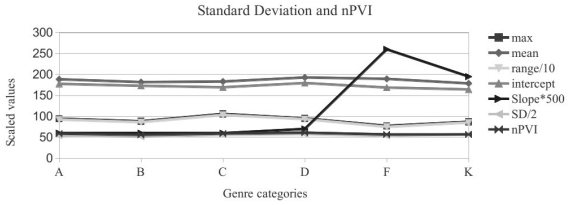

Figure 2: *Scaled annotation mining measures of six sub-genres of British radio speech.*

In addition to the analysis of duration dispersions, the *positive and negative polarities of duration differences* between neighbouring syllables were represented as *tokens*, retaining alternation (unlike the dispersion metrics), and *token sequence* distributions were registered at different *duration difference thresholds*. This technique is a first approximation to identifying actual rhythmic alternation independently of oscillator models, and in contrast to the dispersion measures shown in Table 1.

The token sequences of Table 2 (from the first utterance in the Aix-MARSEC database) show a high proportion of alternations at difference thresholds below about 50 ms; above 50 ms the difference threshold overrides many smaller alternation differences. Whether this transition at 50 ms is perceptually or functionally relevant needs more study.

Table 2: *Ranks of duration change n-grams* ($2 \leq n \leq 5$) *at thresholds 0...60* (\: *increase;* /: *decrease;* =: *same*); +, #: *word boundaries and pauses.*

5 (9)	/\/\/	4 (7)	/\/\/	3 (5)	\=/=\	3 (5)	+====

Preliminary studies show that a similar transition at around the 50 ms duration difference threshold can also be found in other languages and language varieties (cf. Section 3.2). However no hard and fast evidence can be given at this time. If this threshold transition at about 50 ms turns out to be generally valid, the result casts doubt on the validity of the raw duration data of previous duration dispersion studies.

3.2. Case study 2: Chinese regional accent

An issue which has not received detailed empirical attention in recent years is the relation between timing in syllable sequences and grammatical units such as words and phrases. A pilot annotation mining experiment was undertaken with recordings of 6 speakers (3 from the Hangzhou area and 3 from Beijing) reading a Mandarin Chinese translation of the IPA standard text 'The North Wind and the Sun' from the CASS corpus [28], [29]. *Time Tree* relations [21], [30] between syllable relations in interpausal groups, and words (one or more characters/syllables) were investigated.

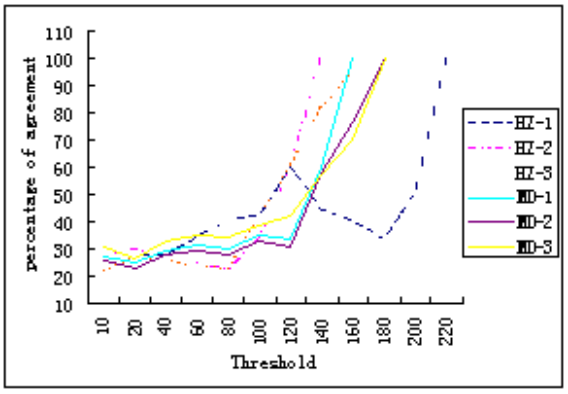

Figure 3: *Relations between duration-based syllable groupings and words for speakers of Beijing and Hangzhou varieties of Mandarin Chinese.*

The constituents were induced automatically from long-short duration patterns, where shorter constituents are prepended to longer constituents with a recursive quasi-iambic (*weak-strong*) *Time Tree* algorithm setting:

1. A syllable is a constituent.
2. A shorter constituent prepended to a longer following neighbour constituent is a constituent.
3. Nothing else is a constituent.

The algorithm was applied with all integer ms thresholds for duration differences from 0 ms to around 200 ms, where the correspondence ratio starts dropping. The following example shows a quasi-iambic *Time Tree* (represented as bracketing) of the Mandarin utterance "zhe4 shi1hou5, lu4 shang5 lai2 le5 ge4 zou3 daor4 de5" (*at that time, on the street came a traveller*), and a grammatical bracketing:

Quasi-iambic Time Tree: (((zhe4 (shi2 hou5)) (((lu4 shang5) (lai2 (le5 (ge4 zou3)))) daor4)) (de5 PAUSE))

Grammatical bracketing: ((zhe (shi hou)), (lu shang) ((lai) (le) (ge) (zou daor de)))

The groups (shi2 hou5) and (lu4 shang5) correspond to words; (ge4 zou3) is not a grammatical constituent. Also, factoring out the effect of the pause, (lai2 le5 ge4 zou3 daor4 de5) corresponds to a grammatical constituent. The correspondences between the syllable groupings and words are shown in Figure 3 (cf. also [31]).

Below a duration difference threshold of about 50 ms, correspondences between syllable groups and words are low, and are comparable among speakers. Correspondences gradually increase, and begin to diverge until about 100 ms, where they rapidly increase and interesting patterns emerge. Correspondences for Beijing Mandarin remain similar as thresholds move beyond 50 ms, while for the Hangzhou variety they are more diverse, as would be expected in a comparison between a standard accent (Beijing Mandarin) and a non-standard regional accent (Hangzhou Mandarin).

Whether the threshold limit of 50 ms is related to the limit found for English at a similar threshold order of magnitude (Section 3.1) needs further study.

3.3. Case study 3: Polish speech styles

In order to analyse syllable durations in Polish, recordings of read speech and dialogues from the Paralingua corpus [32] were used. The aim of the analysis was to look at timing patterns in speech recordings of 20 speakers in three stages of a recording session: (A) read speech produced at the very beginning of the session; (B) telephone conversations (task-oriented dialogues over the telephone); (C) read speech produced at the very end of the session after participating in a dialogue with time constraints imposed.

The time constraints were imposed only in the dialogue part of the experiment while for the final reading there were no time limits and the instruction was exactly the same as with session-initial reading (i.e. in both cases the speakers were requested to read the text in their normal, habitual way). Segmentation into interpausal time groups assumed minimal significant pause duration to be about 100 ms (cf. e.g. [5] for German). However, in some cases the minimal value of only ca. 50 ms was used, based on auditory perception and visual inspection of spectrograms by two experienced annotators. The study investigates the question whether consistent influence of the recording procedure on syllable timing could be associated with durational variability between time groups (see also [33]).

The most significant differences between the three types of speech were observed for slope, as with the English genres (Section 3.1). The overall mean values are included in Table 3. The overall mean of slopes for the dialogue recordings was significantly higher than for read speech of both types. Also, the overall means of intercepts and *nPVI* measures appeared to be highest for conversational speech.

Table 3: *Overall means of duration difference slope, intercept and nPVI for recording stages A, B and C.*

	Slope	Intercept	nPVI
A. Read 1	0,0925	145,05	43,83
B. Dialogue	0,2121	177,00	48,28
C. Read 2	0,0829	145,94	42,50

More detailed information on the individual differences between speakers in the three recording session stages can be found in Figure 4: the plots show the variability of mean slopes, intercepts and *nPVI* values for each of the 20 speakers. As shown in the figure, only in case of three speakers (23, 24, 29) was the mean slope close to the values for read speech while all the remaining speakers differentiated their slopes between read speech and dialogue.

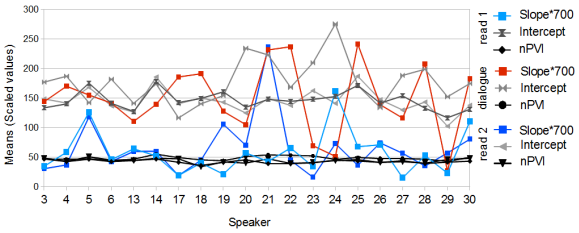

Figure 4: *The variability of selected timing properties in three speaking styles for 20 speakers of Polish.*

The two read speech tasks were very similar as regards the overall values. However, when individual results for particular speakers were investigated it was observed that the values for the initial reading tended to vary more among speakers than those for the final reading. This might suggest that after participating in the preceding tasks (20-30 minutes altogether including the inital reading and three dialogue tasks), inter-speaker differences in speech acceleration or deceleration tended to be less significant than in the earlier stages of the recording session, especially in the dialogues.

Also, speech rate (syll/sec) was measured for each recording stage. The observed overall mean value was slightly higher for the final reading (5.5. syll/sec) than for the two preceding parts (5.3, 5.4 syll/sec, respectively), but the differences were not statistically significant. Individual rate differences between the two reading tasks were mostly negligible, being exactly or almost the same for most speakers. The majority of speakers (except 13 and 17) clearly differentiated read and spontaneous tempi, but using faster or slower rate for a particular type of speech appeared to be individual rather than style-dependent. Overall rate means were in line with values observed for normal reading rate [33] and for dialogues [34] in Polish; [35] reported higher means around 6.9 syll/sec for Polish dialogues, possibly due to the different data type (fluent and coherent utterances with no unintelligible parts, false starts or hesitation sounds).

When comparing these observations with the results of slope variability measurements it was found that the two speakers whose mean rates were the same in both read and spontaneous speech still exhibited different patterns for acceleration-deceleration, as represented by the mean slope values for the two speech styles.

4. Conclusions

We have shown how new computational annotation-mining procedures can be deployed to examine a variety of interesting speech duration parameters in the sociophonetic context of speech genre, style and regional accent variation in typologically different languages. Despite the typological differences of phonology and morphology, the languages showed similarities: in a duration difference (Δt) threshold transition around 50 ms emerged (in different English and Mandarin contexts; not investigated for Polish), and in duration difference slope (English and Polish; not investigated for Mandarin). While the corpora used in the present studies were much larger than the small corpora used in previous manual annotation mining studies, in order to exploit computational annotation mining techniques fully and to move to machine learning techniques, larger annotated corpora for more languages are needed.

An interesting topic for future work is the minimal duration difference of 50 ms found in our production data for English and Mandarin. Present results do not yet permit the formulation or confirmation of relevant difference limen models of the $\Delta I/I$ type, where I is the average time-stamp difference based duration interval Δt, and ΔI is the average interval difference $\Delta\Delta t$.

We foresee applications of our computational annotation mining techniques in foreign language learning and testing studies, in modelling interfaces between phonetics in studies of phonology, prosody, grammar and discourse structure, and in evaluating naturalness in speech synthesis [36].

5. Acknowledgments

Creation of the Paralingua corpus was supported from the Polish financial resources for science in the years 2010-2012 as a development project (O R00 0170 12). The Mandarin corpus is used by kind permission of the Chinese Academy for Social Sciences. The TGA online tool is currently hosted by the Bielefeld University.

Abstract

In this paper we examine the intonation of the interrogative sentence mode in Brazilian Portuguese (BP), and how questions differ from their declarative counterparts. With this purpose, we characterize the nuclear patterns, as well as the prenuclear contours. Our aim is to identify which specific prosodic features, including prenuclear pitch range values, are systematically associated with the interrogative mode of enunciation. In the interdialectal comparison, we contrast how the speakers from Blumenau (SC) in the South and Aracaju (SE) in the Northeast, distinguish themselves from speakers of other varieties in their prenuclear patterns. These are significantly higher for the yes/no interrogatives than for the declarative types, which is not the case within other dialects in our study, including the standard varieties of Rio de Janeiro and Sao Paulo. Perception tests have corroborated the production results.

Index Terms: Phonology and phonetics of prosody, Prenuclear contours, Brazilian Portuguese

1. Introduction

In this paper, we analyse how the interrogative sentence mode is encoded in some dialects of Brazilian Portuguese (BP), and how yes/no questions differ from their neutral declarative counterparts. Our aim is to identify which specific prosodic features, including prenuclear pitch range values, are systematically associated with the yes/no interrogative mode of enunciation.

The distinction between statement and question intonation has been widely studied and has been claimed to be universal. The link between sentence mode and intonational contours has been established and the use of rising question intonation in yes–no questions has been reported for the great majority of languages, including those that are tonal.

In a number of Romance languages, such as Spanish and Brazilian Portuguese (BP), intonation is the sole method of distinguishing a yes–no question from a declarative statement. Patterns are generally assumed to be falling in statements and rising in questions, as they are in English, but as we show, this is an oversimplification. In the case of BP, more accurate is the statement by Bolinger [1] of "higher pitch somewhere in the utterance", mostly but not necessarily, rising intonation.

Indeed, the typical patterns for yes-no interrogatives in BP, although high in pitch, have been reported to have a final 'circumflex' falling intonation, and not a rising one. Lucente and Barbosa [2] transcribe the intonation of yes-no questions in BP as L+H*L%, stating that "there is a peak in the middle of the accented vowel and its fall coincides with the end of the vowel."

Moraes [3] has characterized the nuclear contours for declaratives and yes-no interrogatives in BP as H+L*L% and L+H*L% respectively, that is, both are falling intonations. The final peak for declaratives utterances happens categorically on the pre-stressed syllable, whereas the peak for the yes-no interrogative is on the accented syllable. In this same study the final contour of yes-no questions in BP is characterized as a nuclear tonal rise on the stressed syllable, followed by a fall in the following unstressed syllables. The AM notation used is the 'hat pattern' L+H*L%.

Although the unmarked, neutral yes-no questions in BP have been described as falling, as we saw, this does not exclude rising final contours with H% boundary tones. In our reseach, we have found a number of such rising contours in more marked interrogatives such as confirmatory or incredulous questions [4]. Also, some rising yes-no questions arise from truncation, that is, the incomplete rendition of the rising-falling pattern due to lack of segmental material; this occurs in utterances with stress on the final syllable, and also in cases of final vowel deletion.

It has also been reported that many dialects of BP regularly use a rising contour for the unmarked yes-no questions; for instance, in the South (Porto Alegre-- RS) [5], Lages – SC [6] and the Northeast (Aracaju - SE) [7]. In each of these dialects, a nuclear pattern L H*H% has been proposed for the nuclear region.

Some studies, such as the one in [8] have even proposed a kind of division of varieties of BP based on the final contour of interrogatives, with an isogloss that would divide the country into two halves: the one using rising contours in North, the one using the falling, 'circumflex' contour in the South.

In our data of different varieties of BP, we have found a number of such rising contours, but the analysis of their specific contexts and pragmatic uses (USE) is still in progress.

Our current findings indicate that, for the interrogative tonal nucleus in some southern regions, the pronunciation of the speakers from the cities of Florianopolis and Blumenau show a circumflex contour (L+H*L%), with or without truncation [4,6]. The performance of the two speakers from the city of Lages showed two terminal contours: L+H*H% and L+H*L%, the latter being the most frequent. We noted how the production of these utterances by the Aracaju informant had a recurrent rising contour L+H*H%, in spite of also exhibiting the L+H*L% contour [7].

Our research has also uncovered a kind prenuclear contour that is different from the one described in the literature for BP, which was like the prenuclear reported for Spanish, i. e., higher for questions than for declaratives.

In order to present the results of this research, in the following Section 2 we describe the data collection, analysis and results for the prenuclear contours that resulted from the production tests. In section 3, we present the methods used and results obtained in the perception experiments; and finally we present the conclusions we can draw from our results.

2. Production of prenuclear contours

Studies in languages such as Spanish [9] have established that sentence-initial f0 peaks of interrogatives are significantly higher than those in statements, by values that are strikingly regular in terms of tonal targets. It is for this reason, it has been claimed, that the Spanish spelling system uses the inverted question mark "**¿**" in order to indicate the beginning of the question.

This phenomenon of higher initial peaks has also been noted in languages such as Danish and Swedish and Bengali, but it does not seem to occur in English or French. But what about BP? Given some preliminary observations about this phenomenon, we investigated whether the prenuclear contour marked as well.

Moraes [3] for instance, has observed that the neutral yes-no question is characterized by a melodic rise on its first accented syllable, which is slightly higher than that observed in statements; this rise often reaches the post-stressed syllable. However, he also remarks that perceptual tests for the Rio de Janeiro dialect, have not shown that the distinction observed in relation to statements concerning the pre-nuclear accent, does plays a role in the auditory recognition of the two modalities [10]. Thus it seems that, at least for the Rio variety, it is on the nuclear accent that the contrast is concentrated. Other studies have confirmed that for the Florianópolis variant, the prenuclear region is not significantly different [11].

As we argue, yes/no questions in Brazilian Portuguese differ from declaratives based largely on the tonal structure of the nuclear contour. However, in a number of dialects such as the varieties of BP spoken in Blumenau, Santa Catarina (South), and Aracaju, Sergipe (Northeast), the increased height of prenuclear peaks seems to be a recurrent feature that characterizes yes-no questions (as well), as it occurs in the other languages referred to such as Spanish [9].

In order to test the occurrence of the wider interrogative prenuclear register span, we compared neutral declarative utterances and neutral yes/no questions in these dialects of BP.

2.1. The production experiments

Our data was collected from the AMPER-POR Project [12], with informants of both genders from the target cities in the state of Santa Catarina, Brazil: Florianopolis, Lages and Blumenau; and from the state capital of Sergipe, Aracaju

Our goal was to observe if there were differences in the prenuclear, as well as in the nuclear contours of yes-no questions between the speakers of those localities. For this, we compared the intonations of neutral declarative utterances and their corresponding (the) yes-no questions.

We analised a total of 382 neutral declarative sentences, and 382 yes-no questions. The samples were analysed automatically by the interface software of the AMPER Project [12] which generated figures that overlap the pitch curves of the declarative and interrogative modes, on the basis of three repetitions of the same sentence, as in Figure 1.

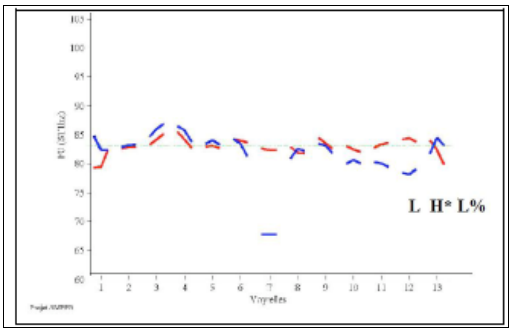

Figure 1: *Yes/no Interrogative (blue) and declarative (red) renditions of the sentence: "O Renato gosta do pássaro nadador" of the Florianopolis speaker.*

The statistical tests were done with SPSS, to verify if there were significant differences in the declarative and interrogative modes. For the statistical analysis we used SPSS Program (SPSS Statistic 17.0. Polar Engineering and Consulting, copyright 1993-2007). The dependent variable was the fundamental frequency (*f*0) and the independent variables were the position of the vowel in the prenuclear region (stressed and post-stressed) and the sentence type (declarative and interrogative). Since the data for each variable group was rather small, around 20 items in each, we chose the non-parametric Mann-Whitney U, which compares two independent groups [13]. With the value $p<0.05$, we could see whether the differences were or not.

2.2. Production results

Now we describe the initial part of sentences in order to characterize the prenuclear contour.

The male speaker from Florianópolis did not have substantial prenuclear differences between declaratives and interrogatives, as we see in Figure 1. For the male speaker from Lages, the prenuclear contour was also virtually identical for declaratives and interrogatives.

For the male speaker from Blumenau on the other hand, the first stressed syllable is much higher in interrogatives than declaratives; this was statistically significant, as shown in Table 1.

Table 1. *Mean values and standard deviation patterns of the fundamental frequency (F0) in Hz, found in the stressed and post-stressed positions of the prenucleus of the declarative and interrogative types, for males and females, and comparison of these types for the Blumenau (SC) data.*

		Declarative		Interrogative		Test*
Position	Subject	Mean (SD)	N. data	Mean (SD)	N. data	
Stressed	Male	125 (3)	20	151 (10)	20	Z = -5,42, ***p*<.001**
	Female	204 (11)	20	283 (47)	20	Z = -3,89, ***p*<.001**
Post-stressed	Male	147 (6)	20	138 (6)	20	Z = -4,64, ***p*<.001**
	Female	253 (29)	20	319 (37)	20	Z = -4,77, ***p*< .001**

*The statistic test was *Mann-Whitney U*, applied to compare the types of sentences (declarative x interrogative). SD = standard

deviation; Z = value of statistical test; *p* = significance; significant results are in bold (*p*<,05).

Our first relevant finding was that in the interdialectal comparison, the speakers from Blumenau, both male and female, distinguish themselves from the speakers of the other varieties in their prenuclear patterns, significantly higher than the declarative counterparts (as in Figure 2). This does not appear to happen with the speakers from Florianópolis [11] and Lages (as in Figure 3).

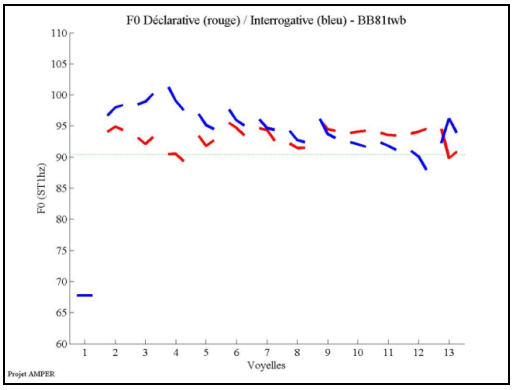

Figure 2: *Contours of yes-no questions and neutral declaratives: production of a Blumenau speaker of a yes-no question (blue) and a neutral declarative (red) of the sentence "O Renato gosta do pássaro nadador"* [7].

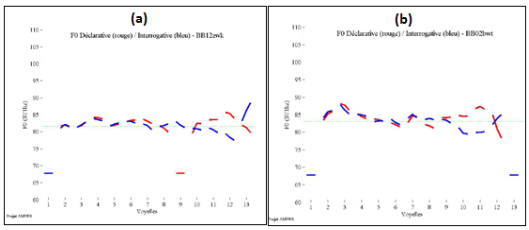

Figure 3: *Contours of yes-no questions and neutral declaratives: in (a) the production of a yes-no question (blue) and a neutral declarative (red) of the sentence "O Renato bêbado gosta do bisavô" by the Lages speaker; and in (b) the production of a yes-no question (blue) and a neutral declarative (red) of the sentence "O pássaro nadador gosta do Renato"* [7].

We found that the Aracaju data also presented this behavior (as in Figure 4), and that difference between declaratives and interrogatives in the prenuclear contour for the Aracaju data are statistically significant, as shown in Table 2.

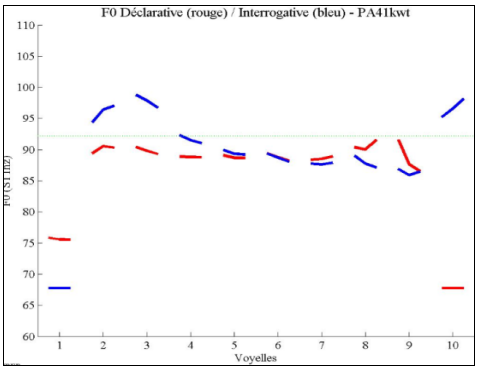

Figure 4: *Yes-no question (blue) and declarative (red) of the sentence "O bisavô gosta do Renato" by the male informant from Aracaju* [7].

Table 2. *Mean values and standard deviation of the fundamental frequency (F0) in Hz, found in the stressed and post-stressed prenuclear positions for the declarative and interrogative, of the Female group, and comparison of the two types for the Aracaju (SE) data.*

	Declarative		Interrogative		Test
Position	Mean (DP)	N. data	Mean (DP)	N. data	
Stressed	191 (22)	20	230 (54)	25	Z=3,30, **p=.001**
Post-stressed	198 (27)	20	231 (51)	22	Z=2,79, **p=.005**

These results were then verified in perception experiments with stimuli that tested whether listeners could perceive the differences in the prenuclear region, as is explained in the next section.

3. Perception of prenuclear contours

3.1. The perception experiments

We conducted three different perception experiments. In these tests, 40% of the items were distractors and 60% corresponded to sentences that showed prenuclear differences between the declarative rendition and the interrogative. The tests were set and applied as follows.

The first one (1) was to verify whether the sentence types would be recognized with only the f0 contour of the whole sentence. In this test, the subjects only heard the f0 contour, without any segmental information (filtered utterance); (2) the second was to verify if the sentence types would be perceived with only the subject NP (the first prenuclear peak) of the sentences with the actual words without hearing the end of the sentence. In this test, the subjects heard the beginning of a sentence in natural speech, either a yes/no question or a neutral declarative utterance. The listener had to decide whether he/she heard the stimulus as a statement or a question, with only the subject NP prenuclear contour to be heard; (3) the third aimed to verity if the listeners could perceive the mode of the sentence hearing only the f0 contour of the subject NP of the sentence. In this test the subjects only heard the filtered beginning of each sentence, and again

had to decide whether he/she heard the stimulus as a statement or a question, purely with the tonal information of this subject NP (see Figure 5).

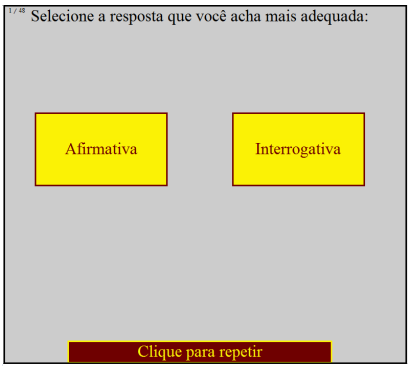

Figure 5: *Sample of perceptual discrimination test of dialects and sentence types.*

For each of the tests there were 116 stimuli for a total of 348. Each of the three types of tests were taken by six listeners. 116 stimuli X 3 tests X 6 listeners = 2088 stimuli in total. This test was staged with Praat and the results were collected automatically, also with Praat. Results proved to be consistent and significant when related to speakers from Blumenau (SC).

3.2. Perception results

Results of the perception tests were far more consistent when related to speakers from Blumenau than those from Florianopolis and Lages. Consistency was considered in terms of the number of correct responses of the subjects in relation to the type of sentence to which the subject NP belongs.

Test 1, which evaluated whether the sentence was declarative or interrogative by means of solely the information given by the filtered stimuli, resulted in the greatest score of correct responses, 67% (Figure 6).

Test 2, which evaluated the stimuli that consisted of the words that integrated the prenucleus of the sentences without any filtering, resulted in 57% of correct responses (Figure 6), with three of the listeners scoring a percentage above 60%.

Test 3, which consisted of the filtered prenuclear contour, only received 51% of correct responses (Figure 6), although two listeners scored a percentage of correct responses close to 60%.

This last result seemed to show more random responses. This was likely due to the very limited information presented to the listeners; in addition to not having the segmental information, the stimuli were very short in duration.

Thus, we can consider the results of test 2 to be more consistent regarding the initial part of the utterance, which presented real words that integrated the prenucleus of the declarative and interrogative sentences. These perceptual results seem to confirm the significant differences found in the prenuclear region in the production of the Blumenau speakers.

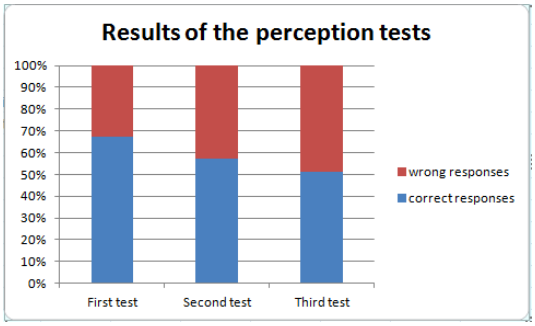

Figure 6: *Graph with the responses to the three perception tests.*

4. Conclusions

The results of our research in Brazilian Portuguese, suggest that at least in some dialects, the vertical, quantitative dimension is used significantly to distinguish sentence modes (Tables 1 and 2), as well as categories of pragmatic meaning. There is overwhelming evidence that it is in the nuclear contour that the distinctive clues are encoded, that is, in the trajectory and direction of the terminal melodic line.

The typical contours of these sentences have been shown in BP to differ in significant ways, based not only on contour shape but also on pitch-height-related phenomena. The final contour can be either rising or falling, but the peaks tend to be consistently higher in interrogatives than in declaratives.

The different sentence types are typically represented by a specific tune, or variety of tunes. Yes-no interrogatives tend to be remarkably regular in terms of the tonal design, as well as in the value of the tonal targets. We have, however, identified more than one typical tune, according to the dialect. These differences are also perceived in the prenuclear contour. We conclude that the prenuclear contour, although significant in at least those dialects of BP we described here, do not seem to be used in all the varieties we have studied thus far.

What the analysis shows is that there are significant differences for Blumenau as well as for Aracaju, and that the percentage of identification of the two sentence types, especially for Test 2, was nearly 60%.

More results and further discussion will be available as our research progresses.

Use of suprasegmental information in the perception of Spanish lexical stress by Spanish heritage speakers of different generations

Ji Young Kim

Department of Spanish, Italian, and Portuguese
University of Illinois at Urbana-Champaign, USA
jkim315@illinois.edu

Abstract

The present study examines the perception of Spanish lexical stress by Spanish heritage speakers of different generations and compares their performance to that of Spanish native controls and English second language (L2) learners of Spanish. Previous studies have shown that English L2 learners experience great difficulty in perceiving Spanish lexical stress. Such difficulty is argued to be derived from English listeners using different strategies from Spanish listeners in the perception of stress. Given that Spanish heritage speakers share the same dominant language with English L2 learners (English), but differ from them with regard to the first language (Spanish), the present study intends to seek whether heritage speakers show similar or different patterns when compared with L2 learners. The present study also intends to account for the heterogeneity among heritage speakers by comparing heritage speakers of different generations. Using a forced-choice identification task with stressed minimal pairs of paroxytone and oxytone verbs, results showed that while 1st generation US-born heritage speakers pattern like Spanish native controls by paying more attention to the acoustic cues of the stimuli, 1.5/2nd generation US-born heritage speakers pattern like English L2 learners by showing bias towards paroxytone verbs.

Index Terms: speech perception, lexical stress, heritage language phonology

1. Introduction

Broadly speaking, heritage speakers are people who grow up exposed to both a majority language and an ethnic minority language. Despite their heterogeneity, heritage speakers share some characteristics in common. Generally speaking, heritage speakers, more specifically heritage speakers in the US, are early bilingual speakers of English (majority language) and a non-English home language (minority language) who have lived most or all of their lives in the US. The parents of these speakers are native speakers of the home language (heritage language), thus, heritage speakers acquire this language as their first language (L1) and, for many of them, systematic exposure to English, which is their second language (L2), does not occur until they enter institutional settings such as kindergarten and elementary school. Since English is the majority language and the heritage language is a minority language, heritage speakers' use of English increases as they grow up, whereas their use of the heritage language becomes limited to familial settings. This subsequently results in a gradual shift of language dominance from the heritage language (L1) to English (L2). Therefore, while heritage speakers have very strong command of English, their command of the heritage language is usually short of the native speaker level of their parents or peers raised in their home countries [9]. Heritage speakers are similar to L2 learners in that they are more dominant in English than the heritage language, but are different from them in that while heritage speakers learn the heritage language as the L1, L2 learners learn it as a L2. Studies on L2 phonology have shown that English L2 learners of Spanish experience great difficulty perceiving Spanish lexical stress [11]. Thus, the present study intends to see whether Spanish heritage speakers show similar patterns to English L2 learners when they perceive Spanish lexical stress.

2. Lexical stress in Spanish and English

Stress may be defined as prominence in a syllable of a word resulting from extra muscular energy that is acoustically manifested in higher pitch, longer duration, and higher intensity, in some cases with segmental effects [7]. Although researchers agree that these three universal parameters are important indices of stress, languages differ from one another with regard to what parameter functions as the primary correlate of stress. Spanish and English are typologically similar in that stress is phonologically contrastive in both languages, but they differ in the realization of stress [5]. With regard to the acoustic correlates of stress in the two languages, recent studies, have shown that when pitch accent is controlled, the primary correlate of stress is duration in Spanish [10], while it is vowel quality in English [1]. Unlike English, in which unstressed vowels undergo vowel reduction, resulting in a schwa [ə], in Spanish vowels maintain their vowel quality regardless of whether they are stressed or unstressed [5]. Thus, Spanish listeners would not be sensitive to changes in vowel quality, but rather to changes in duration and other suprasegmental cues to identify stressed vowels.

English L2 learners of Spanish are shown to have great difficulty in identifying the position of stress in Spanish even after explicit instructions [11], most likely due to influence from their native language (English). Although lexical activation is sensitive to all the information that is available in speech signals, whether it is segmental or suprasegmental, it is likely that listening strategies that are applied in the native language influence the way people listen to foreign language input [2]. English is more segmentally-based [12] and generally suprasegmental cues only provide redundant information [3]. Thus, English listeners are not accustomed to paying attention to suprasegmental information when this is the only cue available in the speech signal, unlike Spanish listeners, who are sensitive to even small differences in suprasegmental cues [3]. Therefore, the goal of the present study is to examine whether Spanish heritage speakers who are dominant in English also show difficulty in perceiving stress contrasts in Spanish due to influence from English, and whether differences are found among heritage speakers, who are found to be highly heterogeneous. Among various factors, the present study will focus on the effect of heritage speakers' generation on their perception of Spanish lexical stress.

3. Experiment

3.1. Participants

In total, 89 subjects participated in the present study: 25 Spanish native speakers (NS) (18F, 7M), 17 Spanish heritage speakers (HS) (13F, 4M), and 47 English L2 learners of Spanish (L2) (36F, 11M). The NSs were recruited in a North-Central region of Mexico. They reported that, although they have learned languages other than Spanish, this did not happen until later in life and they use only Spanish most of the time (avg. 93%). Thus, even though these speakers are strictly speaking not monolinguals, the present study will consider them as such, because they do not use the other languages functionally. The L2s are beginner to intermediate-level Spanish major or minor students recruited from a Spanish grammar course at a university in the Midwest, US. The L2 learners reported that they did not learn Spanish before the age of 9 (avg. 11.62 years) and their daily use of Spanish is less than 10% (avg. 7.34%). The HSs were born and raised in the US, mostly in the Chicago area, to Mexican families. Based on their (1) age of acquisition, (2) language use, and (3) language proficiency, it was determined that the heritage speakers were all English-dominant. That is, the heritage speakers (1) are early bilinguals in that they acquired both Spanish and English before the age of 5, which is before the period when foreign accent starts to appear if a language is not learned by then [4], (2) currently use English more frequently than Spanish, and (3) self-rated their proficiency in Spanish lower than English. The HSs were sub-divided into two groups based on whether they are 1st generation US-born Mexican-Americans (both parents are from Mexico) (HS1: 8F & 3M) (HS1) or 1.5 generation (only one parent is 1st generation US-born) or 2nd generation US-born Mexican-Americans (both parents are 1st generation US-born) (HS2: 5F & 1M) (HS2). 1.5 and 2nd generation heritage speakers were grouped together due to small number of participants (three speakers each) and based on the assumption that these speakers would behave differently from HS1s, given that they are exposed to Spanish less frequently than HS1s and they consider Spanish as a L2, unlike HS1s who consider it as a native language.

3.2. Test materials

32 stress minimal pairs that differ only in the location of lexical stress were used in the present study. The stress pairs consisted of disyllabic Spanish regular *–ar* verbs in the first person singular of the present indicative (e.g., *PAso* 'I pass') and the same verbs in the third person singular of the (simple) past perfective tense (e.g., *paSO* 'he/she/you(formal) passed'). The former case always has stress on the penultimate syllable (paroxytone) and the latter case always has it on the last syllable (oxytone). Apart from the target items, 68 fillers with verbs of both present and past tense were included. Each item was inserted in the second-to-last position of a meaningful sentence with narrow focus on the last word (subject). Whereas English has relatively fixed word order and greater flexibility in assigning the nuclear stress to words in different locations, Spanish has greater syntactic freedom and new information items are generally moved to the end of the sentence, where they receive nuclear stress [5, 6]. In the present case, by locating the subject in the last position, *Por la plaza paso yo* 'I pass through the plaza', the subject carries the narrow focus. Thus, by using such sentence structure, it was possible to separate lexical stress from pitch accent, given that the word that carries the nuclear accent is the subject (*yo*), not the target word (*PAso*). All the stimuli were produced by a male native speaker of Mexican Spanish and were recorded in a sound-attenuating booth using an AKG C520 head-mounted microphone and a Marantz PMD570 solid state recorder. The last word of each sentence was removed, leaving the sentences incomplete (*Por la plaza paso…*). Since transitions always occurred from /o/ (back vowel) to either /e/ or /j/ (front vowel/glide), using the spectrogram display in *Praat*, the cut-off point was determined as the moment when the F2 value started to make a noticeable increase. After removing the last words, all the tokens were played to make sure no transition information was included in the speech signals.

3.3. Procedures

In order to avoid priming effect, two lists were used, each containing only one member of each of the minimal stress pairs, with paroxytones and oxytones randomly distributed between the two lists. Half of the participants completed one list and half of them completed the other. The participants sat in front of a computer and listened to the incomplete sentences through headphones. In Mexico, the stimuli were presented through a Dell Vostro 230 desktop computer with KOSS UR-20 headphones and, in the US, they were presented through a Samsung SENS R410 laptop computer with Sony MDR 7506 headphones. While listening to the stimuli, the participants saw two subject words (e.g., *yo* "I" vs. *él* "he") on each side of the computer screen. Then, they decided which of the two options the following word had to be by clicking on either the left or the right key, which were indicated with colored stickers on the keyboard. The incomplete sentences were presented in pseudo-randomized order and the order of the subject words on the screen was counter-balanced. The presentation of the stimuli was done using *E-Prime*.

4. Results and Discussion

Participants' accuracy and response time (RT) were automatically collected through *E-Prime*. With regard to accuracy, all correct responses were coded as "1" and all incorrect responses were coded as "0". The effect of Group (NS/HS1/HS2/L2), Stress Pattern (paroxytone/oxytone), and the interaction of the two factors on participants' Accuracy (correct/incorrect) was statistically analyzed using logit mixed effects modeling with subject and item as random factors. The *glmer* function in the *lme4* package in R was used for the analysis. The two fixed factors (Group and Stress Pattern) were centered using contrast-coding. The best fitting model according to backwards selection included random intercepts for subject and item with no slope terms. Figure 1 shows the accuracy rate for paroxytones, oxytones, and fillers of each group. All four groups performed close to ceiling when perceiving the fillers, which confirms that the errors that occurred could not be due to problems regarding Spanish verb conjugation, which could be considered as a possible confound due to the experimental design of the present study (i.e., identify the subject of the verb). Results showed that NSs (the baseline group) performed significantly better than HS2s ($\beta = -2.1618$, SE = 0.4121, $z = -5.245$, $p < 0.001$) and L2s ($\beta = -2.8936$, SE = 0.2812, $z = -10.291$, $p < 0.001$), while the difference between NSs and HS1s was only marginally significant ($\beta = -0.6444$, SE = 0.3744, $z = -1.721$, $p = 0.0852$). A significant main effect was found in Stress Pattern ($\beta = 2.1644$, SE = 0.6195, $z = 3.494$, $p < 0.001$), indicating that

overall participants were better at perceiving paroxytones. However, a significant interaction was also found between Stress Pattern and HS2 (β = -3.2335, SE = 1.1367, z = -2.845, p < 0.01) and between Stress Placement and L2 (β = -4.3969, SE = 0.7048, z = -6.239, p < 0.001). This suggests that NSs' accuracy difference between paroxytones and oxytones was significantly different from that of HS2s and L2s. As shown in Figure 1, while NSs performed slightly better when perceiving oxytones, HS2s and L2s performed worse in this stress pattern. Such difference in direction explains why significant interactions have occurred. With regard to HS1s, no significant interaction was found between Stress Pattern and HS1, suggesting that the accuracy difference between the two stress patterns was not different between NSs and HS1s. In fact, HS1s behaved similarly to NSs, with the accuracy rate of oxytones slightly higher than paroxytones.

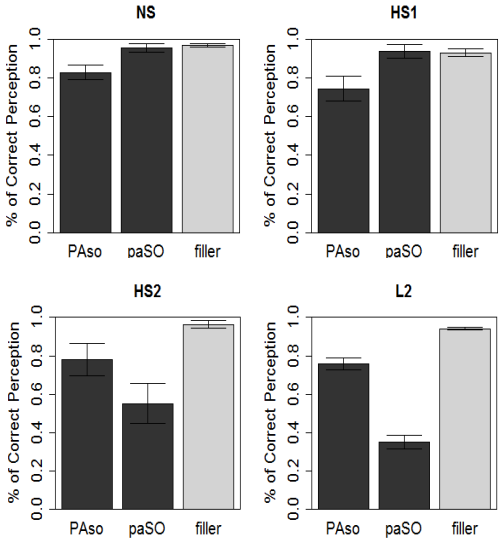

Figure 1: *Accuracy rate of paroxytones (left), oxytones (middle), and fillers (right) in each group*

It is interesting to note that while HS2s' and L2s' perception of paroxytones was target-like, their accuracy rates for oxytones were either close to chance level or lower, implying that HS2s and L2s have a bias towards selecting paroxytones. Participants' sensitivity and response bias towards paroxytones were analyzed by calculating their d-prime scores and response criterion (C scores), respectively. HIT was considered as the case in which participants selected a paroxytone when the stimulus was a paroxytone and FALSE ALARM was considered as the case in which participants selected a paroxytone when the stimulus was an oxytone. A one-way ANOVA with Group as independent variable was conducted on participants' d-prime scores and C scores. A main effect was found for both d-prime scores ($F(3,85) = 54.13$, $p < 0.001$) and C scores ($F(3,85) = 19.31$, $p < 0.001$). TukeyHSD post-hoc analyses showed that for both scores, the L2s differed from both the NSs and H1s ($p < 0.001$), while no significant difference was found between the L2s and H2s. Likewise, no significant difference was found between NSs and HS1s. Figure 2 shows that HS2s and L2s performed differently from NSs and HS1s in that their d-prime scores were close to zero, indicating that they had very low sensitivity in distinguishing the two stress patterns. The negative C scores confirm that this low sensitivity is due to bias towards selecting paroxytones. It is important to note that the perception pattern shown in the HS2 group was not consistent for all speakers in this group. Among the 6 HS2s that participated, half of them showed a strong bias toward paroxytones (paroxytone: avg. 83.33% accuracy; oxytone: avg. 20.83% accuracy). Among the remaining three speakers, two showed similar accuracy rates in the two stress patterns (paroxytone: avg. 81.25%; oxytone: avg. 84.38%) and one showed 100% accuracy rate in paroxytones, while in oxytones the accuracy rate was only chance level (56.25%). According to the HS2s' language profile, the three participants that showed a strong bias toward paroxytones had not been exposed to Spanish before avg. 7.33 years of age, while the other three acquired Spanish from birth. This finding may explain why different patterns were found among HS2s.

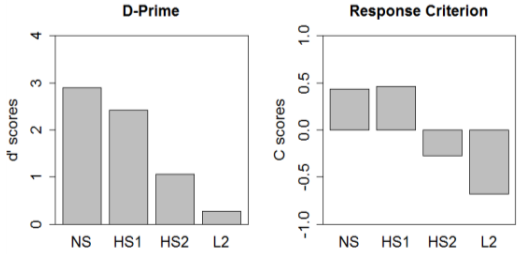

Figure 2: *D-prime (sensitivity) and response criterion (response bias) scores in each group*

Given that all the participants listened to the same stimuli, the different patterns found between NSs and HS1, on the one hand, and (half of) HS2s and L2s, on the other, can be explained through the way participants attended to the acoustic cues of the stimuli. Further analyses were conducted on the acoustic properties of the stimuli used in the experiment. Regarding the vowel quality of stressed and unstressed vowels, which is considered to be the critical acoustic cue in English, but not in Spanish, raw F1 and F2 values of the stressed and unstressed vowels were extracted and normalized using Lobanov normalization. The effect of Stress (stressed/unstressed) on the normalized F1 and F2 values was analyzed using linear mixed effects modeling with item as random factor. Tokens that were produced with creaky voice were removed from the analysis. Results showed that there was no significant effect of Stress in any of the three vowels used in the study (/a/, /i/, and /u/). Thus, vowel quality could not have had an effect on participants' response.

Apart from vowel quality, the differences in pitch, duration, and intensity between stressed and unstressed vowels were measured by subtracting the pitch, duration, and intensity values of the unstressed vowel from those of the stressed vowel in each item. As Figure 3 shows, the pitch differences were lower than zero in paroxytones, whereas in oxytones they were higher than zero, indicating that regardless of stress pattern the pitch was always higher in final syllables than in penultimate syllables. With regard to intensity differences, stress vowels had higher intensity than unstressed vowels in both paroxytones and oxytones (i.e., the values were higher than zero) and such tendency occurred to a similar degree in the two stress patterns. However, the information obtained from pitch and intensity differences does not explain why NSs and HS1s perceived oxytones with higher accuracy than paroxytones, because higher pitch in final syllables in

paroxytones would have misled their perception to oxytones and similar intensity differences in the two stress patterns would have led to similar accuracy rates. Rather, it is more likely that NSs and HS1s were sensitive to duration, which is argued to be the critical parameter for stress in Spanish [10]. The duration differences of the stimuli were slightly higher than zero in paroxytones, while in oxytones they were much higher than zero. This indicates that in oxytones the stressed vowels were much longer than the unstressed vowels, while in paroxytones, they were only slightly longer, although this difference was statistically significant (β = 60.747, SE = 13.051, t = 5.464, $p < 0.001$). This is a possible explanation of why NSs and HS1s had higher accuracy rates in oxytones. However, despite larger duration differences in this stress pattern, (half of) HS2s and L2s had lower accuracy rate, suggesting that HS2s and L2s may not pay much attention to the acoustic cues in order to understand the message, supporting [2]. Rather, it is likely that they have a bias toward selecting paroxytones, supposedly because these verbs are the first form that is learned in the classroom (present tense), hence the "easier" form to which they are more accustomed.

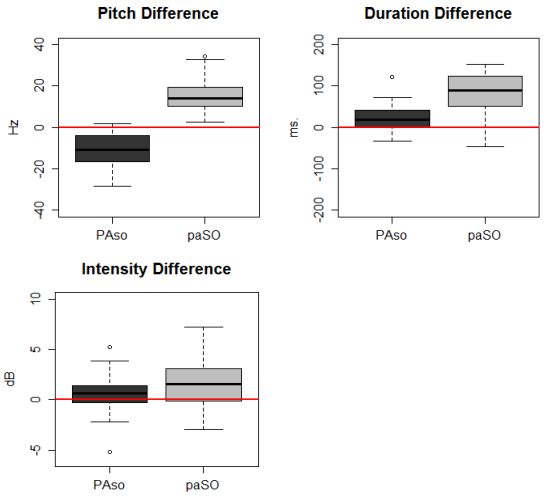

Figure 3: *Difference in pitch, duration, and intensity between stressed and unstressed vowels of stimuli*

RT was calculated as the amount of time (ms) elapsed after the onset of the target word. Only RTs of correct responses were considered in the analysis. The effect of Group, Stress Pattern, and the interaction of the two factors on participants' RT was statistically analyzed using linear mixed effects modeling with subject and item as random factors. Results showed that NSs responded significantly faster than HS2s (β = 829.71, SE = 260.76, t = 3.182) and L2s (β = 620, SE = 141.28, t = 4.388). There was no significant difference between NSs and HS1s. Regarding Stress Pattern, no main effect was found and no significant interaction was found between Stress Pattern and any of the three (non-baseline) groups, suggesting that paroxytones and oxytones were perceived with similar RTs across all four groups. That is, although the accuracy rate for oxytones was very low, HS2s and L2s did not take a particularly longer processing time when perceiving these words. This suggests that the low accuracy rate found in oxytones in (half of) HS2s and L2s is not derived from processing difficulty. Rather it is more likely to be due to bias toward paroxytones.

5. Conclusions

In the present study, the perception of Spanish lexical stress by Spanish heritage speakers and English L2 learners of Spanish was examined. Heritage speakers are similar to L2 learners in that English is the dominant language for both groups, but they are also different from each other in that while heritage speakers are exposed to Spanish at an early age, L2 learners do not learn Spanish until later. Thus, it is considered that heritage speakers have better command of Spanish phonology than L2 learners, yet not to the point that they are comparable to Spanish monolinguals, due to influence from English. The present study sub-divided the heritage speakers based on generation (1st generation US-born: HS1 vs. 1.5/2nd generation US-born: HS2). The findings indicate that while HS1s performed similarly to Spanish native speakers, HS2s were more similar to L2 learners. Given that HS2s receive less input in the heritage language than HS1s, such findings may suggest that the amount of input has an effect on heritage language phonology. However, when further analyzing the perception patterns in this group, it was found that regardless of whether a person is 1.5 or 2nd generation, those who acquired Spanish from birth showed a different pattern from those who have not been exposed to Spanish until later. This finding implies a strong effect of age of acquisition on heritage speakers' prosody, which is a linguistic aspect that is argued to be acquired from infancy [8]. However, in order to generalize such argument, it is necessary to further analyze such effect by examining a larger number of heritage speakers while taking into account factors such as language use and generation.

Abstract

One of the goals of the Glissando research project[1] is to enrich a radio news corpus [1] with Sp_ToBI labels. In this paper we present the application of the automatic predictions of a fuzzy classifier to speed up the labeling process. The strategy is proposed after completing the following steps: a) manual annotation of a part of the Glissando corpus with Sp ToBI labels and checking of the coherence of the labels; b) training of the automatic system; c) validation or correction of the automatic system's predictions by a human expert. The automatic judgments of the classifier are enriched with confidence measures that are useful to represent uncertain situations concerning the label to be assigned. The main aim of the paper is to show that there exists a correspondence between the uncertain situations that are identified during an inter-transcriber experiment and the uncertain situations that the fuzzy classifier detects. Labeling time reduction encourages the use of this strategy.
Index Terms:Prosodic labeling, fuzzy classifier, Sp_ToBI

1. Introduction

Prosodic labeling aims to enrich spoken utterances with labels that are representative of the relationship between the prosodic form and function of the constituents of the message. Although prosodic labeling systems establish clear rules and protocols, the difficulty of the task and the inherent subjectivity of the labelers' judgments introduces a high number of inconsistencies. Prosodic labeling systems assume that uncertain situations could appear and reserve special symbols for representing them (like the symbol '?' in ToBI [2] and RaP [3] or the explicit computation of the transcriber disagreement in RPT [4]). Leaving aside these well-known difficulties of the task of manual annotation, the inter-transcriber tests of consistency have identified cases where two different transcribers decide to assign different labels to the same prosodic event. [5] suggested the use of alternative tiers for capturing ambiguities. These facts suggest the existence of an area of uncertainty across the categories, due to the perceptual and acoustic similarity of some pair of labels [6]. Fuzzy sets theory [7] has been widely used to represent those situations where it is difficult to classify a given element into the different possible categories.

It must be noted that recognizing uncertainty in the task of identification of some labels is not equivalent to saying that the prosodic categories used in the ToBI framework are fuzzy categories, since they are based on the description of the intonational phonology of the language, and, as a consequence, each of them is related to a clear phonological content. However, the process of annotation (either manually or with the aid of semi-automatic tools) has shown that the resulting labels can carry uncertain information when they have to be associated to the acoustic signal. In [8] we have shown how fuzzy sets can be used to represent situations where assigning a class to a given prosodic unit is difficult because of the high degree of uncertainty. The BURNC corpus [9] was used in the experiments, which is one of the most important references for studies on automatic ToBI prosodic labeling in English, and in this paper, we will present the application of the same fuzzy classifier to the subset of news of the Glissando corpus[1], which aims to be a reference for studies on Spanish prosody.

Since manual annotation is a time-consuming process and very costly in terms of human resources, efforts have to concentrate on developing tools for automatic prosodic labeling or, at least, to aid the experts to speed the process [10]. The state of the art on automatic prosodic labeling reports identification rates higher than 90% in binary decisions, such as the presence or absence of accent, boundary or break. However, when the system is faced with the classification of pitch accents, boundary tones or level of breaks, the rates dramatically decrease to about 70% (see [11] for a review of the state of the art). In [12], we showed that the reasons for these low accuracy rates are the high similarity among some pairs of classes and the imbalanced nature of the prosodic corpora. As expected, the difficulties of manual annotation are reflected in how successful automatic approaches to prosodic labeling are. This paper aims to show that the use of a fuzzy classifier considerably increases the performance when soft classification is performed, and that there exists a correspondence between the uncertain situations that are identified during the inter-transcriber experiments and the uncertain situations that the fuzzy classifier detects, a reason to consider the application of the tool as a good strategy to speed the process of manual annotation.

The strategy implies fulfilling the following steps: a) manual annotation of part of the Glissando corpus with Sp ToBI labels and checking of the coherence of the labels; b) training of the automatic system; c) correction of the automatic system's predictions by a human expert. Section 2 describes the process of manual labeling of the training corpus and the quality assessment procedure that has been applied. Section 3 presents the architecture and methods of the fuzzy classifier. The small number of editing operations in the revision process (as detailed in Section 4) evidences the quality of the fuzzy predictions. Additionally we show that the most uncertain predictions correspond to labels that are also problematic in the inter-transcriber consistency tests. We end with conclusions and the future work of this ongoing research.

E_ToBI[15]	2	1594	1	0.51 / 86.57%	0.79/ 89.33%	na / na

Table 1: Global inter-transcriber agreement results for Sp_ToBI compared with results reported for other ToBI systems. Columns labelled *Pitch Accents*, *Boundary Tones* and *Breaks* separate results according to the respective ToBI events that have been considered. The figure in the cells are the κ index and the pairwise inter-transcriber rate (as a percentage). **L** is the number of labelers, **W** is the size of the corpus in words and **S** is the number of styles. *(fe)* is female, *(ma)* is male and *(na)* means the information is not available.

2. The Sp_ToBI manually labeled subcorpus

The Glissando news subcorpus contains recordings of eight different Spanish speakers, each of them reading more than 36 news items [1]. For our purposes, two of these speakers were chosen, taking into account differences in gender (i.e. male and female) and reading style (i.e. radio speaker and advertisement actor). The labeled corpus consists of 1100 seconds of reading of news speech recorded by two professional speakers: 12 news read by a radio professional (female voice) and 12 news read by an advertising professional (male voice). These news items include a total of 3202 words (7091 syllables) labeled with 2058 pitch accents, 1115 boundary tones and 1029 breaks.

The news data-set has been annotated using the Sp_ToBI labels proposed in [16, 17], with the modifications advanced in [18] and some adjustements needed for the speaking style, contained in the guidelines distributed in `http://veus.glicom.upf.edu/`. The tonal inventory is adapted to the specific phenomena pertaining to declarative utterances of a news data set in terms of a reduction of the tonal inventory and the definition and representation of boundary tones. In particular, the tag =% is associated to those cases where the pitch keeps the previous tone value (i.e. sustained pitch), and the parentheses stands for allotonic variations of L+H* and L+>H* (that is, when the fall is not perceived in the pre-stressed syllable (L+)H* and (L+>)H* are used).

The procedure was perceptually based: the transcriber was encouraged to focus preferentially on perception: her task consisted in listening carefully to the utterance in order to (a) mark the subjective sense of disjuncture between each pair of words and before each pause (break tier) and (b) mark prominences and tonal events (tone tier).

Since the ToBI framework is phonologically-driven, various methods of estimating the consistency and stability of the labels assigned to the corpus were conducted: (i) periodical meetings to define guidelines to annotate read news; (ii) discussion and resolution of differences in transcription throughout a six-month period and (iii) validation of consistency among transcribers with an interreliability experiment.

In order to measure the confidence of the annotation, four experts labeled independently the same news (108 words) read by a professional speaker. Pair-wise comparisons and values of the kappa index support the stability of the labels among transcribers in the main categories, but they also show that there is confusion among others. The results of the inter-transcriber consistency test can be seen in the table 1. Values of the kappa index between 0.6 and 0.8 like the ones we obtained are commonly considered as substantial agreement. These consistency rates are comparable with the ones reported in similar studies for the prosodic labeling of other corpora in different languages (see table 1). Uncertainty exists, which is the main argument that supports the use of a fuzzy classifier.

3. Automatic labeling with uncertainty

We face the automatic labeling of ToBI events following the multi-class classification approach. The multi-class classification problem has the goal to assign a ToBI label to a given prosodic unit that is, typically, a word or a syllable. The multi-class classification approach contrasts with binary classification where the goal is to determine whether an accent or a boundary is present or not in the given prosodic unit.

In [11] we showed that multi-class identification of ToBI labels can be efficiently done by using *pairwise coupling classification*. The complex multi-class classification problem is divided into several simpler problems, by means of pairwise coupling. The basic idea is that it is easy for the machine to assign a label when only two classes are considered to be possible. For example it is easy to assign the label L+H* or the label L* to a prosodic unit when the only alternatives are these two classes. However, assigning the label L+H* when the alternatives are H*, !H*, H+!H*, L+!H*, L* and L*+H is a much more challenging task. Our proposal is to combine several two-class classifiers (one for every pair of possible labels) in order to achieve the multi-class classification because two-class problems provide higher accuracy results.

Furthermore, in [12] we observed that different *types of classifiers* behave differently in the classification of different tones. Thus, decision trees seem to be specialized in the identification of the most populated classes while neural networks tend to balance the number of predicted labels for each of the classes. The compromise in term of the number of samples in every class is important in automatic prosodic labeling because prosodic corpora are naturally imbalanced. For example in the BURNC corpus, 77% of the words are labeled with two out of the eight possible labels[12]. In this work, complementarity between artificial neural networks (NN), decision trees (DT) and support vector machines (SVM) classifiers has been exploited to improve the final system, combining their outputs using a fusion method.

In order to combine the decision scores that result from the three classifications modules (DT, NN and SVM), we used the comprehensive fuzzy technique proposed in [8]. The fuzzy integral technique has proven useful for combining classifiers in several contexts [19, 20, 21, 22, 23, 24]. We use the implemen-

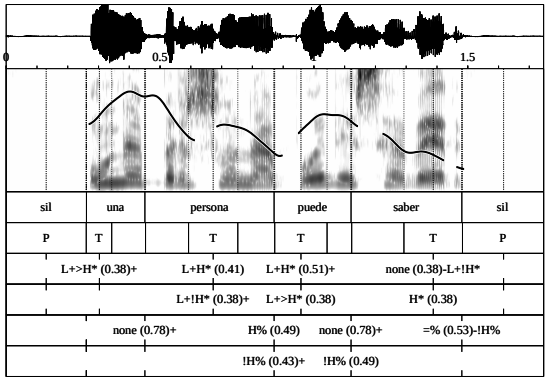

Figure 1: Multi-tier prediction interface that allows a human labeler to check the output of the automatic fuzzy classifier. Word and syllable segmentation appear in the upper tiers (T stands for lexically stressed syllable). The following tiers correspond to the predicted labels for pitch accents (aligned at the middle of the stressed syllable) and boundary tones (aligned at the end of the word).

tation of the Sugeno fuzzy integral [25] as described in [26]. As result, each ToBI category is assigned to the words of the corpus with a degree of certainty. This degree of confidence is a numeric value in the [0,1] interval (the highest the value the more the certainty). The α-cut approach permits to reduce the set of candidate labels assigned to every word. The α-cut value is empirically assigned as explained in [8].

In order to train the classifiers, we have applied a multifold approach that divides the corpus into two sections: 90% training and 10% test. Some categories show a very low number of instances, so we decided to group them with similar types thereby creating particular classes. To do that, we display the inter-label distance into a *Multidimesional Scaling* (MDS) 2D plot following the perspective adopted in [27]. This MDS map is built with the confusion matrix of a decision tree classifier: the more the inter-class confusion the closer the labels in the map. This plot allows experts to make a decision regarding the different categories. The closest categories are good candidates to be collapsed into an alternative category. As result, we use the following Sp_ToBI pitch accents: H*, L* = {L* ∪ L*+H ∪ H+L* }, L+>H*, L+H* ={L+H* ∪ (L+)H*}, L+!H* ={L+!H* ∪ (L+)!H* ∪ !H*}, L+¡H* ={L+¡H* ∪ (L+)¡H* ∪ ¡H*}; and the following boundary tones: L%, H%, =%, !H%, LH% ={LH% ∪ L!H%}. Additionally, the class "none" represents the absence of tone. After performing that clustering, classification rates improved considerably.

The input of the classifier is composed of acoustic information (F0, energy and duraction features) and POS tags as detailed in [11]. More details about this system can be found in [28].

4. Procedure of revision of the automatic system's predictions

The fuzzy classifier has been applied to unseen samples of the Glissando news subcorpus read by different voices than those used in the manual annotation. A total subset of 18 news (6 news read by 3 different voices, 2 female and 1 male) has been annotated by means of the predictions of the fuzzy classifier and a human expert has reviewed all the tags.

	Label	Intertranscriber agreement per symbol	Unique label predictions
Pitch Accent	**none**	53.5%	50.3%
	L+H*	28.6%	37.5%
	L+!H*	6.5%	7.1%
	L+>H*	4.3%	1.7%
	H*	3.2%	0.4%
	L*	3.0%	2.9%
	L+¡H*	0.9%	0.2%
Boundary Tone	**none**	78.1%	77.3%
	L%	8.1%	10.4%
	H%	7.2%	3.1%
	!H%	4.6%	7.5%
	LH%	1.1%	0.5%
	=%	0.9%	1.1%

Table 2: *Inter-transcriber agreement per symbol* is the number of times (in percentage) that two of the transcribers agree assigning the same symbol to the same prosodic unit. *Unique label predictions* is the number of times (in percentage) that the fuzzy classifier predicts only one symbol per prosodic unit.

Figure 1 illustrates the graphical interface used to present the automatic system's predictions so as to a human expert can verify or correct them. The visual interface aligns the tags predicted by the fuzzy classifier with each prosodic event: pitch accents aligned with the stressed syllables and tone boundaries aligned with the end of the word. The classifier predicts presence or absence of break (with the tag "none"), and if a prosodic rupture exists, the type of boundary tone. On the contrary, information related to the levels of prosodic rupture (break indices) is not present. This information can be inferred from the type of boundary tone, since in our results, there is a statistically significant correlation between BI3 associated to H%, !H%, =%, L!H% and BI4 associated to L% (Pearson's chi squared test X-squared = 742.1301, df = 5, p-value $<$ 2.2e-16). There are only marginal cases in which L% is associated with BI3 , and in which H%, !H%, =%, L!H% are associated with BI4.

Compared with conventional crisp classifiers, the main advantage of a fuzzy classifier is that it can provide more than one label per prosodic unit (to a maximum of three in our system), depending on the uncertainty of the predictions. Each tag is accompanied by a numerical value in the [0,1] interval, the higher the value the more the certainty, and tags are ordered from the highest to the lowest degree. At this point, it should be noted that the procedure, according to the fuzzy set theory, is not based on probabilities since the degree of certainty is independently assigned to each category. This is the reason why the values can sum up more than 1, that is, if three tags appear, we cannot infer that there are three complementary possibilities that sum up 1. On the contrary, having more than one tag in the output represents a difficult situation in which more than one label evidences a degree of certainty over the threshold set by the α-cut. Another situation that can be found is that even when only a tag is predicted, it is not necessarily accompanied by a complete confidence (marked with 1).

The task of the human expert is to evaluate the candidates: he/she checks if some of the proposed tags are the right one according to his/her perception and marks it with "+". If she/he

doesn't agree with any of the tags proposed, he/she attaches "-" and writes a new option.

Figure 1 illustrates different types of situations that the human expert can find in the process of reviewing the output of the fuzzy classifier and that reflects the uncertainty that implies using a phonologically-based system such as ToBI. With respect to tone boundaries, the most certain decision is the label "none" associated to the words "una" (a) and "puede" (can): only one label is predicted, with a high degree of certainty (0.78). In this case, the tag "none" (meaning absence of prosodic break and as a consequence, absence of tone boundary) proposed by the system is validated (+), since any tonal nor segmental cue signal a prosodic break.

On the other hand, at the end of the prosodic group "una persona" (a person) the system suggests two candidates, associated to a very similar degree of certainty: a high tone, H% (0.49) or a mid tone, !H% (0.43). Crucially, the transcriber has to decide if the difference of range is phonologically significant in this context: since the transcriber perceives that the tone decreases to a mid-tone from an L+H* nuclear pitch accent, the second option is selected.

As far as pitch accents is concerned, the difficulty in discriminating between rising accents with or without peak displacement is evidenced in the word "puede" (can). As observed in the pitchtrack, the F0 peak is situated in the syllable border, that is, both stressed and post-stressed syllables show a high tone, a fact that makes difficult the decision. The transcriber chooses the rising tone without peak displacement (L+H*), because it is generally accepted that the high tone should be completely placed in the post-stressed syllable [29].

It may also happen that the proposals of the fuzzy classifier are wrong. It is the case of the pitch accent corresponding to the word "saber" (know). The system proposes two tags: "none", meaning absence of pitch accent and a high tone (H*). Since the stressed syllable is tonally accented, but with a rising accent and not with a high tone, the transcriber dismisses both options and writes the correct one, which is L+!H*. The downstep relates to the immediately preceding high tone within the same prosodic group.

At this point, it should be said that the adequate tuning of the α-cut value (that is the number of candidates that are presented in the interface) is crucial for a correct system operation. Lowering the value of the α-cut yields a higher number of positive cases, understanding as positive those right cases found within the set of predicted labels (computed as the soft-classification rate in [8]). For the reviewer it is important to know that the probability to have the right tag in the set of candidates is really high, but on the other hand, the more the labels the harder the selection of the correct one. In our case, in the training stage we obtained soft classification rates of 82% for pitch accents and 85% for boundary tones . These rates are clearly higher than the accuracy rates that we obtain in classic non-fuzzy classification (69.2% and 81.2% respectively). The increase in the confidence rates is expected to improve the performance of the reviewing process.

In the reviewed subset of 18 news, only one label is predicted in the majority of the cases (60% for boundary tones and 45.3% for pitch accents), and few cases have three labels (3.4% for boundary tones and 2.5% for pitch accents).

5. Results

The results coming from the process of revision report that in most cases (81.8% for boundary tones and 72.6% for pitch accents) the labeler choices the first candidate of the fuzzy classifier as the right option. Only 9.2% of the boundary tones and 13.5% of the pitch accents labels needed to be edited, that means, to be corrected with a different label. In a preliminary test, the real time ratio of that labeling process has been observed to be 1:66 when the template of predictions is used. This ratio contrasts with the one obtained without any supporting template which was 1:80. These ratios have been obtained from the comparison of the time that a transcriber needs to manually label a news and the time that he/she needs to label a news of comparable size with the aid of the fuzzy classifier: in the first case, 3600 s were labeled in 44.79 s (including autochecking after the first annotation) whereas in the second case, 3000 s were labeled in 45.23 s (including as well an autochecking). The experiment has been done by the same transcriber in separate days, during a stretch of time without any interruption.

Another encouraging result is that we found a clear correspondence between the results obtained by the fuzzy automatic classifier and the results obtained in the inter-transcriber agreement tests. In the inter-transcriber test, the pair of labels that are most frequently confused by the human experts is the pair L+H* vs. L+!H* for pitch accents and the pair "none" (absence of a break) vs. !H% for boundaries (26.9% and 34.4% of the total disagreement respectively). These pairs also have the highest frequency of appearance when the fuzzy classifier predicts more than one label per word (21.8% and 29.9%, respectively). To sum up, Table 2 shows that in the range of certainty the percentages are also similar: those cases where the fuzzy classifier predicts an unique label and the frequency of intertranscriber agreement per symbol are similar for each tag.

6. Conclusions and future work

We have presented the results of an experiment in which an automatic system has been applied for the Sp_ToBI labeling of the Glissando corpus. The automatic system can generate more than one candidate label per prosodic unit according to its degree of confidence. The revision of the candidate labels provides an alternative to speed up the labeling process.

The efficiency of this strategy to speed up the labeling process is supported by the fact that only a small proportion of the predicted labels is edited. Furthermore, in most cases, the reviewer selects the first label out of the set of predictions.

The use of fuzzy labels adequately resembles the uncertainty that characterizes the human prosodic labeling process in many situations. This is evidenced by the fact that most uncertain situations for the automatic classifier correspond with labels that are the most frequently confused in manual inter-transcriber tests.

This is part of ongoing work in which an iterative training and testing process is being applied in order to improve the predictions. The reviewed labels are reintroduced in the training stage of the classifier so that the knowledge of the system increases iteratively. We are currently investigating definitions of quality metrics that measure the goodness of this iterative approach. The improvement of the revision template interface (currently in $praat$) following the suggestions of the transcribers is also current and future work.

The results of the labeling process, manual, reviewed and predicted label in the different stages, are expected to be freely available for research purposes in the web page of the project `http://veus.glicom.upf.edu/`.

Abstract

This study aims at exploring the production and perception of Dutch word stress by Francophone learners of (Belgian) Dutch. For this purpose a production experiment was first carried out. In line with other studies, it was hypothesized that participants would show a tendency to stress the final syllable. Even though this hypothesis was confirmed, there was also a substantial lack of agreement between the five labellers who perceptually annotated the data for stress position. To further investigate this matter, acoustic measures were extracted. The data suggest that both groups of speakers do not use acoustic correlates to signal prominence in the same way, the Dutch group using intensity, vocalic nucleus duration and pitch movement more, while the French group prefers duration and pitch movement. This study also led us to develop tools to phonetise, syllabify and facilitate the acoustic analysis of Dutch speech.

Index Terms: L2 prosody, Dutch as a Foreign Language, speech perception, speech production

1. Introduction

Due to discrepancies between the Dutch and French prosodic systems and to the lack of attention paid to pronunciation in Dutch didactics, Dutch word stress can be problematic for Belgian Francophone learners of Dutch as a Foreign Language (DFL). Dutch on the one hand is a variable-stress language where stress is a lexical property of words [1] that can be used contrastively (e.g., *voorkomen,* 'to happen', vs. *voorkomen,* 'to prevent'). On the supra-lexical level, Dutch uses 'accents' to signal the informational status (linked to the concept of 'focus') of words. Stress is determined by the linguistic system, whereas accent depends on the communicational aims of a speaker [2: 41]. Dutch word stress (measured on words out of focus) is acoustically correlated (mainly) with duration, spectral tilt, and to a lesser extent overall intensity and timber. Dutch accent is mainly rendered by abrupt changes in f_0, duration, spectral tilt and overall intensity [2].

French, on the other hand, does not have lexical contrastive stress: the standard 'primary accent' typically falls on the last syllable of 'accentual' word groups [e.g. 3, 4, 5]. Rather than being contrastive, this 'primary' accent has a demarcative function [6]. Besides this primary accent, French has several secondary accents falling on any syllable of the word group and covering rhythmic or emphatic functions [7]. The acoustic correlates of the primary accent are mainly duration, a change in f_0 and the potential use of pauses. An initial emphatic accent is rendered by a shorter duration but a change in f_0, potentially preceded by a pause [7].

Although Dutch is taught in most primary and secondary schools in Francophone Belgium, pronunciation and prosody are often neglected in DFL courses according to our surveyed students and teachers [also 8]. This means that most learners may not be familiar with Dutch prosody.

The production of Dutch word stress by Francophones has been addressed in studies on Dutch as a Second Language (DSL) [9] and as a DFL [10, 11]. Based on the results of these studies it seems clear that the DFL population has to be analysed separately from the DSL one, as the latter group, probably as a result of receiving another type of input (viz. native spoken Dutch), has been found to be more proficient in producing correctly located stress in simple and complex words. As for the DFL group, it was concluded that learners tend to stick to their final L1 pattern, but can also evolve to a penultimate stress (yet not always being the required stress position) with time. Research on DFL stress in nominal compounds (with the first compounding part bearing stress as a main rule) [12] has also shown that, in addition to a preference for the final syllable, DFL speakers do not necessarily show a consistent stress pattern across words.

The current research focuses on Dutch stress production by Belgian Francophone learners. Our analysis first concentrates on the realised position of the stress by DFL speakers. This analysis relies on a perceptual annotation by multiple annotators. The considerable amount of inter-rater disagreement also led us to investigate the acoustic realisation of prominences by both DFL and native speakers. Discrepancies between the groups might explain annotation confusion and annotators might rely on different acoustic correlates.

In this paper we also present some methodological aspects of our study. The tools we developed provide a detailed analysis of some aspects of DFL and native Dutch (DL1) prosody.

The paper is organized as follows. Section 2 presents the methodology and tools developed to phonetically align, annotate and analyse our corpus. The analysis of the prominences produced by DFL and native speakers is then presented and discussed in Section 3. Finally, Section 4 concludes the paper and discusses further works.

2. Method

2.1. Participants

20 DFL learners (age range 19-23, mean age 21.1, 14f, 6m) and 10 native speakers of Belgian Dutch (age range 20-51, mean age 28.6, 5f, 5m) took part in the experiment. French was the only mother tongue of the selected DFL speakers.

2.2. Materials

30 existing Dutch three-syllable words were used in the current study. They were selected and classified according to the stress rules for simplicia described in [13]. They were split into three canonical stress positions (SP): initial (*pagina*, 'page'), medial (*collega*, 'colleague') and final (*aoniem*, 'anonymous'). Each word X was randomly presented thrice in a carrier sentence (***X*** *heb ik gezegd* '**X** I said', *Ik heb* ***X*** *gezegd*

'I **X** said' and *Ik heb gezegd **X*** 'I said X'), leading to a 90-sentence reading task. Each target was presented in bold, italics and was underlined, showing focus marking.

2.3. Procedure

Speakers were recorded individually in a quiet room. Prior to the recording they filled in a form containing questions about their learner profile (duration of Dutch learning, age at start of learning, etc.). The trial phase started after an instruction and training session similar to the trial. A Tascam-07 MKII recorder and a Sennheiser PC131 head-set microphone were used.

2.4. Perceptual analysis

The data were perceptually labelled independently by two DFL-speaking native-French speakers and three native Dutch speakers, all of whom were phonetically trained. After listening to the stimuli as often as required, the annotators indicated which syllable they perceived as prominent (1-2-3). Cases of doubt could be expressed as "1?3?", etc. The annotators also gave a certainty score on a scale from 1 (very easy) to 5 (very difficult) representing the difficulty of making their decision as to which syllable was most prominent.

2.5. Linguistic analysis

An alignment between the speech signal and the phonetic transcription was necessary for the prosodic analysis of the syllables. Since manual alignment is a tedious and time-consuming task, several automatic alignment tools have been proposed in the literature [e.g. 14, 15]. They usually rely on pre-trained speaker-independent models to align new corpora. However, they cover a very limited number of languages and might not perform properly for different speaking styles. Most of these existing tools actually do not provide models for Dutch. To resolve this issue, we developed a new automatic phonetic alignment tool, *Train&Align* [16]. Its specificity is that it trains the models directly on the corpus to align, which makes it applicable to any language and speaking style. Previous experiments have shown that it provides results comparable to the other existing tools [17]. It also offers additional options like "bootstrap", allowing for a manually-aligned part of the corpus to be used to improve the model quality. While a basic alignment of our corpus with *Train&Align* achieved rather poor alignment rates, the use of 40 seconds of bootstrap led to significant improvement, reaching alignment rates of about 82% with a 20 ms tolerance threshold. The aligned files provided in TextGrid format were easily imported in *Praat* for further prosodic analyses. This alignment was then manually checked.

The corpus was then syllabified in *Praaline* [18] (cf. 2.6). A basic rule-based syllabifier relies on the sonority sequencing principle (sonority should increase from the first phoneme of an onset to the nucleus), and the maximal onset principle, which states that a syllable's onset should be extended at the expense of the preceding syllable's coda. Such a simple rule-based approach has been shown to achieve an accuracy of 93-95% [19]. The syllabifier was adapted to Dutch by providing a list of valid onsets. The syllabification was manually checked.

2.6. Corpus processing

In order to further process the data, we used *Praaline* [18], a toolkit for corpus management, annotation, querying and visualization. It interfaces with *Praat* and stores corpus data as a relational database, allowing the user to add external data sources. The annotator labels from the perceptual analysis were imported and linked to the corresponding corpus syllables. *Praaline* runs a cascade of scripts and/or external analysis tools, each of which may add features to an annotation level (e.g. syllables, words etc.). Using this interface, we applied *Prosogram* [20] for pitch stylisation on the entire corpus. *Prosogram*'s algorithm operates in two phases; for each syllable, vocalic nuclei are detected based on intensity and voicing. The f_0 curve on the nucleus is then stylised into a static or dynamic tone, based on a perceptual glissando approach. Several syllable features (duration, pitch, pitch movement etc.) were added to the database.

Subsequently, we constructed the datasets for further statistical analysis using a query editor. *Praaline* queries may include data from multiple levels of annotation, and the features of one level may be aggregated or normalised over another level. In this study, we correlated the perceptual annotations to the prosodic features of syllables. For each prosodic feature, we also calculated a z-score value normalised over each speaker. Queries may also include functions to calculate derived measures; we used this feature to obtain relative measures (cf. 3.4). The statistical analysis was performed using SPSS (v. 21) and R (v. 3.0.2).

3. Results

3.1. Perceived stress position

3.1.1. Inter-rater agreement

An inter-rater agreement analysis using the Fleiss' Kappa statistic [21] was performed on the DFL and DL1 data to determine consistency among annotators. "Low certainty" comprises all the cases for which the majority of annotators ($n \geq 3$) expressed a low confidence ordeal about the decision they made as to which syllable was bearing stress (certainty score > 1 on a scale from 1 to 5, see 2.4.). "High certainty" refers to high confidence in the annotators' decisions (score = 1, see 2.4.). As shown in Table 1, the κ-values are always lower for the DFL group than for the control. For all cases taken together the agreement is moderate ($\kappa = 0.570$) for the DFL group [22] and almost perfect for the DL1 group ($\kappa = 0.980$). Cases of high certainty comprise 75.88% of the cases for the DFL and 98.00% for the control group. While κ is substantial for the DFL group and almost perfect for the DL1 group for cases with high certainty, the κ-value drops to fair levels for low-certainty cases.

	DFL	DL1
General	0.570 (n=1799)	0.980 (n=900)
High certainty	0.681 (n=1365)	0.984 (n=882)
Low certainty	0.239 (n=434)	0.385 (n=18)

Table 1: *Inter-rater agreement (Fleiss' κ and counts) for overall annotations ("General"), and cases with high and low certainty per L1 group.*

3.1.2. Consensus

Based on the annotations of each labeller, a consensus variable was computed per word. Consensus is reached when *all* annotators marked the same syllable as prominent. Table 2 shows the consensus values per canonical stress position (SP)

for the DFL speakers. The shaded cells contain the cases where canonical and perceived stress concur, meaning that the stress was perceived and therefore probably produced in the expected position. The overall percentage of "correct" stress amounts to 26.7% (vs. 96.1% for the control group). Consensus over each syllable is not equally distributed over the three canonical SPs (χ^2 (4) = 188.69, p < .001). Canonical SP3 yields the best results (39.90% correct), followed by SP2 (25.8%) and SP1 (14.3%). On the whole DFL speakers tend to stress the 3rd syllable most often regardless of the canonical SP (25.80%), confirming our hypothesis. However this result is mainly due to the high percentage of 3rd-syllable stress in SP3.

Canonical SP	No consensus		Syll 1		Syll 2		Syll 3		Total	
1	53.20	(319)	14.30	(86)	12.80	(77)	19.70	(118)	100.00	(600)
2	52.00	(312)	4.30	(26)	25.80	(155)	17.80	(107)	100.00	(600)
3	57.70	(286)	6.50	(39)	5.80	(35)	39.90	(239)	100.00	(599)
	51.00	(917)	8.40	(171)	14.80	(267)	25.80	(464)	100.00	(1799)

Table 2: *Percentages (and counts) consensus between annotators for 1st, 2nd and 3rd canonical stress position broken down by perceived stress position.*

Strikingly, in 51.00% of the cases no consensus is reached. There are two possible reasons for this: either one or more annotators did not label the same syllable as being prominent due to a difference in perception or in acoustic correlates, or the speakers have produced multiple prominences within the same word, leading to 'doubt' cases (e.g. 1?3?). Table 3 shows all these cases where annotators labelled multiple syllables as prominent. "1?3?" doubt cases should be viewed separately from the other doubt cases as they probably signal double prominences within a word. The other cases might point to the use of ambiguous acoustic correlates.

Doubt cases (n = 623)	DFL	
1?2?	4.49%	(28)
1?3?	80.90%	(504)
2?3?	12.20%	(76)
1?2?3?	2.41%	(15)

Table 3: *Percentage (and counts) of perceived multiple prominences for the DFL group within all doubt cases.*

As previously mentioned (see 3.1.), the annotators also gave a high-certainty score in 75.88% of the cases. This is interesting as it shows that sometimes the annotators showed great confidence in their annotations whereas they did not perceive the same syllable as being the most prominent one.

3.1.3. Analysis of the correct vs. incorrect results

For this analysis all cases where consensus and canonical SP concur were labelled as "correct" and all others as "incorrect". A repeated measures ANOVA with Greenhouse-Geisser correction with canonical SP and word position in the sentence as within-subjects factors and L1 of the speakers as between-subjects factor was carried out on the percentage of (in)correct cases. As expected, an effect of L1 ((F(1, 28)) = 28.92, p < .001), but also of position of the word in sentence ((F(1.761, 49.308)) = 3.917, p < .005) was found. However, there is no effect of canonical SP for both speaker groups taken together ((F(1.80, 50.34)) = 3.04, n.s). The analysis also reveals an interaction between canonical SP and L1 ((F(1.80, 2.47)) = 3.38, p < .05), and position in sentence and L1 ((F(1.76, 68.96)) = 5.92, p < .001).

The same analysis was carried out per L1 group as an interaction between SP and L1 and word position in sentence and L1 had been found. For the DFL group an effect of SP ((F(1.70, 32.13)) = 10.33, p<.001) and position in sentence was found ((F(1.79, 33.95)) = 6.64, p< .05). Pairwise comparisons show that the effect of SP is caused by the difference between SP1 (14.3% correct, see Table 2) and SP3 (39.90%) but not with SP2 (25.8%). The same appears to be true for word position in sentence: 21.3% of cases in sentence-initial, 27.7% in sentence-medial, 31.1% in sentence-final position are correct. Figure 1 shows the percentage of correct results per canonical SP and position in sentence. There seems to be a trend towards more correct results when words are sentence-final, especially on the 3rd syllable (cf. our hypothesis). However, this result does not reach significance as the interaction between SP and position in sentence is not significant ((F(2.44, 45.39)) = 1.85, n.s.).

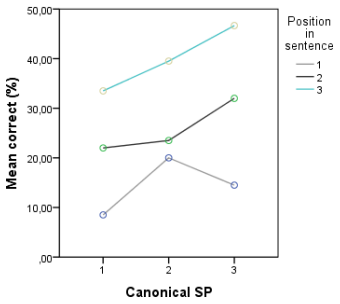

Figure 1: *Percentage correct cases per canonical SP and word position in sentence for the DFL data.*

For the control group, no effect of SP ((F(1.70, 15.31))=1.39, n.s.) or position in sentence ((F(1.68, 15.01))=0.08, n.s.) and no interaction between them ((F(4, 36))=0.41, n.s.) was found.

3.2. Acoustical realisation of prominent vs. non-prominent syllables

In order to study the prosodic correlates of perceived prominent syllables for the DL1 and DFL groups, we extracted several acoustic features of syllables. Inspired by the methodology presented in [23], four features were studied:

- Relative mean pitch: the difference of a syllable's mean pitch relative to the mean pitch of the word (in semitones);
- Pitch movement: intra-syllabic upwards or downwards movement (in semitones);
- Relative vowel duration: the ratio of the vocalic nucleus of a syllable, relative to the duration of the vocalic nuclei of the word;
- Relative peak intensity: the difference of a syllable's peak intensity in the vocalic nucleus relative to the mean intensity of the word (in dB).

These features are typically correlated with syllabic prominence. Syllables were included in the statistical analysis only when pitch could be detected and stylized by *Prosogram* in their corresponding word: in total 6891 syllables were analysed (2319 native, 4572 non-native; 1918 stressed, 4461 unstressed). The distributions of the four acoustic measures are

shown in Figure 2. Relative pitch and relative intensity follow a normal distribution. Relative vowel duration is positively skewed, while pitch movement follows a bimodal distribution, corresponding to falling and rising pitch.

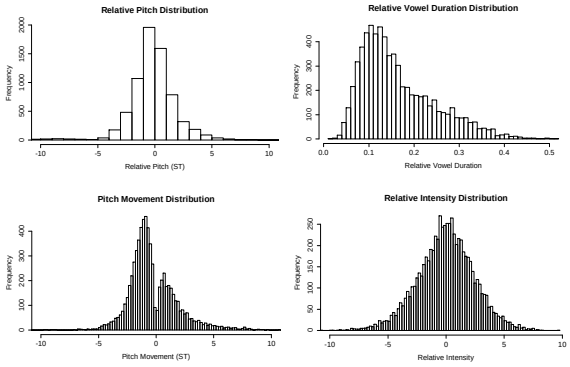

Figure 2: Distribution of the prosodic correlates of syllabic prominence under study (from left to right, top to bottom: relative pitch (ST), relative vowel duration (ratio), pitch movement (ST), relative intensity (dB).

A multivariate ANOVA was carried out on every acoustic measure; the fixed factors were L1 and presence/absence of prominence. Table 4 shows that the language groups make different use of duration ($p < 0.001$) and maximum pitch ($p < 0.05$), but use similar overall pitch and intensity strategies. There is a significant difference for every acoustic measure between prominent and non-prominent syllables ($p < 0.001$) as well as an interaction between both factors ($p < 0.001$, $p < 0.05$ for falling pitch movement).

Acoustic measure \ Factor	L1	Prominence	L1x Prominence
Relative syllable duration	**	**	**
Relative nucleus duration	**	**	**
Relative vowel duration	**	**	**
Relative pitch minimum	n.s.	**	**
Relative pitch maximum	*	**	**
Relative mean pitch	n.s.	**	**
Pitch movement, rising	n.s.	**	**
Pitch movement, falling	n.s.	**	*
Relative intensity	n.s.	**	**

Table 4: Main effects for L1, absence/presence of prominence and interaction between them on all acoustic measures (* $p<0.05$; ** $p<0.001$)

In order to assess the relative importance of each prosodic correlate for prominent and non-prominent syllables for both groups, we applied a binomial logistic regression model. A syllable was considered prominent or not (binary dependent variable) as long as there was a consensus (per syllable) between 4 or all 5 annotators. The acoustic measures were the model's predictors. In the DL1 group, relative mean pitch was found non-significant; all other predictors were significant with $p < 0.001$. Table 5 summarises the standardised beta coefficients and z-scores for each predictor for the two models. The results suggest that DL1 speakers signal prominence mainly through relative intensity, duration and rising pitch movement (in decreasing order of importance). DFL speakers on the other hand, use duration, then rising pitch movement and relative mean pitch. It is noteworthy that these were found to be the main prosodic correlates of syllabic prominence in French (along with succeeding pauses) [7].

Acoustic measure	DL1		DFL	
	β	z	β	z
Relative vowel duration	1.749	10.9	1.942	18.2
Pitch movement, rising	2.083	10.8	1.934	14.2
Pitch movement, falling	0.451	3.1	0.628	5.8
Relative mean pitch	-0.221	n.s.	-0.976	-8.4
Relative intensity	3.715	18.4	0.325	3.4

Table 5: Standardised β coefficients and z-scores for the DL1 and DFL logistic regression models predicting prominence.

4. Conclusion and perspectives

This paper investigated the realisation of Dutch stress by Belgian Francophone learners of Dutch. Our study showed low scores of correct stress position for the DFL group, pointing at their poor grasp of Dutch word stress position. On the whole, the DFL speakers relied on their final L1 pattern but mainly in canonical SP 3. This globally supports our hypothesis. There also seems to be a trend towards more correct 3rd-syllable stress in sentence-final position, but this result does not reach significance.

The manual annotation of perceived prominence in the corpus sometimes reached low agreement rates. In an attempt to explain this phenomenon, acoustical analyses were carried out. The analyses of variance seem to signal a different use of duration and maximum pitch by the language groups. The binomial logistic regression model points out that the DL1 group uses relative intensity, duration and rising pitch movement to signal prominence. The DFL group uses L1 accentuation strategies (duration, rising pitch movement and relative mean pitch). If annotators are more sensitive to different sets of acoustic correlates, this would explain the overall low consensus.

Further studies will focus on the comparison of the acoustic realisation of prominent syllables with high vs. low-certainty score cases. Speaker variability will also be investigated as it might also account for the lack of annotation agreement. Furthermore the analysis of the "doubt" cases (Table 3) should help us find evidence for multiple prominences within words.

While our study relied on a binary prominence label, it should be noted that research [e.g. 23, 24, 25] suggests that syllabic prominence is perceived as a gradual rather than a binary phenomenon. A manual annotation of relative prominence levels might give more insight into DFL stress production. Finally, it should be highlighted that the studied acoustic correlates are actually those of focus accent. While lexical stress should be studied in words out of focus [2], the main goal of our study was rather to compare stress position between DFL and DL1 speakers, stress and accent falling on the same syllable in Dutch. In an attempt to avoid total lack of prominence on the DFL stimuli, all words were put in focus. The acoustic correlates are used here as an attempt to explain perceptual differences between annotators and should not be considered as acoustic correlates of lexical stress.

Abstract

Human listeners can perceive speech signals in a voice-modulated ultrasonic carrier from a bone-conduction stimulator, even if the listeners are patients with sensorineural hearing loss. Considering this fact, we have been developing a bone-conducted ultrasonic hearing aid (BCUHA). The purpose of this study was to assess the usefulness of the BCUHA in transmission of speakers' physical attributes: gender and age. The evaluation used gender and age-identification experiments. The experiments were also conducted under air-conduction (AC) and cochlear implant simulator (CIsim) conditions. The results showed that: the BCUHA can well transmit speakers' gender information; the BCUHA can transmit speaker age information better than CIsim.

Index Terms: ultrasound, bone-conduction, hearing aid, paralinguistic information, speakers' attribute.

1. Introduction

We have developed a bone-conducted ultrasonic hearing aid (BCUHA) for sensorineural hearing-impaired patients [1]. A BCUHA consists of two components: an amplitude-modulated ultrasound processor and a bone-conduction vibrator.

Ultrasound is defined as sound with a frequency higher than the limitation of human perception (about 15 kHz). However, humans can perceive sound transmitted as ultrasound through a bone-conduction vibrator [bone-conducted ultrasound (BCU)] [2]. Moreover, if the ultrasound is amplitude modulated by speech sounds, the original speech sounds can be perceived in addition to the carrier sound by both normal-hearing (NH) and hearing-impaired listeners. We based the development of our BCUHA on these observations.

The cochlear implant (CI) was developed for and widely adopted by sensorineural hearing-impaired patients. A CI also consists of two components: speech signal processors and electrodes mounted in the cochlea. However, despite their widespread use, some problems with CIs have been reported. The biggest problem is that a CI requires surgical positioning, which causes irreversible damage to the cochlea. Another problem is that, because performance is limited by the number of electrodes, the CI transmits only partial or reduced information, not the entire sound. Nowadays, the number of CI electrodes is limited to between 12 and 24, and frequency resolution is limited according to the number of electrodes. This number may be sufficient for transmitting linguistic messages; however, it is reported that CI users have great difficulty perceiving music, speaker identity, emotional state, etc. [3, 4, 5, 6].

In contrast, the BCUHA does not require surgical fitting; users simply attach the bone-conduction vibrator with a hair band-like device (Figure 1). Furthermore, the BCUHA does not have the frequency limitations of CIs. However, in addition to speech signals, BCUHA listeners perceive high-frequency sound owing to the carrier signal [1]. Therefore, the carrier-originated sound may prevent clear perception of speech sounds. Consequently, the speech signal transmission performance of the BCUHA has been assessed using various techniques, such as using monosyllables [7] or word intelligibility scores [1]. These studies found that syllable articulation scores using BCU were over 60% [7] and that word intelligibility scores for high-familiarity words were over 85% [1]. The patterns of confusion in speech perception using BCU have many points in common with air conduction (AC) [7]. However, speech sounds convey not only linguistic messages but also indexical information about the speaker, such as gender, age, identity, and emotional state. As mentioned above, it is difficult for CI users to perceive such messages; thus, if the BCUHA performs better in this regard, it has a great advantage over the CI.

In this study, we focused on the ability to transmit speaker information. Previously, we compared the BCUHA with CI simulator (CIsim) based on speaker discrimination [8]. The results of this previous study showed that the speaker discrimination performance of the BCUHA is as good as that of the CI. However, this evaluation was performed using a discrimination task; the participants were simply requested to judge if the speaker

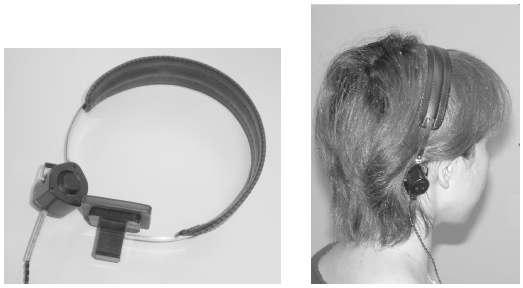

Figure 1: *Ceramic vibrator of the BCUHA attached to the mastoid with a hair band-like device*

of two sounds was "the same" or "different," and the result did not illustrate what types of speaker attributes were transmitted. Therefore, we assessed the ability of the BCUHA to transmit a speaker's physical attributes, including gender and age by conducting a series of listening experiments.

2. Methods

2.1. Stimuli

The experiments were designed as gender- and age-identification tasks, and stimuli were selected using the following procedures.

2.1.1. Speech material

To develop speaker gender- and age-identification tasks, we extracted speech material spoken by a large number of gender- and age-balanced speakers from "The Corpus of Spontaneous Japanese" (CSJ) [9]. From this corpus, we selected a phrase pronounced by various speakers: a short passage reading task "DNA." From the "DNA" task, the first phrase "di:-enu-e:" (DNA) was selected as the speech material. This phrase consists of voiced sounds and contains a nasal consonant. These types of sounds contribute to speaker identification [10]; thus, this phrase is expected to be suitable for the speaker attribute identification task.

Another reason for selecting this phrase was that it was spoken by 229 speakers in the CSJ. The speakers' genders were balanced, and the speakers' ages ranged from the low 20s to the high 60s. The numbers of speakers categorized by gender and age are listed in Table 1, in which "20L" represents low 20s, "20H" represents high 20s, etc.

Table 1: *Number of speakers categorized by gender and age*

	20L	20H	30L	30H	40L	40H	50L	50H	60L	60H	total
M	12	11	12	12	10	13	13	10	10	11	114
F	8	18	12	9	14	6	13	10	17	8	115
total	20	29	24	21	24	19	26	20	27	19	229

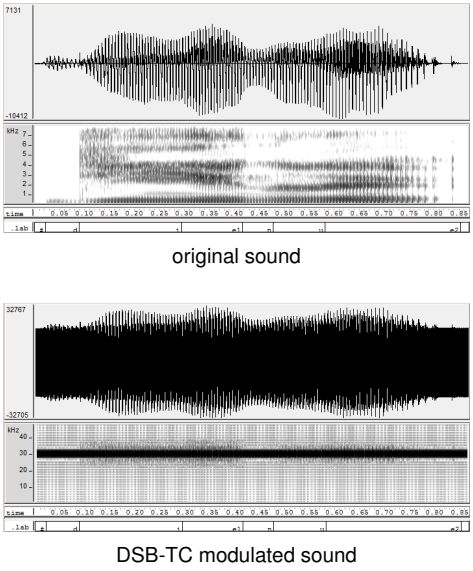

Figure 2: *DSB-TC amplitude-modulation*

2.2. Experiments

2.2.1. Bone-conducted ultrasound

The stimuli were converted to BCU stimuli in the form of amplitude-modulated 30 kHz sinusoid waves. A double-sideband transmitted-carrier (DSB-TC) amplitude-modulation method (Figure 2) was applied for this study because previous studies revealed it to be the best amplitude-modulation method for the BCUHA [1, 7]. With the DSB-TC method, the modulated speech signals $U(t)$ are represented by the following expression:

$$U(t) = [S(t) - S_{\min}] \times \sin(2\pi f_c t) \quad (1)$$

where $S(t)$ is the speech signal, $S_{\min}$ is the minimum amplitude of $S(t)$, and f_c is the carrier frequency (30 kHz).

The BCU stimuli were presented using a custom-made ceramic vibrator (Figure 1). Bone-conducted ultrasound can be perceived when it is applied to various parts of the body, and the mastoids are among the locations where such perception is high. Therefore, we applied the vibrator to the subject's left or right mastoid using a hair band-like device (Figure 1).

2.2.2. Cochlear implant simulator

To generate CI-simulated sounds, the Cochlear Implant Simulation (http://www.ugr.es/~atv/web_ci_SIM/en/ci_sim_en.htm) developed by the University of Granada was adopted in this study, and the software was config-

	AC		BCU		CIsim	
	M	F	M	F	M	F
M	0.996	0.004	0.981	0.019	0.969	0.031
F	0.005	0.995	0.011	0.989	0.141	0.859

ured to simulate the MEDEL COMBI 40+ and TEMPO+ systems (see Table 2).

2.2.3. Participants

Seven native Japanese speakers (age: 19-41 years) with no reported hearing or speech defects participated in the experiments.

2.2.4. Procedures

All experiments were conducted in a soundproof chamber, and the sound levels of the stimuli were adjusted to the most comfortable level for each participant. For the AC and CIsim conditions, the sound stimuli were presented in a counterbalanced order through a set of headphones (Sennheiser HDA200). The participants were then requested to identify the speaker's gender (male or female) and age (10 levels listed in Table 1).

3. Results and Analysis

3.1. Speaker gender information

Table 3 lists the results of the gender identification task. The responses of all participants were pooled. The rows represent stimuli, and the columns show the responses. As shown in Table 3, speaker gender information was well transmitted in each condition. In the AC condition, the percentage of correct perceived ratios was higher than 99.5%, and in the BCU condition, it was higher than 98%. However, a small number of male-to-female errors (14%) were observed in CIsim condition.

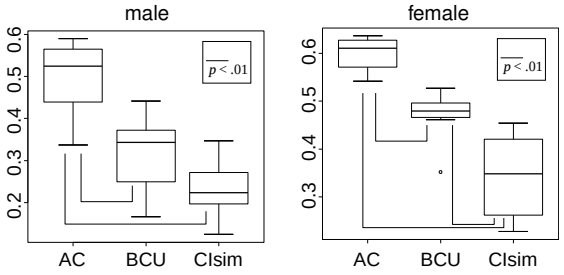

Figure 4: *Kendall's rank correlation coefficients by subjects*

3.2. Speaker age information

Figure 3 shows the confusion ratio and Kendall's rank correlation coefficients for speaker age. The responses of all participants were pooled. The columns represent stimuli, and the rows show the response. "20" represents low 20s, and "25" indicates the high 20s. Black-to-white contrast indicates the response ratio; darker cells indicate higher responses. The upper part shows the results of the male speaker condition, and the lower shows the female speaker condition.

From Figure 3 and the correlation coefficients, a large number of errors were observed. The rank correlation coefficients (τ) were lower than 0.57 (female voice) and 0.43 (male voice) even in the AC condition. In the BCUHA condition, the correlation coefficients were lower than 0.42 (female) and 0.29 (male) and 0.32 (female) and 0.23 (male) in the CIsim condition.

For each gender, the correlation coefficients were the best in the AC condition, then the BCUHA condition, and worst in the CIsim condition. To validate whether this tendency is statistically significant, correlation coefficients were calculated for each participant, and a series of ANOVA and post-hoc tests (multiple comparison with Holm's p adjustment method) was performed. The analyses were conducted for each speaker gender, and the results are shown in Figure 4. In the male speaker voice experiments, significant differences were observed between AC and BCU and between AC and CIsim ($p < 0.05$) and, in the female voice experiments, between all conditions ($p < 0.05$).

4. General Discussion

In each condition, speaker gender information was well transmitted. This result indicated that the BCUHA users can discriminate speaker gender as well as normal-hearing listeners can. This was also consistent with the results of the previous speaker discrimination tests [8], which showed that speaker errors were rarely observed in the AC, BCUHA, and CIsim conditions [8].

These high-accuracy gender identification results can be accounted for by good transmission of F0 information. It is well known that the F0 for an adult male voice is low and that for an adult female is medium. Moreover, BCUHA listeners can perceive the Japanese pitch accent [11] or prosodically salient paralinguistic information [12]. The results of these studies show that the BCUHA can transmit both local F0 modulations and global F0 range. Transmission of local F0 modulations allows pitch accents to be perceived, and global F0 range conveyance enables paralinguistic information, such as the speaker 's gender, to be obtained.

In contrast, BCUHA listeners have difficulty identifying the speaker's age. This result indicates that some voice timbre information is lost during BCU listening. However, this was also observed in the CIsim condition, and the correlation ratios between stimuli and perceived age by BCUHA listeners were superior to those of the CIsim listeners. Thus, the results of this study indicate that the BCUHA performs at least as well as the CI for speaker information transmission and outperforms the CI in some aspects.

5. Summary and Conclusions

The ability of the BCUHA to transmit speaker information was evaluated by conducting a series of speaker gender- and age-identification experiments. The results showed that the ability of BCUHA to make speaker gender judgments reaches the level of AC, whereas the BCUHA outperformed the CIsim for transmitting age information; however, the correlation coefficients between speaker age and perceived age using BCUHA were not sufficient. Further investigations are required to solve this problem.

Abstract

In recent years, there has been increasing interest in whether rhythmic interventions support young children's literacy development [1]. To begin to explore this connection, we assessed several aspects of rhythmicity and expressivity of productions of the notably rhythmic and rhyming children's book, *The Cat in The Hat* by Dr. Seuss. Participants subjectively rated either the rhythmicity or expressivity of speech taken from recordings of the book read aloud. These perceptual ratings were correlated with acoustic measures of rhythmicity and expressivity. Moreover, we observed a surprising lack of consistency between perceptual ratings of rhythmicity and expressivity. However, we observed a consistent relationship between the perceptual ratings of the first couplet of verses and the second, suggesting that readers showed self-entrainment in rhythmicity and expressivity between verse couplets. These findings can inform our investigation of the role of rhythm in literacy development and set the stage for further investigation into rhythmic entrainment across speakers.

Index Terms: rhythm, expression, production, child-directed speech

1. Introduction

1.1. Rhythm in speech perception

Speech researchers have long been interested in what factors contribute to isochronous speech in which stresses are perceived at regular intervals [2]. Although consistent acoustic measures of isochrony have been difficult to identify [3], there is consensus that perceptual isochrony is an important component of speech perception. For example, recent studies demonstrate that perceptual isochrony can help resolve ambiguity in speech perception [4,5]. Moreover, it is clear that babies attend to rhythm from a very early age [6], and can use rhythmic cues to learn words [7].

Many have observed that children's nursery rhymes are rhythmic and have consistent rhyming schemes. Moreover, exposure to rhyming texts has been shown to improve children's phonological awareness [8,9] and expressive vocabulary abilities [10]. However, little prior work has examined whether and how the rhythmic schemes of children's books improves children's literacy development.

There is reason to suspect that the rhythmicity of these texts supports reading acquisition, though this topic has received little direct investigation. For example, dyslexic children have been shown to be less sensitive to rhythm than normally reading children [11,12]. In addition, reading researchers have long advocated that rhythmic reading, including the use of an Interactive Metronome program, is an effective instruction tool [13]. One possibility, that we begin to explore here, is that rhythmic texts support self-entrainment [14], such that, within a verse, readers produce stresses at a consistent rate.

What can certainly not be denied is the fact that children like to encounter rhythm when reading, as evidenced by the popularity of books by Dr. Seuss and others. The goal of the current study is to explore the nature of the structure of rhythmic texts in order to begin to understand what aspects of their composition might support reading acquisition.

1.2. Rhythm in child-directed speech

A parallel line of inquiry in speech comprehension is determining the circumstances under which speech is most likely to be rhythmic. Recent investigations have demonstrated that multiple factors can contribute to the rhythmicity of speech, including the syntactic/semantic structure of the speech [15,16], the cognitive load of the speaker [17], and the audience to which the speech is directed.

It is this final factor that serves as the starting point for the current study. Recent work has demonstrated that the same speakers produce more rhythmic (even-timed) child-directed speech and singing than adult-directed speech [18,19] suggesting that readings of *The Cat in the Hat* will be good candidates for investigating speech rhythmicity.

1.3. Expression in child-directed speech

It is clear that expression plays a large role in child-directed speech. Acoustically, the greater perceived expressivity of child-directed speech is realized primarily by higher, and more variable, F0 than adult-directed speech [20]. Moreover, there is evidence that this expressivity facilitates speech comprehension. Examinations of child-directed speech indicate that exaggerated pitch peaks at the ends of utterances marking focused words may facilitate speech processing [21]. Moreover, previous research has demonstrated that infants are able to distinguish words from syllable sequences spanning word boundaries after exposure to infant-directed speech but not after exposure to adult-directed speech [22].

The current study further investigates the role of expression in children's literacy development, specifically examining how expressivity of child-directed speech may relate to the rhythmicity of child-directed speech.

1.4. Current Study

The objective of the current study was to investigate the rhythmic and expressive characteristics of child-directed speech; specifically, the book *The Cat in the Hat* by Dr. Seuss. The research questions we addressed were:

(1) Is there a consistent relationship between perceived rhythmicity and perceived expressivity in productions of *The Cat in the Hat?*

(2) Does the rhythmicity of the first couplet of a verse predict the rhythmicity of the second couplet?

(3) Does the expressivity of the first couplet of the verse predict the expressivity of the second couplet?

We could imagine two possible answers to question (1). On the one hand, if greater expressivity and greater rhythmicity are both predictive of better outcomes for audiences (of children), then it could be the case that these two factors will be correlated such that greater perceived rhythmicity corresponds to greater perceived expressivity. On the other hand, rhythmic variation is one marker of expressiveness in production. Therefore, we may observe a negative correlation between perceived rhythmicity and perceived expressivity of verses such that greater perceived rhythmicity corresponds to lower perceived expressivity.

Regarding (2) & (3), we were interested in whether there is rhythmic and expressive consistency within verses after accounting for within-speaker factors. That is, are there characteristics of the verses themselves that predict how expressive or rhythmic their productions will be?

2. Method

2.1. Participants

Participants were sixteen native speakers of American English (all female), ages 18-35. All received course credit for participating.

2.2. Materials

Participants all read "The Cat in the Hat" by Theodor Seuss Geisel (aka "Dr. Seuss") in its entirety. This text was written in an anapestic tetrameter such that every couplet (1A, 1B) consists of four anapestic (weak-weak-**strong**) feet. Two couplets form a verse (1). There are a total of 71 verses in the book.

(1) *A: "Put me **down**!" said the **fish**.*
*This is **no** fun at **all**!*
*B: Put me **down**!" said the **fish**.*
*"I do **not** wish to **fall**."*

2.3. Procedure

Participants were randomly assigned to read the hardcover book aloud in one of two environments: In a quiet room in the lab with no audience present; or to an audience of between three and five 5- and 6-yr-olds in a pre-kindergarten classroom. Both groups were instructed to read as naturally as possible. Their productions were recorded with Praat [23] through a Shure SM10A head-mounted microphone, connected to a Rolls Mini-Mic pre-amplifier. Productions were recorded with a sampling rate of 44100 Hz.

Initial analysis of acoustic measures demonstrated no significant differences between the productions recorded in the lab and those recorded in the classroom. This may be because our participants were all familiar with *The Cat in the Hat* and couldn't help but read it expressively and rhythmically regardless of whether there was an audience present. We will, therefore, report data from all productions together.

2.4. Acoustic Measurements

All productions were aligned with the book text in Praat using the Prosodylab-Aligner software [24] and then hand-corrected. Productions were segmented into verses (as in 1) and further divided into (A) and (B) couplets. All verses which contained a disfluency in either of the two couplets were excluded from further analysis. Of the 71 total verses in the book, we selected 18 for further analysis which met the following criteria: First, they were primarily anapestic tetrameter (though the first foot could be iambic); second, they appeared on four adjacent lines on one page of the book; third, they were fluently produced by at least 14 of the 16 speakers. These constraints resulted in a total of 252 verse productions (504 couplets).

These couplets were distributed across three lists which were balanced, as much as possible, across speakers and verses. The couplets that comprised each verse (e.g., (1A) & (1B)) did not appear on the same list, so that each couplet was rated by different listeners. The lists were comprised of 173, 166, and 165 couplets, respectively.

Using Praat, we extracted measures of duration, average F0, maximum F0, minimum F0, and average intensity from every word. For the current study, we looked only at measures of duration and mean F0.

2.5. Perceptual Evaluation

An additional 30 female participants were recruited to participate in a perceptual evaluation task. None had participated in the production experiment. They were randomly assigned to rate either the expressivity or the rhythmicity of the verse couplets.

Half of the participants (n= 15) rated their perception of the each couplet's rhythmicity on a scale of 1-4 where 1 was "very rhythmic" and 4 was "not at all rhythmic." Instructions were adapted from [5] such that raters were asked to determine how well they could find a steady beat for the couplet. Each of these 15 participants was assigned to one of the three lists, so that five participants rated each couplet. They were first presented with 8 practice couplets; four were categorized by the authors as "very rhythmic"; four were categorized as "not at all rhythmic." We observed agreement on these ratings which was significantly greater than chance, Fleiss' $\kappa = .09$, $z = 10.5$, $p = 0$ [25], indicating that raters were sensitive to couplet rhythm. Ratings from all five raters were averaged, resulting in an average Rhythmicity score for each couplet.

Half of the participants (n=15) rated their perception of the each couplet's expressivity on a scale of 1-4 where 1 was "very expressive" and 4 was "not at all expressive." Each of these 15 participants was assigned to one of the three lists, so that five participants rated each couplet. They were first presented with 8 practice couplets; four were categorized by the authors as "very expressive"; four were categorized as "not at all expressive." We observed agreement on these ratings which was significantly greater than chance, Fleiss' $\kappa = .29$, $z = 34.5$, $p = 0$, indicating that raters were sensitive to couplet expressivity. Ratings from all five raters were averaged, resulting in an Expressivity score for each couplet.

3. Results

3.1. Acoustic and perceptual ratings

Before investigating our research questions, we measured the consistency between acoustic and perceptual ratings of expressivity and rhythmicity.

3.1.1. Acoustic and perceptual measures of rhythmicity

In order to objectively quantify the rhythmicity of productions, we identified the timing of the onsets of strong syllables (**bolded** in (1)): For each couplet, we computed the standard deviation of the latencies (SD_Latency_Strong) between the onset of strong syllables 1 and 2 (***down*** and ***fish***), syllables 2 and 3 (***fish*** and ***no***), and syllables 3 and 4 (***no*** and ***all***). SD Latency ranged from 1 ms to 850 ms. This measure was highly correlated with the average Rhythmicity rating, R = .48, p < .0001, such that higher variability in the timing onsets of strong syllables was associated with lower Rhythmicity ratings (Figure 1). Recall that a lower number indicates a higher rating of Expressivity. This result suggests that timing variability was one factor that raters used in their Rhythmicity judgments.

3.1.2. Acoustic and perceptual measures of expressivity

As intonational variability has been identified as a strong marker of expressivity in speech [20], and child-directed speech exhibits greater pitch variability [21], we computed an acoustic measure of expressivity based on pitch. For each couplet (e.g., 1A, 1B), we computed the standard deviation of the mean F0 (SD_F0_Word) for each word. This measure was highly inversely correlated with the average Expressivity rating, R = -0.18, p < .001 (Figure 2). Recall that a lower number indicates a higher rating of Expressivity. This result demonstrates that F0 variability was one factor that raters used in their Expressivity judgments.

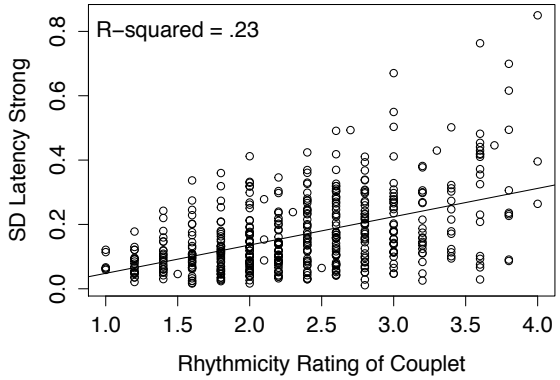

Figure 1: *Correlation of average perceived rhythmicity rating of a couplet and the standard deviation of the latency of onsets between the strong syllables of the couplet.*

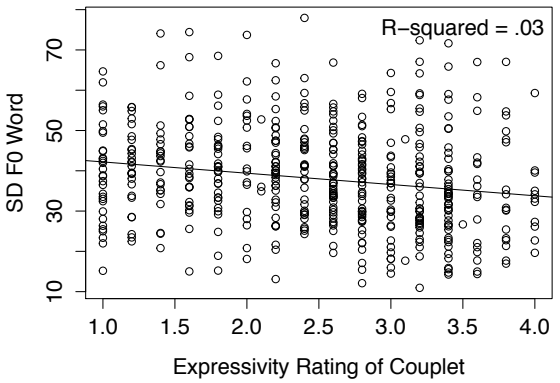

Figure 2: *Correlation of average perceived expressivity rating of a couplet and the standard deviation of the mean F0 of each word in the couplet.*

3.2. Relationship between Expressivity and Rhythmicity

In order to determine whether there is a consistent relation ship between rhythmicity ratings and expressivity ratings, we conducted a correlational analysis comparing the Expressivity and Rhythmicity scores for each couplet. Pearson's correlational coefficient was R = .03, which did not reach significance, p = .48, indicating no systematic relationship between perceived expressivity and perceived rhythmicity.

3.3. Intraverse Expressivity and Rhythmicity

In order to investigate the consistency between the Rhythmicity and Expressivity scores of the first and second couplets of a single verse, we analyzed these scores separately on a single-couplet basis using a linear mixed-effects model implemented in the languageR package [26] implemented in the R statistical programming language (R Core Development Team, 2012).

We computed models in which we predicted an A couplet's Rhythmicity/Expressivity score from one fixed effect (the B couplet's Rhythmicity/Expressivity score) and two random effects: The individual reader and the verse that the couplets comprised. In this way, we could see whether the Rhythmicity/Expressivity of one half of a couplet predicted the Rhythmicity/Expressivity of the second half after accounting for differences across speakers and items. We estimated the significance level of the fixed effect using Markov Chain Monte Carlo sampling [27].

Fixed Effects	Est.	SE	t	pMCMC
Intercept	2.045	0.17	12.06	<.001
Rhythmicity of couplet A	0.16	0.07	2.35	<.05

Table 1. *Parameter estimates of mixed-effects model predicting Rhythmicity of couplet B.*

Fixed Effects	Est.	SE	t	pMCMC
Intercept	1.45	0.18	8.08	<.001
Expressivity of couplet A	0.43	0.06	7.61	<.001

Table 2. *Parameter estimates of mixed-effects model predicting Expressivity of couplet B.*

Across speakers and verses, the Rhythmicity rating of the first couplet of a verse was predictive of the rating of the second couplet, $t = 2.35$, $p < .05$ (Table 1). The simple correlation between the Rhythmicity ratings of the first and second couplets are presented in Figure 3. This result demonstrates that, across speakers and items, the rhythmicity of the first couplet was predictive of that of the second couplet.

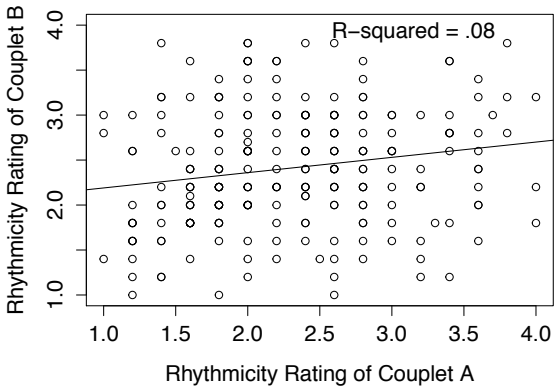

Figure 3: *Correlation of average perceived rhythmicity rating of the first and second couplet of verses.*

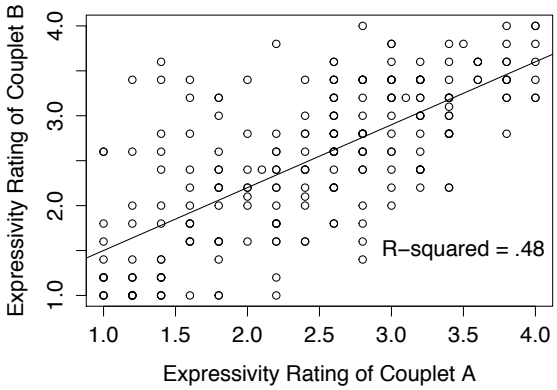

Figure 4: *Correlation of average perceived expressivity ratings of the first and second couplet of verses.*

Across speakers and verses, the Expressivity rating of the first couplet of a verse was predictive of the rating of the second couplet, $t = 7.61$, $p < .001$ (Table 2). The simple correlation between the Expressivity ratings of the first and second couplets is presented in Figure 4. This result demonstrates that, across speakers and items, the expressivity of the first couplet was predictive of that of the second couplet.

4. Discussion

In order to begin to explore the features of rhythmic children's books that support literacy development, we have constructed a spoken corpus of sixteen productions of *The Cat in the Hat* by Dr. Seuss. We gathered perceptual ratings of both the rhythmicity and expressivity of many of the verses from the text, and identified acoustic correlates of these perceptual ratings. Specifically, we found that rhythmicity ratings were correlated with variability in the timing of the onsets of the strong syllables of couplets and that expressivity ratings were correlated with F0 variability across words. These results demonstrate that naïve raters can successfully rate perceived expression and rhythm in speech [5].

We found no correlation between the rhythmicity and expressivity ratings of the individual couplets. This result demonstrates that expressive speech is not inherently any more or less rhythmic than non-expressive speech. Furthermore, it shows that participants are able to rate speech rhythmicity independently of speech expressivity, disproving an original concern of the study that participants would not be able to differentiate these two features.

Finally, we observed intraverse relationships for both the rhythmicity and expressivity ratings. That is, even after accounting for differences across individual speakers and individual verses, it is still the case that the rhythmicity or expressivity of the first couplet of a verse is significant predictor of the rhythmicity or expressivity of the second couplet. These results are particularly striking as the rhythmicity and expressivity of the first and second couplet of a verse were always rated by different sets of participants. This result suggests that readers of rhythmic texts are consistent in their productions of whole verses, suggesting that readers engage in self-entrainment in both their rhythmicity and expressivity.

It may be the case that, like the adults in the current study, children demonstrate self-entrainment when reading rhythmic prose, and that this process helps improve their rapid auditory processing, leading to improved reading fluency [13]. Follow-up studies will investigate (1) whether children reading *The Cat in the Hat* also show self-entrainment within verses and (2) whether reading overtly rhythmic prose improves children's overall fluency.

5. Conclusions

We have generated a corpus of child-directed speech that varies in its rhythmicity and expressivity. Moreover, we have identified acoustic correlates of these perceptual measures. We have demonstrated that there is no consistency between the rhythmicity and expressivity ratings of individual couplets. However, there is strong intraverse consistency for both rhythmicity and expressivity.

6. Acknowledgements

The authors would like to thank Suyin Taunton and Julia Karron for help with sound file alignment and Molly Morgan and Cam Vilain for assistance with running participants.

Lengthened Consonants are Interpreted as Word-Initial

Abstract

Prosody facilitates listeners' segmentation of the speech stream into a sequence of words and phrases. With regard to speech timing, vowel lengthening is interpreted as a cue to an upcoming boundary, in accordance with the iambic-trochaic law. However, the impact of consonant lengthening on segmentation, in the absence of other boundary cues, has not been tested.

In a series of artificial language learning experiments, we examined how durational variation affects listeners' extraction of novel trisyllables defined by transition probabilities. In line with previous research, syllables containing lengthened vowels were interpreted by listeners as word-final. However, syllables with lengthened onset consonants were interpreted as word-initial. Thus, the structural interpretation of durational variation depends upon localization: longer vowels cue a following boundary; longer consonants cue a preceding boundary.

Index terms: speech timing, speech segmentation

1. Introduction

Variations in suprasegmental dimensions – pitch, duration, loudness – are consistently associated with speech structure at prosodic heads and edges [1]. Firstly, the heads of prosodic domains – stressed syllables and accented words – are more prominent through a combination of higher pitch, greater duration and greater loudness, although the relative contribution of these dimensions is language-specific. Secondly, boundaries between words and between phrases are associated with intonational and durational variation. Boundary-adjacent intonational contours vary between languages [2], but upcoming boundaries may be universally associated with segmental lengthening [1]. Indeed, the slowing of articulation as boundaries approach has been associated with a non-linguistic principle of deceleration at the end of motor sequences [3,4].

It is well established that listeners use suprasegmental variations to segment speech into words and phrases [5,6,7]. Considering specifically speech timing, lengthened vowels are interpreted as word-final in artificial language streams [8]. Similarly, with natural language stimuli, long stressed syllables were more likely to be interpreted as monosyllabic words rather than the start of disyllables (e.g., *ham* vs *hamster* [9]). Additionally, greater magnitude of syllable lengthening is associated by listeners with higher-level phrase or utterance boundaries [7].

Such results are in line with the iambic-trochaic law [10], which proposes that the interpretation of prosodic salience depends on its phonetic realization: in particular, sounds made salient through greater loudness are recognized, other things being equal, as sequence-initial, whilst sounds made salient through lengthening are perceived as final.

Despite English and French differing markedly in the distribution and realization of phrasal prominence, support for the iambic-trochaic law was found with both English and French listeners, and with speech and non-speech sounds [11]. Expanding salience cues to consider also pitch, high-low disyllables were better recalled than low-high; thus, pitch salience, like loudness, is interpreted as sequence-initial [12]. However, considering durational contrast in the same study, recall of disyllabic sequences was better when second syllables had longer vowels compared to when both vowels had similar durations or when first syllables had the longer vowel [12].

For native English-speaking listeners, lengthened syllables promote segmentation of artificial language streams when word-final but not when word-initial [8,13]. In particular, lengthening of vowels in word-initial syllables does not facilitate segmentation for English listeners, despite English having predominantly word-initial stress, associated with segmental lengthening within the syllable, together with pitch excursion, increased loudness and other cues [14]. This raises the question of whether lengthening can only ever serve as a cue to an upcoming boundary rather than a preceding boundary.

Listeners' relative weighting of durational *vs* other cues to prosodic structure (e.g., lexical, segmental, suprasegmental) may be modulated according to language-specific patterns of occurrence [15]. Compared to Dutch, for example, vowel duration in English may be less important for signaling stress than is vowel quality [16, 17]. Additionally, the distribution of lengthening effects within words may serve to disambiguate their different structural interpretations [18, 19]. For example, analysis of a corpus of English speech showed that the distinct patterns of lengthening within words due to lexical stress and word-/phrase-finality appear sufficient to allow listeners to distinguish the two structural interpretations [20]. If so, lengthening could be disambiguated and reliably used as a pre-boundary or stress cue by listeners, even in the absence of additional segmental and suprasegmental cues.

Of course, a full account of the distribution of durational effects associated with prosodic structure must also include consonantal lengthening. In particular, lengthening of consonants in word-initial position is consistently observed in several studied languages. For English, syllable onset consonants are substantially longer when uttered in word-initial position than word-

medially [21], an effect subsequently observed in French, Korean, and Taiwanese [22]. Whilst multiple consonants within the onset may be lengthened, the durational effect does not extend to the vowel nucleus of that syllable [18, 21]. As with lengthening of domain-final vowels, the magnitude of the consonant-lengthening effect increases at higher prosodic boundaries [23, 24], although consonants may be as short in absolute utterance-initial position as when word-medial, perhaps in part because the termination of silence serves as an unambiguous cue to prosodic structure [18].

Several studies have investigated the impact of consonant length, in conjunction with other durational and segmental cues, on word -level segmentation [5, 25, 26, 27]. Typically, these studies have manipulated a within-task contrast between consonants in initial and medial/final position. For example, in segmentally ambiguous phrases like *two lips* vs *tulips* (near-homophonous in American English), a longer consonant in word-initial position (/l/) encouraged cross-modal priming of *lips* [25]. Also for English, word-initial consonant lengthening, together with word-final vowel lengthening and other naturally occurring cues to prosodic boundaries, affected the interpretation of ambiguous sequences such as *paper* vs *pay per* in adults and infants as young as ten months [5, 6].

In Dutch, listeners' interpretation of segmentally ambiguous sequences like *diep in* vs *die pin* was affected by duration of the pivotal consonant, which tended to be interpreted as word-initial when relatively long [26]. Consonant duration affected Italian listeners' judgements regarding both lexical segmentation and identification of geminates *vs* singletons [27], whilst French listeners interpreted longer consonants as more likely to be word-initial than in liaison context (e.g., *dernier oignon* vs *dernier rognon*, [28]). There is also evidence that phrase-initial lengthening and articulatory strengthening affect listeners' interpretation of the structure of ambiguous phrases [29].

All of the foregoing studies suggest that lengthened consonants tend to be interpreted as word-initial by listeners. However, all used natural speech – sometimes resynthesized to manipulate segment durations – with multiple potential cues to word boundaries. In particular, segmental cues, such as boundary-related allophonic variations, and other suprasegmental cues, including lengthening of word-final vowels, were also available to listeners [26]. Furthermore, participants' awareness of the implicit contrast between the two interpretations of near-homophonous sequences (e.g., *two lips* vs *tulips*) might modulate their use of segmentation cues relative to when there is only one lexical solution available.

To address these confounds, we used an artificial language learning paradigm to focus on lengthening of consonants and lengthening of vowels, both separately and together. Listeners have consistently been shown to be able to learn and subsequently recall novel words from a nonsense speech stream when the syllable-to-syllable transition probabilities within words are higher than those between words [8]. Using such a paradigm, with artificial speech streams created through diphone synthesis, we obviate the need to use near-homophonous sequences from natural languages, and eliminate the presence of other potential cues to word boundaries. This allows us to focus precisely on the question: does longer duration increase the tendency for consonants to be interpreted as word-initial?

2. Experiment 1

2.1. Method

Three durational manipulations of two artificial languages were used to determine the impact of consonantal lengthening on segmentation, and thereby on subsequent recall, of statistically-defined words. We predicted that words should be better recalled when word-initial consonants are lengthened during language exposure, relative to when all consonants had the same duration or when word-medial consonants were lengthened.

2.1.1. Participants

We tested 120 native British English speakers, with no reported speech or hearing problems. They were randomly allocated to the three duration conditions (40 in each condition). Within each duration condition, 20 participants were allocated to Stream 1 and 20 to Stream 2. All participants received a small honorarium or course credit for their participation.

2.1.2. Materials

We prepared two different artificial languages, similar to those used in earlier studies [30], each comprising four trisyllabic words (C1V1-C2V2-C3V3).

Stream 1 words: *pabiku, golatu, tinudo, daropi*

Stream 2 words: *tudaro, bikuti, golatu, nudopa*

Six-minute streams containing these words in random sequence were generated using the *en1* male British English voice in the diphone synthesizer MBROLA [31]. Fundamental frequency was a constant 120Hz. To eliminate the strong segmentation cue of hearing silence at the beginning and end of the stream, the streams were faded in and faded out with five-second ramps.

As each word could be followed by any of the other three words, but not by itself, the transition probability between words was always 1/3. As each syllable only occurred once within the language, the transition probability between within-word syllables was always 1.

Total trisyllabic word duration was kept constant at 720ms, whilst the duration of individual segments was manipulated to generate three "lengthening" conditions.

Flat: All segments – vowels and consonants – were 120ms.

C1: The onset consonant of the first syllable of each word (*pabiku* etc.) was 170ms *vs* 110ms for all other segments.

C2: The onset consonant of the second syllable of each word (*pabiku* etc.) was 170ms *vs* 110ms for all other segments.

In the test phase, following exposure to the six-minute stream, isolated words and foils were played to participants. Test-phase foils were constituted of the syllables of the language, either part-words derived from the end of one word and start of another (e.g., Stream 1: *bikuti* from *pabiku tinudo*) or non-words, syllable strings that never occurred in the language (e.g., *tipala*). The words in Stream 1 were part-words in Stream 2 and *vice*

versa. Words and foils for the test phase were synthesized with flat durational profiles (all segments 120ms) in all three conditions.

2.1.3. Procedure

Participants were told they would hear an artificial language through headphones for six minutes, and that their task was to listen and try to discover the words in the language. After the exposure phase, they were given test phase instructions. In the test phase, they heard 24 pairs of trisyllabic strings, where one string was a word in the language stream just heard and the other string was a part-word or non-word. The two trisyllabic strings were separated by 500ms. For each pair, participants had to press the left shift key on a computer keyboard if the artificial language word was the first string of the pair, and the right shift key if it was the second string.

2.1.4. Statistical analysis

All analyses were carried out on the raw response data – "correct" or "incorrect" – using mixed-effects logistic regression models, including the random factors of subjects and trials (*lmer* package in *R*, [32]). Models were compared using log-likelihood χ^2 tests.

2.2. Results and discussion

Mean correct responses by lengthening condition are shown in Figure 1. In the Flat condition, mean correct was 67%, $z = 5.07$, $p < .0001$, replicating previous findings that listeners can recognize words defined by transition probabilities in novel streams of syllables [8]. Above chance performance was also found in the other lengthening conditions: C1 – 73%, $z = 6.12$, $p < .0001$; C2 – 63%, $z = 4.29$, $p < .0001$.

A logistic regression including fixed factors of Lengthening (*Flat vs C1 vs C2*) and Stream (1 *vs* 2) found a main effect of Lengthening, $\chi^2(2) = 11.59$, $p < .005$. There was also a main effect of Stream, $\chi^2(1) = 4.51$, $p < .05$, with words from Stream 1 recalled better than those from Stream 2. There was no interaction between Lengthening and Stream, $\chi^2(5) = 0.11$, $p = .95$. Thus, the advantage of Stream 1 over Stream 2 was consistent across the three lengthening conditions, and so further pairwise analyses were collapsed across streams.

Lengthening of the consonant in the first syllable (C1) improved performance compared to lengthening of the consonant in the second syllable (C2), $\chi^2(1) = 9.93$, $p < .005$, and compared to the Flat condition, $\chi^2(1) = 4.20$, $p < .05$. There was no difference between *C2* vs *Flat*, $\chi^2(1) = 2.15$, $p = .14$. These results indicate that segmentation of the artificial language was promoted by localized lengthening of the word-initial consonant. Thus, consonantal lengthening appeared to cue listeners to the presence of an immediately preceding boundary.

Lengthening of a vowel in a similar artificial language stream has been shown to act as a cue to a following boundary [8]. This suggests a functional difference in listeners' interpretation of vowel and consonant lengthening. An alternative hypothesis is that longer syllables – whether through greater vowel or consonant duration – tend to be perceived as word-edges, which could be either initial or final. This view is not encouraged by findings that vowel lengthening in word-initial syllables failed to facilitate segmentation relative to no lengthening [8]. However, in that experiment, initial syllable vowels were only lengthened in half of the six artificial words. In order to confidently assert our interpretation – that consonant lengthening, in contrast with vowel lengthening, is a cue to a preceding boundary – we attempted a more direct replication of [8] with our artificial language materials, testing the effect on segmentation of lengthening the first syllable vowel in every trisyllabic word.

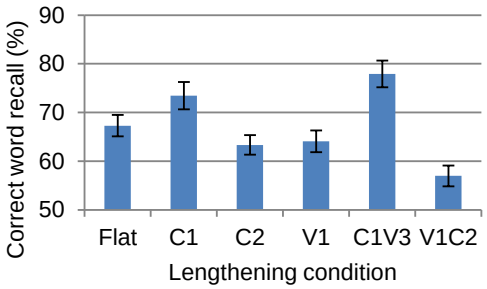

Figure 1: *Mean correct responses and standard errors: Exp1 – Flat, C1, C2; Exp 2 – V1; Exp 3 – C1V3, V1C2.*

3. Experiment 2

3.1. Method

The participants and experimental procedure were as for Experiment 1. However, in Experiment 2, participants heard the artificial language streams with the first vowel of each word lengthened: thus, the underlined vowel in *pabiku* etc. was 170ms vs 110ms for all other segments. This *V1* condition was implemented for both artificial language streams, with 20 participants hearing each one. As before, after exposure to the streams, participants heard 24 pairs of trisyllabic strings – words and foils – with all segments having 120ms duration, and had to choose which string within a pair belonged to the artificial language.

3.2. Results and discussion

Overall mean correct word recognition in the *V1* condition was 64%, reliably above chance, $z = 4.66$, $p < .0001$. To test the hypothesis regarding the localization of durational segmentation cues, the important comparisons are with the *Flat* and *C1* conditions in Experiment 1. Figure 1 shows the mean correct responses for the three critical conditions.

Collapsing, as before, across the two artificial language streams, there was no difference in recognition between the *Flat* and *V1* conditions, $\chi^2(1) = 1.15$, $p = .28$, replicating previous findings that lengthening of the vowel in a word-initial syllable does not serve as a cue to a preceding boundary for English listeners, despite the prevalence of word-initial stress in English [8, 13].

Performance on the *C1* condition was reliably better than the *V1* condition, $\chi^2(1) = 7.57$, $p < .01$. This supports the hypothesis that localization of lengthening is important for segmentation: a lengthened consonant cues a preceding boundary; a lengthened vowel cues a following boundary. In Experiment 3, to explore the power of such cues further, we tested the efficacy of vowel and consonant lengthening in combination. In particular, we examined whether a lengthened vowel

immediately followed by a lengthened consonant was a strong cue to an intervening boundary. We contrasted two cases, one where the lengthened consonant-vowel sequences coincided with the location of boundaries indicated by syllable transition probabilities and the other where the durational and statistical cues conflicted.

4. Experiment 3

4.1. Method

The participants and experimental procedure were as for Experiment 1, but here the duration of the artificial language streams was manipulated in two new conditions. In condition *C1V3*, the first consonant and the final vowel of each word (e.g., *pabiku*) were 160ms, *vs* 100ms for all other segments. In condition *V1C2*, the vowel of the first syllable and the consonant of the second syllable (e.g., *pabiku*) were 160ms, *vs* 100ms for all other segments. This was effectively a composite of the V1 and C2 conditions. Note that the lengthened segments were 160ms and the others 100ms, in contrast with 170ms and 110ms in the other experiments: this was to preserve total word duration at 720ms in all conditions across the three experiments.

4.2. Results and discussion

As shown in Figure 1, performance was reliably above chance in the *C1V3* condition, 78%, $z = 8.15$, $p < .0001$, and the *V1C2* condition, 57%, $z = 2.29$, $p < .05$. However, performance was significantly better in the *C1V3* condition, where the lengthened vowel and consonant straddled a statistically-defined word boundary, $\chi^2(1) = 31.69$, $p < .001$.

Comparison with the earlier experiments showed that performance on *C1V3* was no better than on *C1*, $\chi^2(1) = 1.10$, $p = 0.29$. However, performance on *C1V3* was better than on all other conditions ($p < .001$ in all cases). This may be due to intrinsic performance limitations on this type of language learning task, given the memory component combined with the repeated exposure to words and foils during the 24 two-alternative forced-choice test trials.

Performance in the *V1C2* condition was worse than in all other conditions ($p < .05$ for all comparisons). In this case, the word boundary implied between the lengthened vowel and the subsequent lengthened consonant was incongruent with that defined by transition probabilities. This accords with previous findings that statistically-defined trisyllables that straddled intonationally-defined boundaries in artificial language streams were not well recognized [33].

5. Conclusion

The three experiments demonstrate that segmental lengthening can serve as a cue to both preceding and following prosodic boundaries, depending on its distribution. As shown in Figure 1, performance was best in the two conditions (*C1* and *C1V3*) where the onset consonant of the first syllable in each word was lengthened. The worst performance was in condition *V1C2*, where a lengthened vowel was followed by a lengthened consonant within the same word.

Thus, even in the absence of other segmental and prosodic cues, listeners interpret lengthened consonants to indicate the start of a new word. This suggests that a modification is required to the iambic-trochaic law for spoken language to reflect the perceptual importance of the *locus* of prosodic lengthening effects [18, 19]: lengthened vowels cue a following boundary; lengthened consonants cue a preceding boundary.

The relative importance of timing compared to other boundary cues is not examined here. Natural speech typically provides multiple congruent sources of information about segmentation: when higher-level cues, such as lexicality and syntactic structure, offer an unambiguous guide to structure, acoustic-phonetic cues appear to be minimally exploited by listeners [15].

Our proposal for a functional division between vowels and consonants is congruent with claims that they carry distinct informational loads in speech processing, even for neonates [34, 35]. Language experience is probably required, however, before the development of differential sensitivity to localized durational effects in vowels and consonants. A similar preference for initial pitch-salience to that established in adults has been shown with 7-month-old infants, but no distinction between initial and final length-salience was found at the same age [12], indicating that more linguistic exposure is required before vowel lengthening is associated with a following boundary. The same probably applies for the interpretation of consonant lengthening as a cue to a preceding boundary. It remains to be seen whether this functional distinction holds in languages other than English.

Abstract

Speech communication incorporates non-verbal signals and semi-lexical vocal phenomena as well as words used as the listener's responses to the speaker's message. They are most common in conversation with various functions regardless of language. A specific subcategory is feedback expressions (FEs) that can be found in the listener's production as well as in the current speaker's speech production when reacting to the former speaker's message. This paper reports on the temporal and intonational characteristics of four types of FEs identified in 20 interviews and conversations from the BEA Hungarian database. Altogether 262 occurrences were categorized into four discourse functions signaling 'attention', 'comprehension', 'agreement' and 'other attitude'. Durations showed statistically significant differences across discourse functions. They were significantly longer in females than in males in all functions. The pitch range data revealed a statistically significant difference depending on discourse function and gender only in the case of the 'attention' function. The dominant frequency contour was a rise in the functions of 'attention' and 'agreement' (90%). The same contour was observed only in 75.5% of the 'comprehension' function. An integrated approach is proposed to analyze these phenomena in spontaneous speech.

Index Terms: discourse functions, prosody patterns, speaker–listener interaction

1. Introduction

Verbal communication incorporates verbal and non-verbal signals that interact both in speakers' speech production and in listeners' speech comprehension [1], [2], [3]. Semi-lexical non-verbal phenomena, short sound sequences like *ah, eh, ehm, er, erm, hmm, huh, mm, mmhm, oh, ooh, oops, phew, uh, uh-huh, um,* and even words like *yes, I see, right, okay* occur in conversations underlying cooperation between the participants of the dialogue (e.g., [4], [5]). A specific subcategory can be interpreted as 'feedback expressions' (FEs) that can be found in the listener's production as well as in the speaker's speech production when reacting to the former speaker's message. There are various terms referring to the nature of the listener's reactions like 'listener responses', 'accompaniment signals', 'continuers', 'assessments', 'acknowledgments', 'reactive tokens' (cf. [4], [6]) with meanings similar to that of the most commonly used term 'backchannel'. Backchannels have diverse definitions and descriptions (e.g., [4], [7], [8]). They are produced by one participant (the listener) in a conversation while the other one is talking. They do not cause the other speaker to cede the floor, fail to signal any intention to interrupt the speaker, and are generally non-information seeking phenomena (see [8]). The most widely identified and accepted function of backchannels is to signal attention, i.e. that the listener is attending to the speaker, reassuring the latter about his/her continuous attention [7], [9], [10]. The discourse function of a phenomenon like *uh-huh* notifying the speaker that the listener is listening was defined as early as in 1961 by Trager [11]. In a broader interpretation, however, backchannels may have various other discourse functions (such as signaling recognition, comprehension, emotional state, agreement, disagreement, attitude, support, etc., see [7], [8], [12], [13], [14], [15]), give feedbacks that make verbal communication more accurate or more continuous, and they may either support the mutual agreement between the participants or signal that some problem has arisen between them.

Backchannels signaling attention are reported to be prosodically well-defined in American English dialogues as opposed to affirmative words expressing other pragmatic functions, and the L-H% pattern was found to be characteristic of the analyzed phenomena (e.g., [7]). In addition, these backchannels were longer than affirmative words in other functions and similar to those expressing agreements.

In this paper we use the term 'feedback expression' in order to emphasize that both the listener's and the speaker's multifunctional feedback phenomena are considered in our analysis (see also [16]). In addition, FEs can occur both within turns and at turn-taking points and all of them were nonverbal phenomena.

The purpose of our study was to characterize the temporal and intonation patterns of most frequent types of FEs by measured data in Hungarian spontaneous speech. Our main question was how speakers indicate and listeners interpret the functional variations of FEs in their feedback expressions. We identified FEs as expressions that (i) responded directly to other participants' messages (irrespective of the turn of the participants), and (ii) did not require acknowledgement by the speaker. The FEs could be characterized by the following articulation gestures in most of the cases: (i) voicing emerges from the nasal cavity, potentially accompanied by an [h]-type noise component while the oral cavity is inactive, (ii) an [h]-type consonant-like (mostly voiced) sound is inserted between two low vowels. (In cases where the consonant is replaced by a very short pause, the sequence indicates negation.) In general, both versions sound as disyllabic sequences and are more or less stable in their articulation (although shorter forms might occur). The first version will be indicated by the sequence *mhm* while the second one by *uh-huh*. The articulation gestures described seem to be similar to FEs found in other languages (see 'phonetic components' in non-lexical conversational sounds in [6], [15], [17]). Former studies about some types of FEs in Hungarian supported the claim that the affirmative and interrogative functions can be correctly identified in FE extracted from spontaneous speech [18], [19], and shed light on some of their acoustic properties [20]. The prosodic structures of FEs with various functions were analyzed using experimental settings [18]. The data obtained demonstrated that the three basic types (meaning 'yes', 'no', 'question') differed in their temporal complexity and their melodic patterns. The high proportions of the listeners' correct identifications of their semantic contents confirmed the mutual

interaction between speaker(s) and listener(s). In this study, we address the acoustic patterns that disambiguate the interpretation of the three analyzed types of FEs.

Our main hypothesis was that both the durations and melody patterns of FEs are dependent on their discourse functions (see [7]). We supposed that there would be large gender differences in the various functions of FEs in all measured data.

2. Subjects, material, method

Conversations and interviews of twenty subjects (10 females and 10 males, aged between 20 and 76, mean age: 39 years) from the BEA Hungarian Spontaneous Speech Database [21] were used. All of the participants were native speakers of Hungarian from Budapest. The interviewer was always the same young female speaker (her FEs were not considered in the analysis). The total duration of the recordings was 15.2 hours; 45.7 minutes per recording, on average. All instances of FE produced by the 20 participants (irrespective of their being a listener or a speaker) were marked and labeled together with turn properties in Praat [22] by two of the authors independently of each other. Discourse function was identified by analyzing the semantic context and the speaker–listener interaction. In case of rare disagreement between the authors (below 10%), the third author was consulted. Durations, mean, minimum and maximum values of F0, pitch range (based on voice reports that were corrected manually if it was necessary) as well as the intonational structures were measured. Since a great number of FEs occurred as overlap phenomena, the melody structures could be analyzed only in 68.3% of all instances (the categorization was not problematic even in these cases). The data were subjected to various statistical analyses (one-way ANOVA, Tukey's post hoc test, Mann–Whitney U test, Kruskal–Wallis test as appropriate) using SPSS 15.0.

3. Results

3.1. Discourse functions of FEs

The majority of instances of FEs were categorized according to three main discourse functions while the fourth one contained various other attitudes that occurred in our corpus. (i) The term 'attention' will be used here when the listener signals that s/he is aware of what is being said. This is the function of notifying the speaker that the listener is listening [7]. (ii) The term 'comprehension' will be used when the listener's intention is to reassure the speaker that s/he has understood the message. (iii) The term 'agreement' will be used when the listener obviously agrees with the speaker, supports their ideas. These FEs were frequently accompanied by words like *yes*, *I see*. (iv) The term 'other attitude' serves as an umbrella term referring to phenomena that express attitudes or semantic content other than the former three types (such as surprise, disagreement, etc.). The examples demonstrate how FEs provide information about some hidden cognitive processes of the listener.

(i) Discourse function 'attention':
Interviewer: *én ugye még a régi rendszerben érettségiztem* ('well, I graduated in the old system')
Listening partner: *ühüm* ('mhm' meaning attentiveness)

(ii) Discourse function 'comprehension':
Interviewer: *mesélj egy kicsit arról hogy milyen szakos vagy, illetve hogy mivel akarsz majd későbbiekben foglalkozni* ('tell me about your university subject and about your plans for the future')
Listening partner: *ühüm öö hát én ugye magyar szakra járok* ('mhm /meaning I understand the task/ [*öö* = filled pause] well my main subject is Hungarian')

(iii) Discourse function 'agreement':
Interviewer: *az olvasáshoz hozzátartozik a színház is nyilván és az is ilyen ellenkezéseket szokott kiváltani a diákokból* ('reading is connected with theatre, obviously, and the latter often provokes disagreement from the students')
Listening partner: *aha igen persze ühüm* ('uh-huh, yes, sure, mhm')

(iv) Discourse function 'other attitude':
Interviewer: *az expressz járattal közlekedtem hát öt percenként indult* ('I used buses operating as express routes well that started in every 5 minutes')
Listening partner: *hm* ('hm' expressing surprise)

3.2. Occurrences of FEs

Altogether 262 instances of FEs with various discourse functions were found in our corpus (135 in the conversations, and 127 in the interviews). The mean occurrence of these phenomena was 13.1 per speaker (SD 11.74). Although the majority of the speakers used FEs less than 10 times in their spontaneous utterances (see the histogram in Fig. 1), great individual differences were found among them (from a single instance to 68). 142 of FEs were produced by female speakers while 120 by male speakers. No statistically significant difference was found depending on gender (mean occurrence for females is 14.2 per speaker, SD 11.44 and for males 12.0 per speaker, SD 11.6).

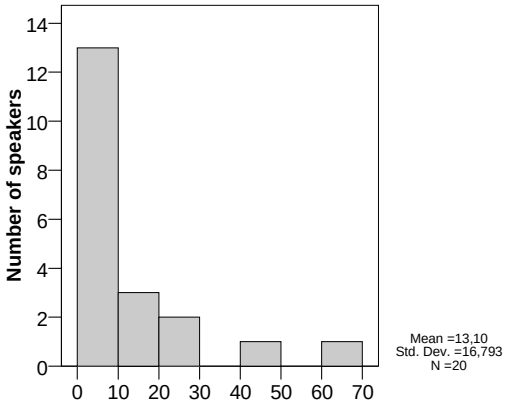

Figure 1: *The instances of tokens (FEs) across speakers (x axis = Frequency of tokens).*

The instances of FEs were heavily dependent on discourse function (Fig. 2). Females preferred FEs in the function of attention and used them more frequently than males did while males produced more instances in the discourse function of 'comprehension' than females did (Fig. 3). Since FEs occurred in the function of 'other attitude' rarely they were not included in our statistical analyses.

As expected, the majority of FEs (n = 130; 49.6% of all) occurred signaling **attention** and were produced both as in-between or overlap phenomena (see [23]), meaning that they were inserted (by the listener) during the speaker's turn in a pause period or they were uttered while the speaker was continuously speaking. The dominant form was *mhm* (90.8%; n = 118); *uh-huh* occurred in 8.5% (n = 11) of the cases and

one instance of *uh-hum* (1.7%) was also found. The latter is supposed to be the blending of the sequences *mhm* and *uh-huh.*

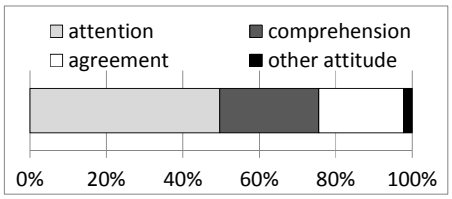

Figure 2: *The proportion of discourse functions of FEs in the corpus.*

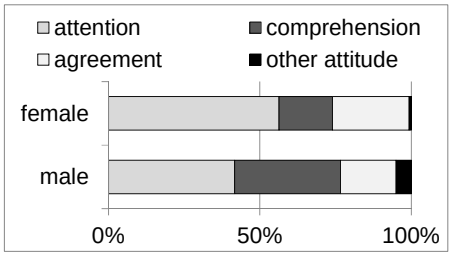

Figure 3: *The proportion of discourse functions of FEs depending on gender in the corpus.*

The discourse function signaling **comprehension** accounted for 25.6% of all instances (n = 67), and a greater variety of forms was used than in the 'attention' function. The type *mhm* was found in 70.1% (n = 47) of all instances in this function, while *uh-huh* occurred in 28.4% (n = 19), and one blended *u-um* form (1.5%) was found here, too. The instances of this function were produced during the speaker's turn in 77.6% of all cases, and 17.9% of them occurred at turn boundaries (Fig. 4).

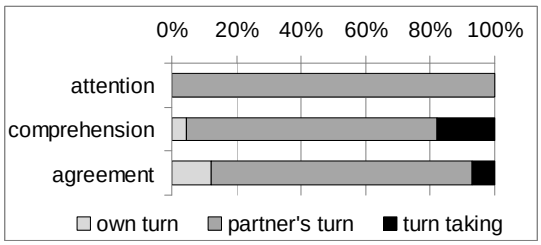

Figure 4: *The proportion of the placements of the three types of FEs.*

The discourse function **'agreement'** occurred in 22.1% of all cases (n = 58). 75.9% of them (n = 44) was identified as *mhm* and 24.1% of them (n = 14) as *uh-huh*. The great majority of the instances in this function (81.0%) were found during the speaker's turn and 6.9% of them occurred at turn boundaries, while some (12.1%) were found in the former listener's own turn.

3.3. Durations of FEs

The interrelations of the discourse functions and their durations are demonstrated in Figure 5. The forms *mhm* are longer (mean 250 ms, SD 56 ms) than those of *uh-huh* (mean 247 ms, SD 55 ms) in the function of 'attention'. The mean duration of *mhm* in the function of 'comprehension' is 289 ms (SD 70 ms) while that of *uh-huh* in the same function is 253 ms (SD 41 ms). The mean duration of *mhm* in the function of 'agreement' is 258 ms (SD 71 ms) while that of *uh-huh* in the same function is 232 ms (SD 63 ms). Instances in the function of 'comprehension' had the longest durations while no large differences were found in the cases of the other two functions. Statistical analysis confirmed a significant difference in the durations of instances depending on discourse function (one-way ANOVA: $F(5, 239) = 3.443$, $p = 0.005$). The Tukey's post hoc test shows, however, that the difference was significant only in the duration of *mhm* forms, and only between the functions of 'attention' and 'comprehension' ($p = 0.004$).

Durations were also analyzed in terms of gender. In this analysis only the *mhm* forms were considered due to the low number occurrences of the other forms. The mean duration of *mhm* in the function of 'attention' was 267 ms in the females (SD 40) and 200 ms in the males (SD 49). In the function 'comprehension' it was 335 ms (SD 42) in females and 262 ms (SD 69) in males, and in the function of 'agreement' it was 291 ms (SD 38) in females and 198 ms (SD 44) in males (Fig. 6). Statistical analysis including Tukey's post hoc test revealed a significant difference in durations of FEs between females and males (one-way ANOVA: $F(5, 196) = 21.011$, $p < 0.001$).

3.4. Pitch ranges and melody contours of FEs

Both the fundamental frequency values and the intonation patterns of all measurable instances of FEs were analyzed. In the discourse function of 'attention' 84 tokens were eligible for analysis in terms of pitch, as well as 49 instances of signals of comprehension, and 40 occurrences of the discourse function of 'agreement'. In other functions altogether 6 tokens were analyzed. The pitch range data are shown in Table 1.

Table 1. *Pitch range values depending on discourse function and gender.*

Discourse functions	Pitch range (semitone)			
	Females		Males	
	Mean	SD	Mean	SD
Attention	4.15	1.48	2.74	1.06
Comprehension	3.54	1.55	3.26	1.16
Agreement	3.48	1.35	3.80	1.67

Statistical analysis confirmed a significant difference in the pitch ranges (Kruskal–Wallis test: $\chi^2(5) = 15.813$, $p = 0.007$) while the Mann–Whitney U test revealed that there was significant difference in pitch ranges depending on gender only in the function of 'attention' ($Z = -4.004$, $p = 0.001$).

The prototypical element of the melody patterns of FEs was, in general, a final rise which was frequently preceded by a fall, a descent or monotonous contour as a preparatory one. Sometimes glottalized syllables occurred preceding the rise (e.g., [4]). 94.0% (n = 79) of all instances in the function of 'attention' ended with a rise (Fig. 7).

A similar rising contour or preparatory contour + rising was characteristic of the function of 'comprehension' in 75.5% (n = 37) of the cases. However, the descent contour was also produced in this function, in 24.5% (n = 12) of all cases. Acoustically, the steepness of these contours was diverse and various complex structures like descent + step up/rise + descent, fall + monotonous, rise + descent were also found.

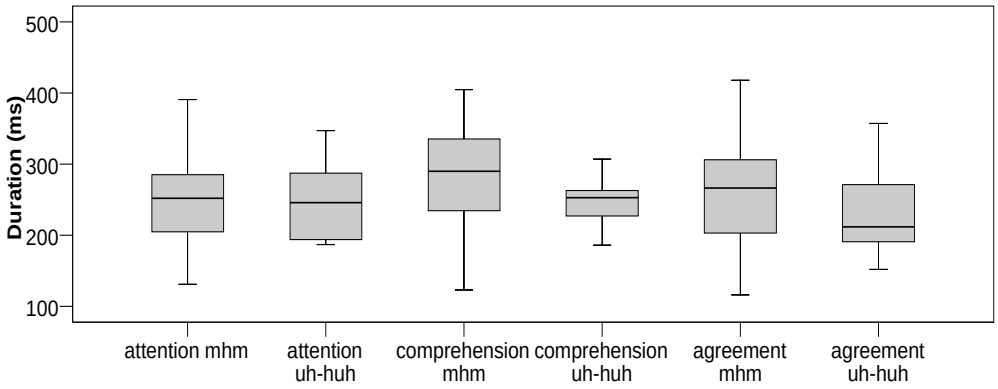

Figure 5: *Durations (medians and ranges) of various forms of FEs in the various discourse functions.*

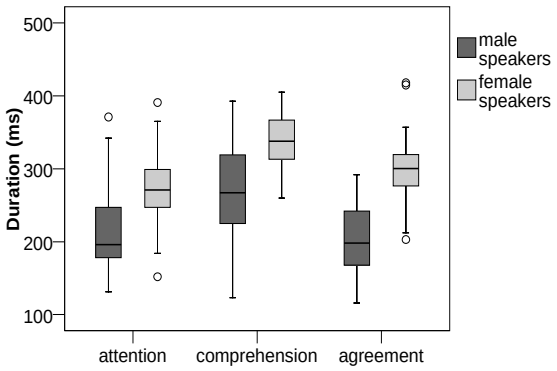

Figure 6: *Durations (medians and ranges) of* mhm *depending on the discourse function and as a function of gender.*

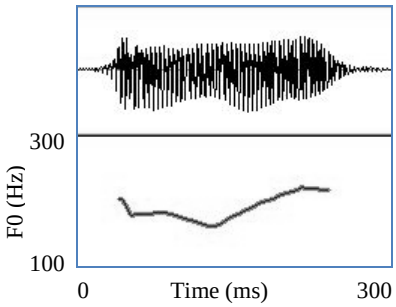

Figure 7: *Prototypical melody pattern of a* mhm *signaling attention.*

In the function of 'agreement', the dominant melody contour was also the rise (92.5%; n = 37), while a small portion (2.5.0%; n = 3) showed intonation structures with no rising contours.

Four instances of the mixed type function expressing surprise and disagreement showed descent melody contours. One token expressing a question had a rising contour while another one expressing 'no' had a monotonous contour.

4. Discussion

In this study we provided measured data on instances of FEs concerning their occurrences, temporal and melody patterns in view of the three main discourse functions they reflect. As expected, listeners felt it to be the most important to notify the speaker about their attentiveness. However, females and males behaved differently: the former used FEs in the function 'attention' more frequently than males did while the latter preferred to signal their comprehension during conversation. Males' frequent signaling of comprehension might be explained by the fact that the interviewer was a female speaker.

The main hypothesis of the research, however, was only partly confirmed. The closest interrelations were found between the durations of the various forms of FEs and their discourse functions, suggesting that speakers seem to differentiate the discourse functions by articulating them differently along the durational scale. In addition, the different forms (*mhm* and *uh-huh*) with different durations depending on function support the listeners' intention to inform the speaker about their attitudes. Females seem to express certainty and reassurance concerning the speaker's message by longer durations of FEs than males do. The non-neutral rising intonation contours of the majority of FEs reinforce the information that the discourse functions convey, while the relatively frequent fall/descent contours signal that the utterance is self-contained and finished (see [24]).

5. Conclusions

Our research findings evidenced speaker and listener interactions in conversations by measured acoustic-phonetic data of FEs with three main discourse functions. The temporal and melody patterns that the speakers produced do not seem to be incidental; however, differences in the actual acoustic patterns could be shown across languages like English, Italian, Japanese, Swedish, and Hungarian [4, 7, 10, 13, 17, 25]. However, identification of a discourse function must take into account various other factors (like gaze direction). We can conclude that analyzing feedback expression phenomena using an integrated approach considering communication situation, participants, contexts, various types of feedbacks, function, and acoustic patterns [e.g., 2, 3, 10] is crucial to fully understand spontaneous conversations.

Intonation Patterns of Morelos Nahuatl

Eduardo Patricio Velázquez Patiño[1]

utka@yahoo.com

Abstract

There are still relatively few studies on the phonetics and phonology of the indigenous languages of Mexico, and just a minority of them deals with less explored areas like prosody or, specifically, intonation. This study reports a preliminary analysis of Nahuatl intonation, taking into account its phonological characteristics: a) trochaic binary rhythm; b) generation of secondary stress inside rhythmic structures; c) generation of rhythmic groups according to clause structures; d) phonetic syllable lengthening at the end of sentences; e) laryngealization or voicelessness at the end of utterances, and f) vowel lengthening. Data collected by means of different methods, developed in order to obtain authentic and spontaneous utterances, show that different sentence types tend to have specific intonation patterns with many typologically common features and some original characteristics.
Index Terms: prosody, intonation, acoustic phonetics, indigenous languages, language documentation, Nahuatl

1. Introduction

Nahuatl is part of the Uto-Aztecan family and its ten dialects are spoken in vast regions of Mexico and Central America. Dialectal differences cause varying levels of intelligibility among speakers. Moreover, there are few monolingual speakers, since the language is rapidly losing ground to Spanish [1]. Here we focus on Morelos Nahuatl. In 2000, Morelos Nahuatl was spoken by 18,700 persons [2]. In the village of Cuentepec, the most dynamic community of all Morelos Nahuatl-speaking villages, there were 3,052 Nahuatl speakers who were older than five years, but only 69 of them were monolinguals [3].

Although classical Nahuatl or Aztec is one of the most documented and studied indigenous languages in the Americas, especially with respect to its polysynthetic morphology, but the phonology of its current dialects, and specifically its prosody, which is usually regarded by non-specialists as 'very simple', has not been studied from the approach of experimental and acoustic phonetics [cfr. 4, 5, 6, 7]. The model presented in this paper takes into account specific features of Nahuatl phonology and how they influence intonation.

2. Previous studies

2.1. Phonological inventory of Morelos Nahuatl

The phonological system of Morelos Nahuatl, specifically the variant spoken in the village of Cuentepec, is shown in Table 1. Phonemes borrowed from Spanish, used in non-assimilated loanwords, are not included. The system has a characteristic absence of voiced stops affricates and fricatives, as well as a squared vowel system. Regarding phonotactics, Table 1 shows consonantal phonemes appearing only in the onset (/h^{w}-/) or coda position (/-ʔ/). Phonetically, short and long vowels differ not only in their length but also in their quality and tension, with short vowels being lower and lax, especially the high front vowel, /i/ → [ɪ], and the back vowel, /o/ → [ɔ ~ ʊ]. However, in spite of the existence of minimal pairs, the vowel length contrast is not robust in the variant of Cuentepec, Morelos, since it tends to be neutralized and subordinated to rhythmic structure and emphatic speech. Moreover, syllables with a glottal stop /ʔ/ or fricative /h/ in coda position, which tend to neutralize, produce a shortening of the vowel's modal portion followed by a glottalization, which is produced as creaky voice or voicelessness. This phenomenon occurs only at the end of an utterance [6]. Other allophonic phenomena not shown in Table 1 are velar stop fronting before a front vowel, /k/ → [c], nasal velarization at the end of a word, /n/ → [ŋ], and devoicing and fricatization of the lateral consonant at the end of a word, /l/ → [ɬ ~ tɬ].

Table 1. Phonological Inventory of Morelos Nahuatl.

	CONSONANTS						
	bilabial	dental	alveolar	palatal	velar	velar-labial	glottal
Stops	p	t			k	k^{w}	(-ʔ)
Affricates		t͡s	t͡ɬ	t͡ʃ			
Fricatives		s		ʃ		(h^{w}-)	h
Nasals	m	n					
Lateral			l				
Approximants				j		w	
	VOWELS						
				iː i		o oː	
				eː e		a aː	

2.2. Syllable structure

Nahuatl syllable structure has been traditionally (e.g. [8]) said to allow four possible syllable patterns, which are derived from the generic pattern (C)V(C), i.e. V, CV, VC, and CVC. Allegedly, there are no consonant or vowel clusters inside a single syllable (dipthongs are regarded as CV or VC structures), and a syllable is composed at most of three phonemes. However, in Cuentepec Nahuatl there is evidence of CGVC (e.g. [ˈtjaŋ.kɪs] 'market') and CVGC (e.g. [k^{w}ejtɬ]'skirt') structures. Last but not least, lexical stress functions as a culminative, hierarchical, delimitative and rhythmic unit [9], falling regularly on the penultimate syllable.

Typologically, Nahuatl has a polysynthetic structure with the possibility of the object and even some modifiers being incorporated to the verb root. Structures above five or six syllables are not the most frequent, but they are not unusual either. In such words secondary stress is found. According to Kager's classification [9], these synthetic structures in Morelos Nahuatl are typical of a bound or limited system,

which is also non-sensitive to quantity, and it assigns stress from right to left, producing left-oriented, i.e. trochaic feet:

[nik.ˌkʷah.kʷal.ˌt͡ɬaʃ.kal.ˈma.ka] (1)
/ni-k-kʷaːhkʷal-t͡ɬaʃkal-maka/
1SG.SUJ-3SG.OBJ-beautiful-tortilla-give.PRES
'I give him/her beautiful tortillas.'

All three acoustic correlates (intensity, duration, and fundamental frequency or F_0) signal, to a greater or lesser extent, the location and prominence level of primary stress, secondary stress, and lexical stress throughout the sentence. As such, the only constant acoustic correlate of stress is F_0 [6].

2.3. Influence of stress and length on vowel quality

In a previous study [10] a young male speaker of Morelos Nahuatl was asked to read and record a series of sentences. From this recording, we obtained 542 vowel tokens (including 246 short vowels, and 296 long vowels, in both stressed and unstressed syllables), after eliminating every observation in unclear contexts, adjacent to a semivowel, or before any sonorant consonant. Values for the three first formants were calculated using a Praat script [11]. The values were obtained from the most stable portion of every vowel. F2' [12] was calculated from the F2 and F3 values (see Table 2, Figure 1).

Table 2. Formant values of Nahuatl vowels.

Stress	Length	#	$\overline{F_1}$	$Q_{F1}(0.1)$	$Q_{F1}(0.9)$	$\overline{F_2'}$	$Q_{F2'}(0.1)$	$Q_{F2'}(0.9)$
-	a	17	594	501	658	1640	1434	1774
	aː	24	702	651	758	1703	1529	1790
+	a	76	669	566	734	1739	1592	1893
	aː	60	721	669	788	1733	1573	1846
-	e	24	503	428	582	1918	1782	2049
	eː	22	535	495	573	2095	1957	2174
+	e	30	520	452	586	2072	1916	2243
	eː	33	536	474	586	2068	1844	2207
-	i	29	376	259	455	2283	2018	2539
	iː	70	313	279	358	2462	2253	2641
+	i	21	316	286	350	2392	2315	2500
	iː	20	321	311	331	2553	2416	2707
-	o	26	473	383	540	1476	1341	1627
	oː	15	515	493	546	1398	1335	1479
+	o	23	559	484	629	1459	1340	1604
	oː	52	582	521	635	1409	1308	1511

In Table 2, the resulting data are presented according to their timbre, presence or absence of stress, and length. The next column indicates the number of occurrences (#) for each vowel category, their mean values, as well as the 0.1 and 0.9 quantiles inside every category for F_1 and F_2'. These latter values were used to plot ellipses with the most stable 80% of the occorrences of all four vowel extreme values.

In Figure 1, we observe that long vowels (depicted with dashed lines) are better delimited, since they occupy a smaller acoustic space; their spaces between stressed (black line) and unstressed (gray line) vowels intersect to a lesser or greater extent, and the different vowel timbres are clearly differentiated. Meanwhile, short vowels (depicted with solid lines) occupy larger acoustic spaces, where short unstressed /i/ covers a vast space towards /e/, whereas short unstressed /o/ and /a/ tend to occupy higher spaces, causing /a/ to intersect large areas occupied by phonological /o/. The Nahuatl vowel system is thus square, not triangular.

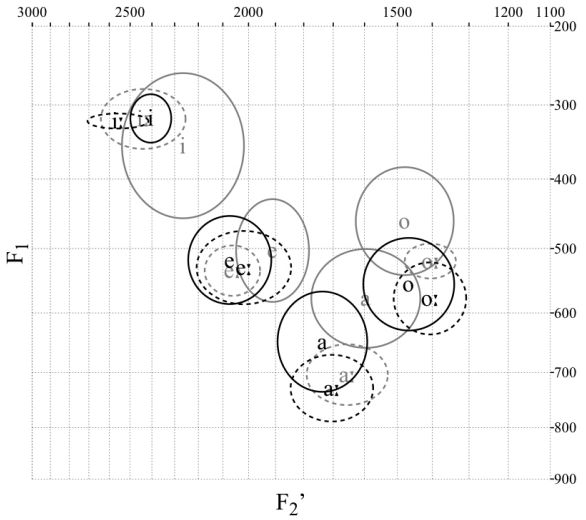

Figure 1: Distribution of Nahuatl vowels.
(Black line = stressed vowel, gray line= unstressed vowel, solid line= short vowel, dashed line= long vowel)

2.4. Tones and break indices (ToBI)

For this study, we use the ToBI (Tones and Break Indices) prosodic transcription system, based on the autosegmental-metrical model or AM [13, 14, 15, 16, 17, among others]. In this transcription sstem, F_0 contours are analyzed as a sequence of local pitch variations based on the metrical structure of sentences. As such, there are two types of phonological elements: *pitch accents*, associated with lexically stressed syllables coinciding with nuclei of syntactic clauses, and *boundary tones*, associated with the borders of prosodic domains. There are just two basic tones: *L* (low tone) and *H* (high tone), which are combined thoughout the utterance.

3. Data Elicitation

For the macro-project on the prosodic analysis of Nahuatl, within which the present investigation is placed, we have taken into account the elicitation techniques used in other projects, such as the Atlas interactivo de la entonación del español [18] the HCRC Map Task Corpus [19], and the CHILDES Project [20]. We have developed a whole series of methods and materials in order to elicit close-to-natural intonation. These materials include interviews, map tasks, narratives, and communicative situations. We have used these materials to obtain data from a number of Nahuatl varieties, including those spoken in Morelos, Guerrero, Huasteca Veracruzana and Sierra de Zongolica. This paper focuses exclusively on the results obtained for Morelos Nahuatl.

3.1. Interviews

The topics presented during interviews are previously prepared, but also improvised in order to help the native speaker talk about his/her life experiences and interests, such as life stories, descriptions of his/her work or trade, daily life, family, community, as well as folk stories, tales or legends. Ideally, the recordings should be more like a conversation than an interview, and performed by another native speaker. They yield mostly declarative sentences.

3.2. Map Task

Another elicitation technique that we have employed is the one known as 'Map Task' [19]. This is a cooperative task between two native speakers performing different roles: the instruction giver and the instruction follower. The instruction giver gives instructions about a path to be followed through a village map in order to arrive somewhere, and the other participant follows those instructions, trying to trace the route. However, the maps are slightly different, and both participants have to figure out how to navigate through them successfully [19, 21]. This method yields declaratives, interrogatives, and imperatives.

3.3. Narrative

In order to elicit narratives, booklets were created with image sequences depicting a story. However, this technique was not always successful for this purpose, as illiterate participants described individual images in detail instead of producing a narrative. This situation yielded mostly declaratives, but also other types of sentences.

3.4. Communicative situations

The researcher read aloud 75 common situations, intended to elicit different types of sentences as a response: declaratives, (absolute, partial, and reiterated) interrogatives, imperatives, and vocatives. For each main type of sentence, neutral and non-neutral variants were elicited. Native speaker participants were asked to act out a sentence, or to interact in a close-to-natural way, according to the given situation (see Figure 2). The questionnaire was not just translated [18, 22, 23], but also culturally and thematically adapted in order to create topics and characters, which would appear familiar to native speakers of Nahuatl. Sometimes, a Spanish version was used and adapted on the fly in order to obtain different answers.

Figure 2: *Sample from the 'Communicative Situations' task.* (4a. Look at this image and tell me what they are doing. [Possible answer:] –A woman is giving water to her son.)

4. Methodology

For this study, three native speakers of Morelos Nahuatl, one man and two women from the community of Cuentepec, were selected for the *Communicative Situations Questionnaire*. They were asked to answer every question three times. Four different speakers were also selected for the Map Task, the narratives and the interviews, in order to provide complementary data.

All linguistic productions were recorded in audio as stereo WAV files with an Olympus LS-11 recorder at a 44.1MHz sample rate, and in video as a backup. The questionnaire was recorded in a soundproof room at the Universidad Autónoma de Querétaro, Mexico, while the complementary data were recorded in quiet spaces in Cuentepec. The resulting audio files were edited in Audacity, and then segmented, transcribed and prepared in Praat [24, 25].

5. Results

Figure 3 shows a sample image obtained by means of superposing all three utterances of the male speaker, corresponding to three superposed emissions of a partial interrogative sentence, with a H% [H*+H] [H*] [h* H*] LH% pattern, where brackets show the domain of phrasal structures.

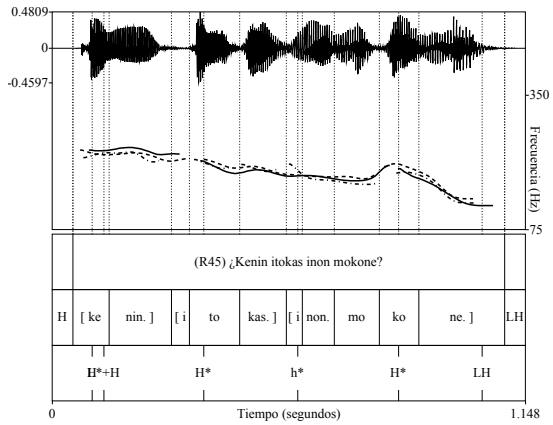

Figure 3: *Three emissions of the same partial interrogative sentence.* ('How will you name your child?')

The results obtained from the quantitative and qualitative analysis of all sentences in a given category, their pitch accents and their simplified global contours were mapped on to the stylized contours shown in Figure 4. For the sake of simplicity, secondary stress pitch accents (notated with lower case h* in Figure 3) are not depicted here, since they show the same inventory as is used for primary stress, and the difference between primary and secondary accents is just relative and contextual. On the other hand, H* differs from * in that H* is a perceptually clear F_0 peak (over +1.5 semitones), while * is not so easily perceivable, because its F_0 is under 1.5 st, relative to its surrounding syllables. Parentheses and slashes show second-best alternative pitch accents (also depicted with a thinner line), which correspond mostly to local emphasis.

5.1. Declaratives

Neutral declaratives (A.1. in Figure 4) have by far the simplest contours: low initial and final boundary tones (L%) and unperceivable nuclear and prenuclear stresses (*) or, alternatively, peaks within the stressed syllable domains (H*). Non-neutral declaratives (A.2.) differ from neutral ones in that the initial and final accents are early rises (L+H*). Their final boundary might be a fall or a steep fall (L% or LL%).

5.2. Absolute interrogatives

Both neutral (B.1. in Figure 4) and non-neutral (B.2.) absolute interrogatives have a low nuclear accent followed by a rise to a level tone (L* HL%). However, neutral ones have a high initial boundary tone followed by a low/falling tone, while non-neutral ones have a similar contour with respect to non-neutral declaratives, except for the nuclear pitch accent and final boundary tones (L+H* L% vs. L* HL%, which is a low tone followed by a steep rise that ends at a mid/neutral level).

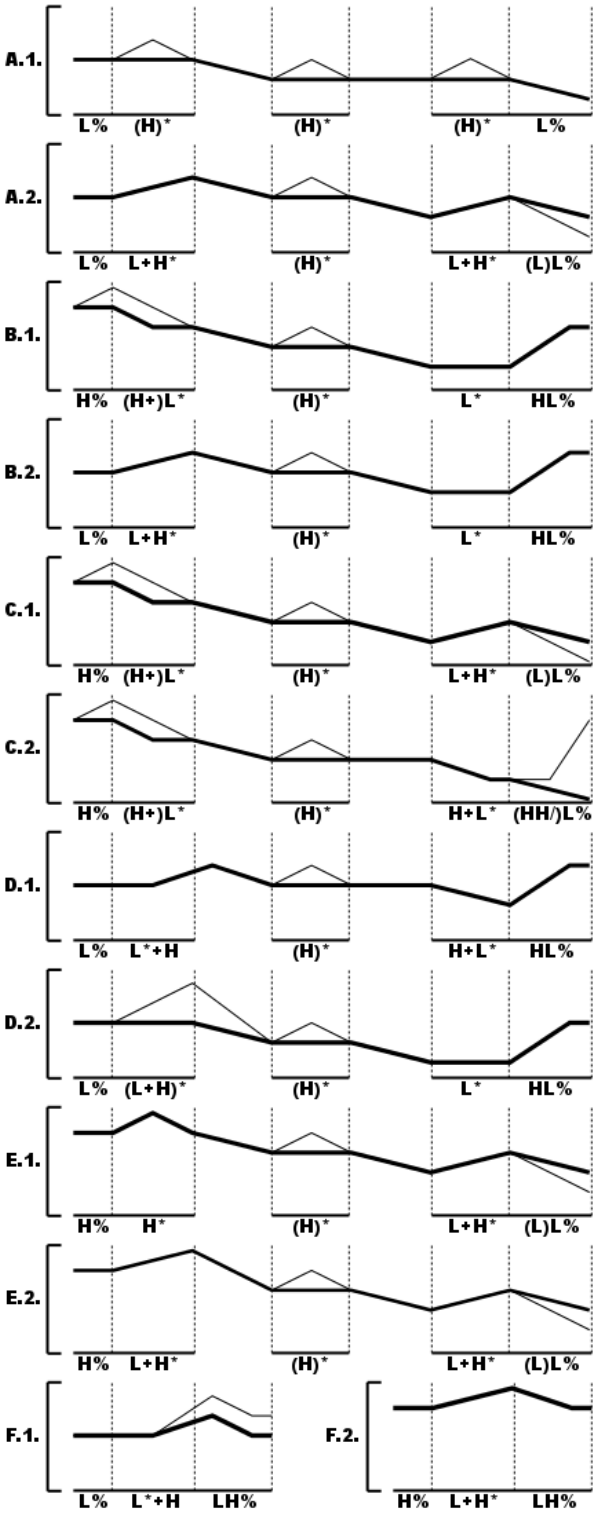

Figure 4: *Intonation Patterns of Morelos Nahuatl.*

5.3. Partial interrogatives

Partial interrogatives, both neutral (C.1. in Figure 4) and non-neutral (C.2.), have the same contours as neutral absolute interrogatives (H% L* or H% H+L*), but they have different nuclear pitch accents: neutral ones resemble non-neutral declaratives (A.2.) and non-neutral ones have a falling tone (H+L*) followed by totally different contours: a fall or a steep rise, L% vs. HH% (maybe due to pragmatic factors).

5.4. Reiterated interrogatives

Neutral (D.1.) and non-neutral (D.2.) reiterated interrogatives have a characteristic low initial boundary tone, and a rising to level final boundary tone. They differ only in the first prenuclear tone (L*+H vs. * or L+H*), and the nuclear tone (H+L* vs. L*).

5.5. Imperatives

Imperatives, both commands (E.1.) and pleas (E.2.), begin with high tones, and end with nuclear early rises followed by low/extra low final tones (L+H* L% / LL%). Their prenuclear accents differ in peak alignment (H* vs. L+H*).

5.6. Vocatives

Vocatives have falling to level final tones (LH%), but they have different initial tones, L% vs. H% for calls (F.1. in Figure 4) and phrase-edge vocatives (F.2.), respectively, and nuclear F_0 peak alignments (L*+H vs. L+H*), where calls have a deeper pitch range.

6. Conclusions

We propose a combinatorial model made up of isolated tones, which also takes into account the trochaic binary rhythm of Nahuatl, and its automatic generation of secondary stress inside rhythmic structures according to phrasal (clause) structures, as shown in Figure 5. So far, we have identified slightly different intonation contours for each of the main pragmatically neutral sentence types, where neutrality is mainly expressed by means of simpler or less salient tones. The combinatorial model in Figure 5 must be taken as provisional and subject to revision based on the results of further data collection and analysis.

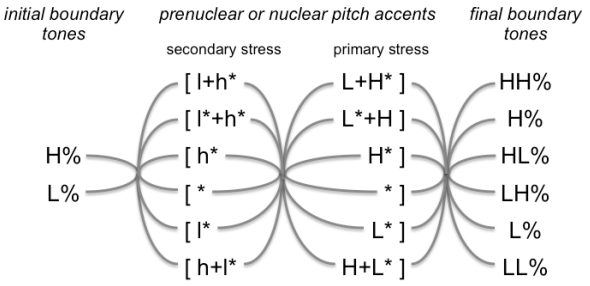

Figure 5: *Tone combinations in Morelos Nahuatl.*

Abstract

In this paper, we study the intonational patterns observed in learners' productions in order to evaluate what motivates the deviations observed: systemic differences between the learners' L1 and the L2, differences in phonetic implementation, etc. The analysis consists of a cross-comparison of the intonation of yes-no questions in French, English and English as an L2. It is based on five information-seeking yes-no questions that were extracted from the AixOx corpus, which contains a set of 40 texts that were read by 10 native French speakers, 10 Native English speakers and 20 French learners of English. The analysis of the data showed that the differences between native and non-native speakers do not affect the form of the nuclear contour. It mostly shows that French speakers of English have a tendency to assign a rising pitch movement at the end of any prosodic words, which leads to a clear difference in rhythm.

Index Terms: acquisition of prosody in L2, intonation, prosodic phrasing, rhythm, prosodic modelling, learner corpora, interphonologies.

1. Introduction

Research on interlanguage intonation has shown that the intonational patterns observed in learners' productions are often influenced by their L1s (see, among others, [1], [2] and [3]). As a consequence, the notion of L1 transfer is often invoked to account for the observed patterns. As pointed by [4], however, transfer may apply at the phonological as well as at the phonetic level. Transfers at the phonological level result from differences in the metrical structure or the tonal inventory. In a study on the intonation of tag questions in English, [5] have shown for instance that Spanish speakers of English use rises at the end of the question tag for confirmation request, whereas native English speakers will use falls, these patterns being thus analyzed as resulting from a phonological transfer. By contrast, transfers at the phonetic level occur when an identical phonological form differs in the way it is phonetically implemented in both languages. Differences in the temporal alignment of pitch accents may be for instance a case of phonetic transfer (see [1] for concrete examples). The distinction between different types of transfers or deviations is of great help to study interlanguage intonation, as pointed by [6].

In this paper, we will show however that classifying the observed deviations is not an easy task since the deviation type may change over time, and a mere cross-comparison of the surface forms may not always be sufficient. This will be done through the analysis of information-seeking *yes-no* questions realized by French learners of English and extracted from the AixOx corpus ([7] and [8]).

The paper is organized as follows: in section 2, the prosodic characteristics of information-seeking *yes-no* questions in French and English are described; section 3 presents the data and methodology used for the prosodic analysis; the results obtained in the cross-comparison are given in section 4; section 5 discusses the results and offers perspectives and concluding remarks.

2. The intonation of *yes-no* questions

2.1. Yes-no questions in French

From a morpho-syntactic point of view, three distinct constructions may be used in French to build up a *yes-no question*: (i) declarative structures similar to the ones observed in assertive sentences (1); (ii) subject-object inversion, be the subject nominal or pronominal (2); and (iii) an interrogative particle *est-ce que* can be inserted in sentence initial position, the rest of the sentence having the same syntactic structure as in assertions (3).

(1) *Vous avez appris des langues étrangères ?* ('Did you learn any foreign languages?')
(2) *Pierre est-il venu ?* ('Did Pierre come?')
(3) *Est-ce que c'est vrai?* ('Is that true?')

As far as intonation is concerned, rising tones are seen as the canonical form associated with declarative questions (see, among others, [9] and [10]). By contrast, in *yes-no* questions in which the modality of the utterance is indicated by a morpho-syntactic or a lexical marker (subject-verb inversion or *est-ce que* particle respectively), non-rising tunes may be used on a par with rising ones (see, amongst others, [9], [11] and [12]). Note, however, that the rising tune is by far the most frequently used in information-seeking *yes-no* questions, regardless of the construction (see, amongst others, [13]).

2.2. *Yes-no* questions in English

Contrary to French, in English information-seeking *yes-no* questions, the modality of the utterance is always indicated by morpho-syntactic means: either by subject/auxiliary inversion (4), or by the use of auxiliary *do* (5).

(4) *Is Peter coming?* (*vs. Peter is coming.*)
(5) *Does he live in Paris?* (*vs. He lives in Paris.*)

Declarative questions can be found in English, but they are usually echo-questions, which are not present in our corpus.

As opposed to *wh*-questions, for which the default tone is a fall in English, *yes-no* questions are uttered with a rising tone, even if a falling tone can also be heard, but less frequently (see amongst others [14], [15] and [16]).

3. Corpus and method

3.1. Corpus

3.1.1. The AixOx corpus

The AixOx corpus ([7], [8]) is a multilingual learner corpus which consists of recordings of 40 1-minute passages in English and French read by native speakers and L2 learners (all aged 20-35, see [8] for details about the informants). The passages were extracted from the Eurom 1 corpus ([17]). Non-native speakers were divided into two groups, B and C, according to their level of proficiency in the Common European Framework of Reference for Languages (CEFR). Learners of group B are independent users, B1/B2 in the CEFR and learners of group C are proficient users, C1/C2. Hence the corpus is composed of 6 groups of speakers, as shown in table 1 below. For each group, 10 speakers were recorded (5 females and 5 males), the corpus thus amounting to 60 speakers and about 30 hours of speech.

Table 1. *Speaker groups in AixOx.*

Language of recording	Native speakers	L2 learners B1/B2	L2 learners C1/C2
English	ENEN	FRENB	FRENC
French	FRFR	ENFRB	ENFRC

3.1.2. The extracted questions

Before extracting the questions on which the study is based, we had to take a few facts into account:

- The English and French corpora are not word-to-word translations, even if they are very close, since the pragmatic contexts in which the texts are uttered are similar; hence the English corpus contains 23 questions when the French one contains 22.
- *Yes-no* and *wh*-questions are present in the corpus.
- For the total questions, the French corpus includes different types of constructions, whereas yes-no questions in the English corpus all display subject/auxiliary inversion. In order to compare the data, only questions with an interrogative marker have been taken into account in the present study.
- Some yes-no questions in both languages are not neutral questions since they may be rhetorical questions addressed to oneself (‘*What will 1992 really mean to the person in the street?’*), disguised orders (‘*Can you give me a firm date now?*’) or have the meaning of partial questions (‘*Can you tell me what’s on television tonight?’*).

In order to make a cross-comparison between *yes-no* questions, we took into account the same types of questions, both on the syntactic and pragmatic levels. We therefore concentrated on 5 information seeking *yes-no* questions, in which the modality of the utterance is indicated by morpho-syntactic means. They are listed below (the English and French questions are not necessarily translations, since some of the French questions have been disregarded because of their declarative structure):

- French questions

F1 : Est-ce que vous pourriez me donner leur nouveau numéro de téléphone ?
F2 : Est-ce que c'est vrai ?
F3: Est-ce que vous pourriez me donner la liste des restaurants de mon quartier ?
F4 : Est-ce que vous avez des tarifs spéciaux pour les collectivités ?
F5 : Est-ce qu'un organisme universitaire peut en bénéficier ?

- English questions

E1 Can you give me their new number please?
E2: Could you please tell me the best connections to Sheffield from East Greenstead?
E3: Do you take reservations by telephone?
E4: Can you give me a list of the restaurants in the neighbourhood?
E5: Do you have special corporate academic institutions?

We therefore studied 5 questions uttered by 30 speakers (10 in the three groups – natives and learners from groups B and C - for the 2 languages) in the two languages, the corpus thus amounting to 300 sentences.

3.2. Method for the prosodic analysis

In order to compare the intonation of the extracted questions uttered by the native speakers and by the B and C learners, we used two distinct approaches to encode the tones observed in the various utterances: a perceptual approach, and a semi-automatic approach.

3.2.1. The perceptual approach

Following [18] and the British tradition, the perceptual analysis relies for English on tonality (the division into intonation phrases), tonicity (the place of nuclear syllables) and tones (the distinctive pitch movements).

We consider, following [19], that there is only one level of boundary, associated with the intonation phrase (IP). In short questions, one IP will be realized but longer questions like *Could you please tell me the best connections to Sheffield from East Greenstead?* can be divided into 2 IPs by the natives, and even more by the learners. The IP boundaries are marked by a slash in the paper.

The place of the tonic syllable, the nucleus, is looked at. The principle that there is only one nuclear syllable in an IP is adopted. It is the most prominent one, that bearing the tone (the distinctive pitch movement) of the IP (see for example [20] or [21]). The nuclear syllable is underlined in the given examples.

Finally, the tones are encoded. The tone is the distinctive pitch-movement, that bearing on or starting on the nucleus and extending on the post nuclear syllables (if any). The symbols used are F for a simple fall, R for a simple rise, HF for high fall and FR for fall-rise, again according to the British tradition but with a limited tone inventory, following [22] and [23].

The questions are therefore encoded as follows in (6), (7) and (8), respectively a native speaker, a learner from group B and a learner from group C:
(6) *Can you give me their new <u>num</u>ber, please F /*
(7) *Can you give <u>me</u> F / their <u>new</u> number, please FR /*
(8) *Can you give me their new num<u>ber</u>, please R /*

So as to allow cross-comparison, the French questions were encoded in the same way, as shown in examples (9), (10) and (11), respectively a native speaker and learners from groups B and C. The global contour of the IP was taken into consideration in our study, and not the contours of the accentual phrases.
(9) *Est-ce que vous pourriez me donner leur nouveau numéro de télé<u>phone</u> R /*

(10) *Est-ce que vous pourriez me donner F / leur nouveau numéro de téléphone R /*
(11) *Est-ce que vous pourriez me donner leur nouveau numéro de téléphone R /*

3.2.2. The semi-automatic approach

A semi-automatic approach was also performed. The questions studied were extracted under PRAAT [24], automatically aligned into words with SPPAS [25] and manually labelled into syllables. The SAMPA phonological representation of our syllabification is: k@n / ju / gIv / mi / @ / lIst / @v / D@ / rEst / rQnts / In / D@ / neIb / @ / hUd. The syllable tier of the annotation was used for automatic extractions of acoustic parameters using ProsodyPro [26].

3.3. Revisiting the intonation of English yes-no questions

The first result we obtain concerns the intonation produced by native speakers. Table 2 below shows the results of the perceptual analysis: only the global contours (on the final IP), *i.e.* Falling (F and HF) or Rising (R and FR) of the questions studied are reflected in the table:

Table 2. *Contours for ENEN and FRFR questions*

Questions	English natives	French natives
E1/F 1	F 80%	R 100%
E2/F 2	F 100%	R 90%
E3/F 3	R 70%	F60%
E4/F 4	F 60%	R 90%
E5/F 5	F 80%	R 80%
Total	**F 70%**	**R 80%**

The table clearly shows, contrary to what the literature claims, that the rising tone is not the most frequent for information-seeking *yes-no* questions in English: 70% of the 50 English questions under scrutiny are uttered with a falling tone. For French, our data confirm that the rising tone is the default tone for *yes-no* questions.

3.4. The intonation of learners: global contour and phrasing

Table 3 gives the results for the French learners of English:

Table 3. *Contours for FRENB and FRENC questions*

Questions	FRENB	FRENC
E1	R 90%	R 60%
E2	R 80%	R 70%
E3	R 90%	R 60%
E4	R 80%	F 60%
E5	R 90%	R 80%
Total	**R 86%**	**R 66%**

The learners of both groups massively pronounce the questions on a rising tone, as in their mother tongue, but the tendency is less strong for the proficient group: 44% of the questions are uttered with a fall, which is quite a lot compared to the tendency for the native English speakers.

But the global contour is not the most relevant feature for proficiency. The phrasing is probably the most salient difference between the independent (group B) and the proficient (group C) learners. The independent learners tend to paste the French phrasing to the English sentence: they produce a pitch movement at the end of word groups which would correspond to accentual phrases in French, as exemplified in (12) and (13):

(12) *Can you give me a list R / of the restaurants R / in the neighbourhood R /*
(13) *Could you please R / tell me R / the best connections R / to Sheffield R / from East Greenstead R /*

A clear evolution can be noted for the proficient learners, who no longer group words as in French, but, as a few native speakers do so too, divide E4 in 2 IPs for 8 speakers out of 10 (3 IPs for 1 speaker and 1 IP for 1 speaker) and E2 in 2 IPs for 100% of the speakers, as in the occurrences below:
(14) *Can you give me a list of the restaurants F / in the neighbourhood F /*
(15) *Could you please tell me the best connections to Sheffield F / from East Greenstead R /*

3.5. Multi-speaker modelling

With the semi-automatic approach, it is possible to visualize and compare the curves for the natives and the learners using R [27], as is shown in figure 1below for question E4:

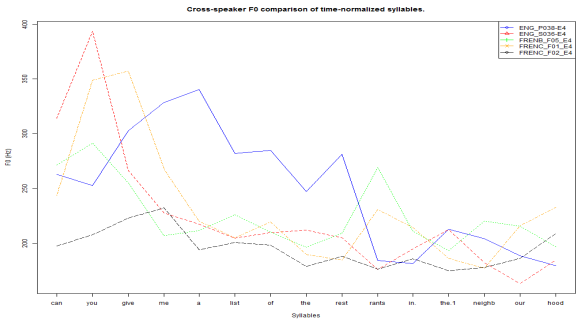

Figure 1. *Comparison between two natives, two C learners and one B learner*

For clarity's sake, the number of speakers represented has been limited and only female speakers have been taken into account in Figure 1. In addition, one should be made particularly aware that the curvature does not represent F0 variation *per se*, but the statistical software interpolations between the points representing the means estimated for each syllable. ProsodyPro offers a finer-grained representation, which is based on 10 successive measures of pitch over the same syllable. This corresponds to a kind of time normalization: the duration of each syllable might be different from one speaker to another, but each tenth of a syllable duration can be compared across speakers.

The nuclear syllables are easily identifiable on the curves. Figure 1 shows that for one native a pitch movement occurs on *RESTaurants* (the blue curve). For one FRENC learner, a peak is also clearly visible on *RESTaurants* (blackline), but the prenuclear part of the curves is quite different from those of the natives. As for the other C learner (yellow curve) and the B learner (green curve), a pitch movement also occurs on the word *restaurant*, but we see that the peaks have moved right, on the final syllable of *restauRANTS*. It is to be noted that the natives and the learners of group C pronounce *restaurants* with 2 syllables while many learners of group B pronounce 3 syllables as in French. The non compression of the median

syllable and the stress shift on the right are typical of a French learner's pronunciation. A closer look at the curves also confirms the perceptual impression that pitch movements take place on words preceding *restaurants*. The pitch contour in Figure 2 is representative of that tendency: peaks on *me* and *list* appear.

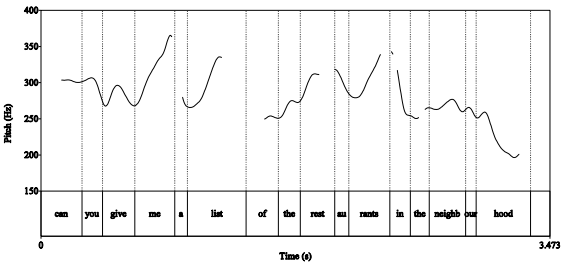

Figure 2: *Pitch track of E4 uttered by a B learner*

4. Discussion and conclusion

With the automatic procedure, cross-sectional comparisons are established on the basis of normalized duration, so that performances are equally considered on the basis of the prosodic target (here, pitch) for each syllable. In that sense, the semi-automatic procedure consists in discourse alignment, not in time-alignment, allowing prosodic realizations to be compared. This simplifies speech time variability and enables the design of "confidence intervals" for native prosodic realizations and potential non-native mismatches. A tentative representation of this modelling lies in the graphing and statistical representation, using R once more. Due to space limitation, we do not include the corresponding boxplot, but annotation at the word level is not so telling and syllable-based analysis is much more convincing. This semi-automatic approach paves the way for the characterization of learner profiles and their interaction with criterial features [28]. We give a rough outline of some of the interlanguage stages that can be detected with this kind of approach. Figures 3, 4 and 5 represent the boxplots synthesizing inter-speaker variation of mean fundamental frequency (computed for each syllable) for E4 realized by respectively the female natives, some of the female learners from group B and from group C. In the figures, the small rectangles show that the dispersion is limited and that there is a consensus on the prominence of the syllable. The large rectangles on the contrary point to a larger variation, *i.e.* some sort of non-consensus. The median (central line in bold) allows the visualization of the melody. If we first compare the median on the three figures, we clearly see that the natives (figure 3) divide the sentence into 2 IPs and favour a falling pattern on the first IP (on *RESTaurants*) and a rising one on the second (*NEIGHBourhood*); learners from group C (figure 4) also divide the sentence into 2 IPs, with similar nuclei as the natives, but realize a rise on both IPs; the less advanced B learners (figure 5) divide the sentence into what corresponds to the French phrasing with rising movements on *me*, *list, restauRANTS* and *neighbourHOOD,* followed by an F0 resetting after the first three words. If we now look at the rectangles, a large dispersion noticeably appears in figures 3 and 4 on tool words like *you*, *me*, *a* and *of*, which are far less important prosodically, as opposed to the stressed syllables of *restaurants* or *neighbourhood* for example, which display small rectangles (in figure 4 even more strikingly): the natives and the C learners therefore show strong agreement as to which syllable they should make prominent. The prenuclear contour, however, is still somewhat hesitant for the C learners (the dispersion is very high on *you* and *give*). Finally, the rectangles for B learners (figure 5) show much less difference in the dispersion, this reflecting isosyllabic realizations, typical of French rhythm.

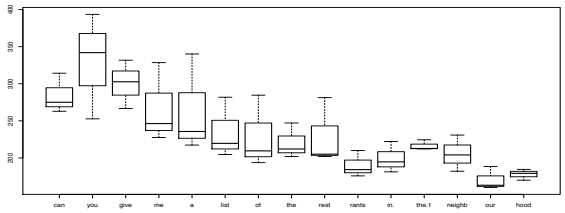

Figure 3. *Native female speakers*

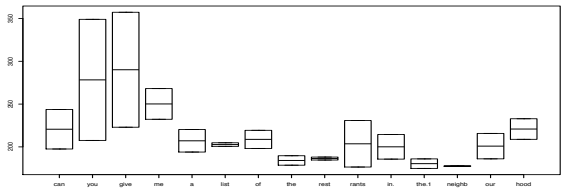

Figure 4. *Female learners from group C*

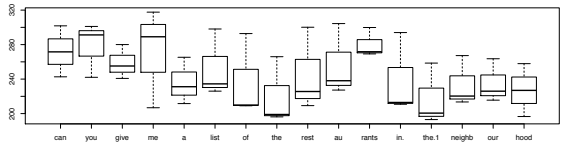

Figure 5. *Female learners from group B*

As explained in [29], there are limitations to this methodology (resyllabification issues, neutralization of rhythmic variation, pitch detection errors), but one consequence is for sure: modelling interlanguage intonation like this means that syllable division is high on the agenda for this kind of spoken learner corpus research.

The comparison of the productions of information-seeking *yes-no* questions by natives and learners showed that the form of the nuclear contour is not so much affected. The most important differences concern rhythm, and the prenuclear syllables. French speakers of English, in particular at B level, have a tendency to assign a rising pitch movement at the end of prosodic words, which leads to a clear difference in rhythm. The study of the intonation of the questions by English learners of French (which could not be developed in this paper for lack of space) also shows that the nuclear contour is somehow well realized too and it is to be noted that it seems easier for English learners of French to utter questions than for French learners of English, probably because the prenuclear syllables are better realized. Most studies on L2 intonation focus on the phonological nuclear form. The present paper encourages further study on the phonetic implementation of the prenuclear contour.

Avoidance of Stress Clash in Perception of Conversational American English

Amelia E. Kimball, Jennifer Cole

Abstract

We examine evidence for a regularity bias in the perception of sentence-level stress patterns, asking to what degree listeners perceive speech as *metrically regular*, with few or no occurrences of stress clash. We assess regularity through a stress perception task carried out by untrained listeners annotating transcripts of recorded speech, with sentences designed to have regular stress, and sentences drawn from a corpus of spontaneous conversational speech. Results show listeners report perceiving fewer stress clashes than predicted by random placement of stresses or by concatenating the citation form stress patterns of each individual word in a given sentence, though some incidence of stress clash is reported for both the regular and irregular speech materials. These findings suggest that listeners perceive English speech in accordance with a weak regularity bias. Inter-transcriber agreement rates also reveal substantial disagreement in perceived stress patterns at the sentence level, for regular and irregular sentences alike, suggesting variability in the perception of acoustic cues to stress at these levels.

Index Terms: stress clash, meter, stress perception, rhythm, metrical regularity

1. Introduction

Metrical patterns in speech arise from the sequencing of stressed and unstressed syllables across words and phrases [1]. In English, regular patterns occur when words are sequenced such that stressed syllables occur at regular intervals. For instance, the sentence 'HEIdi SOMEtimes SAW the JUry LEAving' has the stress pattern [SW SW S W SW SW], with a recurring pattern of stressed (strong) and unstressed (weak) syllables. However, due to the frequency of mono-syllabic words and the variety of patterns of word-level stress in English, metrically irregular phrases and sentences are also very common, e.g., 'JILL LIKES to SKI CAREfully' with the stress pattern [S S W S SWW]. To avoid confusion with notions of isochrony based on acoustic duration (discussed below), here we use the terms regular and irregular to refer to *metrical patterns of phonological stress* in sentences.

Despite the fact that sentences and phrases in English are not necessarily—or even typically—regular in their stress patterning, there is evidence that listeners are biased to perceive stress in terms of such regular patterns, and that more generally, regular stress patterns are privileged in speech processing. Early evidence for a regularity bias comes from studies of English phrasal stress. In phrases where stress clash results from the sequencing of word-level stresses, (e.g. *thirTEEN MEN*), speakers have the option of resolving the clash in favor of an alternating stress pattern (*THIRteen MEN),* or a pattern with only a single stress (*thirteen MEN*). When asked to identify the stressed syllables in such instances, listeners report hearing the alternating, clash-free pattern (THIRteen MEN) when listening to the entire intact sentence [2,3], but do not reliably perceive the resolved stress (THIRteen or thirteen) in the first word in the sequence when it is extracted and presented by itself [3]. These findings suggest that English speakers are biased to perceive stress patterns in phrases or sentences as regular, even when the acoustic evidence is not particularly strong.

The bias for listeners to perceive phrasal stress as regular may reflect a more general bias for regular stress patterns in speech processing. Studies on the perceptual processing of speech show that sentences with regular stress patterns yield faster and more accurate phoneme and word recognition [4-6]. In addition, ERP studies have shown that regularity modulates the amplitude of the n400 response [7], suggesting that speech perception and semantic integration are made easier by predictable, alternating stress patterns. In speech production, strings of non-words with regular stress patterns are easier to produce than irregularly patterned strings of the same non-words [8]. These experimental results point to a basis for a regularity bias in the mechanisms of speech processing, e.g., in neural oscillatory processes, as claimed by [9].

The studies cited above investigated stress regularity in speech production and perception with experimenter-controlled, read speech materials. This leaves us to wonder about the production and perception of speech that is produced under more natural conditions, e.g., conversational speech. This paper represents an initial step in the investigation of the effects of stress regularity in everyday speech, with an experimental approach combining experimenter-designed sentences read aloud by a model speaker with speech samples from a corpus of conversational speech that are re-enacted by the same speaker. Our focus in this paper is on **perceived** stress patterns. The goal is to compare the observed patterning of listeners' reported stress perception to random placement of stresses and to word stresses as reported in the dictionary. If there is a bias towards regularity, we expect observed patterns will be more regular than predicted patterns.

Note that in this paper metrical regularity is defined as an alternating pattern of strong and weak syllables. This is distinct from temporal measures of regularity as defined over acoustic intervals [e.g., 10,11]. In other words, in this paper we are interested in whether listeners report adjacent stressed syllables, regardless of when these syllables happen in time. Acoustic measures of our sample are not within the scope of the present paper, but are the subject of our ongoing investigation.

2. Experiment

This experiment tests the hypothesis that listeners' perception of stress patterns in naturally occurring sentences of English will be biased towards regular patterns. Specifically, we predict that listeners will report fewer instances of stress clash (stress on adjacent syllables) than are expected based on the location of stress within each content word, and also fewer than expected by three other calculations of chance occurrence, described further below. Listeners' perception of stress is assessed through a beat annotation task presented in a web survey format.

2.1. Stimuli

The test materials consisted of twenty sentences of conversational speech from the Buckeye Corpus of Conversational American English [12]. Also, twenty

sentences designed to have regular stress patterns, selected from previous experiments by the first author and from published studies, were included in this experiment as a control condition where no stress clash is expected to be perceived. To minimize the effects of speaker-dependent variability in speech rate, in patterns of phonetic reduction, or in other aspects of the phonetic realization of stress, all speech materials used in this study were re-enacted by a model speaker who is a native speaker of American English trained in linguistics, but who had no knowledge of the research goals of this study. A text transcript of the speech excerpts was presented to the model speaker, and the speaker was instructed to repeat the utterances in a natural and conversational style.

The form of the Buckeye corpus is informal sociolinguistic interviews with 40 speakers in the Columbus, Ohio area. Buckeye sentences were taken from interviews with four different speakers, chosen randomly from the larger corpus. Sentences were selected by the first author and chosen for the absence of disfluencies or major internal prosodic phrase breaks. For each of the four interviews the first five prosodically-demarcated utterances of the target duration and with no significant internal prosodic breaks were taken. Excerpts were approximately 1-2 seconds in duration. The 20 Buckeye excerpts taken together consisted of 159 words with a total of 205 syllables. The sentences with regular stress patterning (prepared by the experimenter) consisted of 140 words with a total of 198 syllables.

The regular sentences conformed to three metrical patterns: trochaic (SWSW…), iambic (WSWS…), or dactylic (SWWSWW…). The model speaker read all sentences of one stress pattern together. Examples of each sentence type are listed in table 1 below

Buckeye	My grandmother's from Ireland I go to Northland high school right now
Trochaic	Read a bedtime story. Heidi sometimes saw the jury leaving.
Iambic	Michelle foresees mistakes. My shoes are beige and black.
Dactylic	Sally is hoping to travel to Canada. Thomas has already taken geography.

Table 1. *Stress patterns for sample sentences*

2.2. Participants

55 participants total (31=Female) were recruited on Amazon Mechanical Turk, an online marketplace for human intelligence tasks. Participants' age ranged from 19 to 55 (mean =32.5, s.d.=8.8). Built-in Mechanical Turk screening tools ensured that the posting was displayed only to those workers who reported their location as in the United States. Only data from the 48 native English speakers with no reported hearing problems were eligible for inclusion in this study.

2.3. Procedure

Participants were presented with a display via an online survey built with Qualtrics survey tools [13]. Instructions stated that they would listen to a series of sentences and should "mark the beats" in a sentence by checking boxes. They listened to an example sentence ("I like to run and jump") and wrote the last word of that sentence in an answer box, in order to confirm that their audio was working. All participants correctly identified the last word in the example sentence. Participants were then shown an example of checked boxes for that sentence, and told "this person thinks the beats are on *like, run*, and *jump*." An example of the user interface is below in Figure 1.

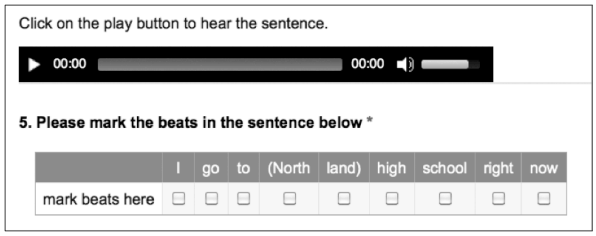

Figure 1: *User interface for the experiment.*

Participants were explicitly told to mark beats as the speaker said them in the audio recording, and not how the participant would say them. They were told that if they were unsure, they should "make their best guess", and that experimenters expected that listeners "may differ in where they mark beats." The listeners could play the audio as many times as they wanted, and were required to check at least one box. They were told that if they could not hear the audio they should check all the boxes. Two catch questions were presented in which the speech was purposefully obscured. Data was analyzed only from the 46 participants who (in addition to reporting as native speakers with no hearing problems) followed directions and identified the catch questions by marking all boxes.

3. Results

This experiment tested the hypothesis that listeners have a regularity bias in the perception of stress in conversational speech. If this hypothesis is true, we expect that when asked to mark stressed syllables in a corpus, listeners will report fewer clashes than predicted by chance or than are predicted by the concatenated stresses from the dictionary entry for each individual word. Results showed 7 out of 8 predictions of clash frequency were greater than the observed rate of clash, meaning that listeners hear fewer clashes than predicted.

3.1. Clash measures

For both the regular and Buckeye sentences five different frequency counts of the number of clashes were conducted: the observed number of clashes, plus four measures of the expected number of clashes.

Observed clashes were calculated based on participant responses. For every n sequential checkmarks, n-1 clashes were counted, such that four beats in a row would be marked as three clashes. This same counting method was used for the expected clashes.

The first rate of expected clashes was calculated based on the rate at which an individual participant marked syllables as beats for each sentence. For example, if a participant marked 2 beats out of every 4 syllables in a given sentence, their rate for that sentence was 2/4. This rate was squared to get the probability that two adjacent syllables would be marked as beats (a clash) and then the rate was multiplied by the number of adjacent syllable pairs in a given sentence, which represents the number of clashes possible for that sentence. Equation 1 below shows the method. Where C is the number of checks and N is the number of syllables:

$$\left(\frac{C}{N}\right)^2 (N-1) = \text{Number of expected clashes} \quad (1)$$

The second measure of expected clashes was created through a random sampling simulation using the R statistical computing language [14]. Separate simulations were run for dummy sentences with the same number of syllables as the test sentences, and for all possible numbers of beat marks within those sentences. 10,000 trails were run for each sentence length. Each trial looped through the total number of syllables, randomly selecting either a check or no check for each syllable, without replacement. Clashes were counted for each trial, and a mean clash occurrence was calculated across trials and compared with observed values.

The third measure of expected clashes was the number of clashes predicted by the dictionary entry of the citation form of the word. This was done by marking the primary stress of each word as reported in the Oxford English Dictionary and then counting occurrences of adjacent stressed syllables. Though this method was expected to overestimate because of the preponderance of monosyllabic words, it was included nonetheless because all words, including function words, may be variably stressed in conversational speech.

The last measure of expected clashes was also calculated based on the stresses marked in the dictionary for each word, but this time marking only the stressed syllables of content words as beats, with no beats marked on function words.

Figure 2 below compares the total clashes counted by each measure across sentences. Clashes are reported in clashes per syllable, to normalize for the differing number of syllables in the two samples.

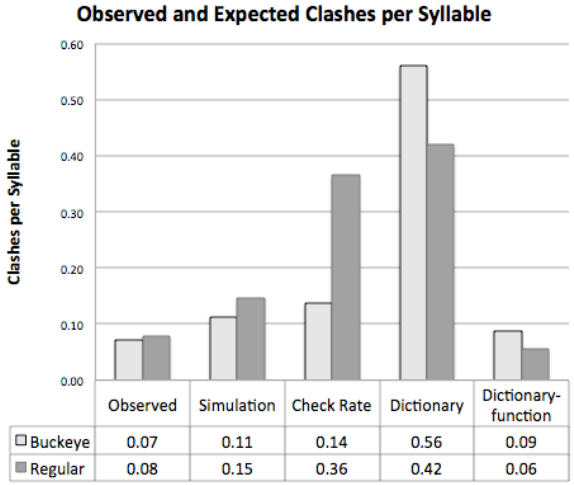

Figure 2: *Observed vs. expected clashes per syllable in both regular and conversational sentences*

Paired sample t-tests comparing the observed number of clashes vs. expected number of clashes under each calculation showed that for both samples the observed number of clashes was statistically significantly smaller than the expected number of clashes based on participant check rate, simulation, or the dictionary with and without stressing function words. The dictionary prediction that includes function words proved to be an especially poor model, grossly overestimating the amount of observed clashes in both regular and conversational sentences. However, the expected values based on dictionary stress markings *not including function words* provided the closest approximation of participants' responses, though it still differed significantly from the observed clash rate—in the case of the *regular* sentences, dictionary stress without function words predicted *fewer* clashes than observed, in the case of *Buckeye* sentences dictionary stress without function words predicted *more* clashes than observed. Table 2 below lists the *t* statistic, degrees of freedom, mean of the differences, and *p* value for each measure of expected clash frequency as compared to observed clash frequency.

REGULAR	t	df	mean of the differences	p
Check rate	-54.4861	919	-2.827624	<.001
Simulation	-24.1348	919	-0.6640634	<.001
Dictionary	-28.7383	919	-3.365217	<.001

BUCKEYE	t	df	mean of the differences	p
Check rate	-28.0077	919	-0.6749942	<.001
Simulation	-18.1389	919	-0.4359521	<.001
Dictionary	-48.3472	919	-5.026087	<.001
Dictionary- function	-3.532	919	-0.176087	<.001

Table 2. *Results of paired sample t-tests comparing observed and expected clash rates. Negative mean differences indicate that expected measures were higher than observed.*

3.2. Agreement

In addition to a comparison of observed clashes to expected clashes, we also calculated the inter-transcriber agreement for each syllable. Each syllable received a rating based on the number of listeners that marked it as a beat. Agreement scores are proportions ranging from 0 to 1. If listeners were in total agreement, the distribution of these scores would be bimodal, with peaks at 0 (meaning many syllables were marked by no listeners) and 1(meaning many syllables were marked by all listeners). Instead, as is clear from figure 3 below, the distribution was spread within the conversational Buckeye sentences. Relatively few syllables were marked by a majority of listeners, though many syllables were left unchecked by all listeners.

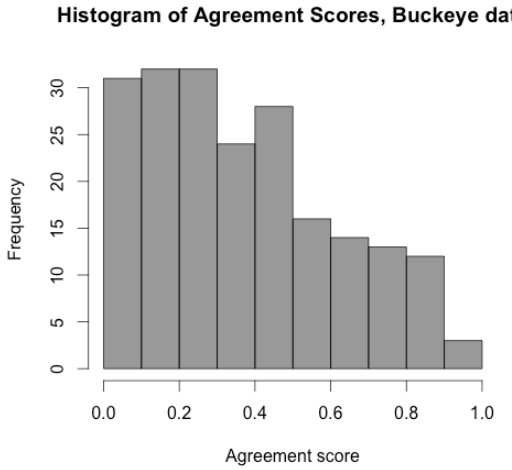

Figure 3: *A histogram of the distribution of agreement scores in the Buckeye sentences.*

It was expected that stress patterning would be more salient in the regular sentences, making them easier for listeners to annotate, and yielding higher levels of inter-transcriber agreement. Contrary to this expectation, we find that in both samples listeners fail to agree on the transcription for a majority of syllables.

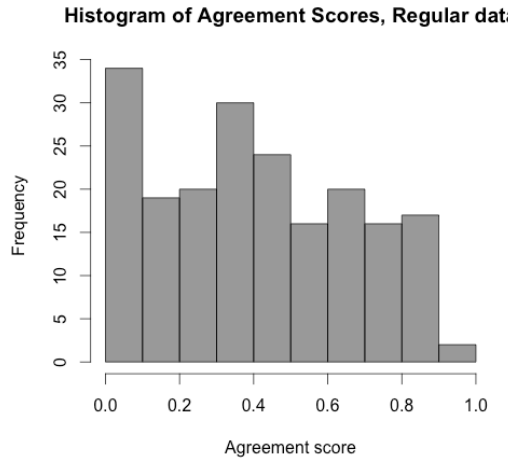

Figure 4: *A histogram of the distribution of agreement scores in the Regular sentences.*

4. Discussion

Given that metrically regular speech is advantaged in production and perception, we predicted that listeners would hear speech as regular and report few clashes. Our results bear this out—participants mark significantly fewer clashes than would be expected if syllables were randomly marked as beats, and also fewer than are expected based on the dictionary stress of the citation form of the words. This finding is consistent with the experimental hypothesis, suggesting the influence of a regularity bias in the perception of sentence-level stress. However, despite this apparent bias participants *do* report stress clashes, even in the regular sentences which were designed to have no clashes. This finding was surprising and points to the difficulty English speakers have in identifying and reporting lexical stress. Overall, these results support a 'soft' regularity bias [15,16], which favors regular alternating stress patterns at the sentence level, but which also allows for deviation from the preferred regular pattern in speech perception (and, we hypothesize, in speech production).

An important finding of this study is that listeners do not achieve a high level of agreement in their responses. Phonological theory which projects stress from accented syllables to the phrase level [1] would lead us to assume that patterns of word stresses are straightforwardly determined by the words of the utterance. However, our results show that individual listeners report different stress placement after being exposed to the same acoustic stimuli.

Some of this variation my be due to listeners defining "beat" differently, or interpreting the task somewhat differently. Then too the current results do not address individual differences in listeners, who varied in age (and no doubt in various cognitive measures). However, we believe that despite these potential sources of noise, the variability in the reported results point to variability in the perception of the acoustic cues to stress at the sentence-level. If listeners were uniform in their stress perception, we would expect high levels of agreement when a group of listeners were presented with the same acoustic stimuli, designed to be metrically regular. Our results are not consistent with this prediction.

The tendency to minimize clash in the perceived pattern of stresses in a sentence is shown to be all the more robust when inter-transcriber agreement in the marking of stress beats is taken into consideration. Though listeners did not agree in their placement of "beats," they nonetheless as a group avoided marking clashes. The low incidence of reported stress clash, together with the low rates of agreement in the marking of stress beats suggests a regularity bias in perception. These results motivate a thorough investigation of acoustic correlates of stress in these stimuli as predictors of listener responses, and individual differences in stress perception. This investigation is currently underway.

5. Conclusions

There are three main conclusions of this study. First, the comparison of observed rates of perceived stress clash with expected rates suggests a regularity bias in the perception of sentence-level stress, in that listeners report perceiving fewer clashes than would be expected. Second, despite the fact that listeners as a group report fewer stress clashes than expected, individual listeners disagree on stress placement for a given sentence, suggesting that the perception of stress may vary from listener to listener. Lastly, this study shows that concatenating citation form stress as marked in a dictionary provides a poor model of listeners' perception of sentence-level stress. Though citation stress without function words is a better model of perceived stress patterns, it still differs significantly from listeners' reported perception.

Further research is called for to determine which measure of stress is most accurate as a representation of stress as produced by a speaker, or as perceived by a listener, and whether the two measures converge on a common stress pattern. Finally, we note that inter-transcriber variability in the perception of stress beats, as reported here, is similar to the variability in pitch accent perception reported in studies of prosodic transcription [e.g., 17]. This parallel is expected if stress beats at the sentence level are equated with prominence-lending pitch accents in prosodic transcription systems.

Transitions, pauses and overlaps: Temporal characteristics of turn-taking in Czech

Abstract

This study aims to describe temporal characteristics of pausing and turn-taking phenomena in conversation. The material comes from the VASST corpus of contemporary Czech and uses four spontaneous dialogues in the form of an informal interview. We describe both general and idiosyncratic effects found in our data and compare them with results from other languages. In our material, transitions with a silent gap, overlaps and back-channels all display notably similar temporal distributions with the median around 360 ms and a marked skewing. The four dialogues did not differ in the proportion of turns belonging to the interviewer (58 %) vs. interviewee (42 %), which is hypothesized to characterize the experimental task. Despite a number of general tendencies, individual differences in pausing and turn-taking behaviour of the speakers were found as well. For instance, the ratio of pauses and gap transitions proved to be highly dialogue-specific. We also gathered evidence for a substantial change in the speech behaviour of the interviewer resulting from a change of her communication partner.

Index Terms: conversation, turn-taking, transition, overlap, back-channelling, pause

1. Introduction

The structure of conversation and turn-taking has been systematically investigated since the 1970s. A pioneering study in this regard is that of Harvey Sacks and his colleagues [1], who introduced an early model attempting to describe and explain the organization of turn-taking in natural conversation. A key assumption is that the structure of syntactic and semantic units should allow the listener to anticipate the end of the speaker's turn and to take over at a *transition-relevance place* (TRP). In addition to these syntactic cues, however, prosodic features (intonation contour, final lengthening, loudness) also play an important role [2], [3], [4].

The model in [1] takes into account several further assumptions that are supposed to describe any modifications in the organization of conversation. One of these is the temporal principle of "minimizing gap and overlap", i.e. of making the transition of speakers as smooth as possible. Several studies (e.g. [5], [6]) challenged this principle, providing a new set of data that yielded the most frequent pause duration at speaker transitions approximating 200 milliseconds, while gaps or overlaps of less than 10 ms were scarce. Thus the close succession of turns remains to be further investigated [6].

The distribution of *gaps* (pauses at turn transitions) and *overlaps* (intervals with overlapping speech at transitions) has been widely investigated in English and a few other languages. In the material of [6] overlaps appeared in approximately 40 % of all turn transitions. The importance of overlaps was also emphasized by ten Bosch et al. [7] and Shriberg et al. [8]. The latter, investigating multi-participant dialogues, found overlaps in 17 % of all words, and in 54 % of intonation units without a pause. Similarly, in an analysis of 26 meetings featuring several participants, overlaps took up 12 % of all speaking time [9]. These findings imply that overlaps represent a relevant feature in the organization of conversation, and it is thus necessary to include them in any model of turn-taking.

Naturally, pauses (not only) at turn transitions have been the focus of much research. Discontinuities in speech may be classified in several ways based, for instance, on their function in conversation (pause, gap, lapse; [1], [6]), their form (silent vs. filled pauses, different forms of hesitations; [10], [11], [12]), their relation to syntax (boundary vs. hesitation pauses; [13]), their duration [14], [15] or on the speaker's intention to continue or pass the word [11], [16]. This also influences the used terminology which is not unified. The issue of what constitutes a pause is also debated. Usually, the authors determine a minimum cut-off boundary in the range of 100-150 milliseconds [4], [17], [18], [19], [20], but other decisions are possible, e.g. [13], [14], [21]. The detection threshold for a pause in turn transitions was determined to be 120 milliseconds [22]. Nevertheless, it is important to keep in mind that decisions on both pause type and minimum pause duration always depend on the purpose of the analysis.

One of the central concerns of this study is the relation between turn transitions and the duration of pauses. This was investigated for instance by Wennerstrom and Siegel [4]. Their results suggest that the probability of a turn transition decreases within the first 500 milliseconds of the pause, and then increases for longer pause durations (approximately 1500 milliseconds). The probability of giving the floor to another speaker is thus highest for short and long pauses, while lowest for pauses of middle duration – which, in other words, tend to occur within a single turn.

Both duration and occurrence of pauses demonstrate a great amount of variability in different languages, speech styles and speech tempos. Studies also dealt with a strong influence of individual habits on the duration of pauses [23], [24]. However, it was ascertained that pauses are connected to major syntactic breaks and coincide with prosodic boundaries of intonational phrases [18], [25]. The duration of the pause has been shown to correlate with the strength of prosodic boundaries [26] and the length of the phrase (e.g. [27]).

We may hypothesize that the organization of conversation is to a certain degree universal and independent of the particular language. To our knowledge, none of the above mentioned experiments have been replicated in Czech. The present paper therefore aims to compare the findings from well-investigated languages with our data on Czech, but also to enlarge the scope of interest and explore idiosyncratic patterns of speakers and accommodation towards the dialogue partner.

2. Method

2.1. VASST corpus

The speech material was taken from the VASST corpus (the acronym meaning *group and style variation* in Czech, see [28]), which is currently being built at the Institute of Phonetics in Prague. The aim of the corpus is to capture the variability of contemporary spoken Czech in different styles and sociolinguistic groups. To this day, the corpus comprises 168 speakers from eight different regions and three specific social groups. Each subject provided five different speaking styles (ordered by formality): a read list of sentences, read continuous text, picture description, controlled interview and spontaneous dialogue.

For this study, the last part of the corpus – spontaneous dialogue – was used. It should be noted that the level of spontaneity of the dialogues is subject to discussion and depends on several factors (familiarity with the interviewer, character of the subject, position within the dialogue, etc.). The fact of being recorded and interviewed presented a rather unnatural situation for the subjects, however it was done in a familiar environment (at the participants' homes) and the experimenters were instructed to make the subjects as comfortable as possible. It could be stated that the recordings we selected from the corpus show a high degree of spontaneity.

2.2. Speech material

Four dialogues were analyzed with a total duration of 85 minutes (on average 21 minutes per speaker pair). The speakers were female, aged 75 to 85, who all came from the same region in Northern Bohemia and spoke colloquial Czech. The experimenter (i.e. their dialogue partner) was in all cases the same, a female student of Phonetics.

The utterances were recorded on a portable professional device Edirol HR-09, with a sampling frequency of 48 kHz and a 16-bit quantization. Afterwards, the recordings were downsampled to 32 kHz and manually post-processed and labelled in Praat [29] by experienced phoneticians (including two of the authors). The boundaries of breath-groups were marked for both dialogue partners, as well as pauses and turn transitions. A breath-group was defined as a stretch of speech of one speaker between his two breath intakes. A turn is the stretch of speech (consisting of one or more breath-groups) of one speaker uninterrupted by the second (with the exclusion of back-channels, see below). Another solution was adopted by [30] and [31] whose main analysis unit was the interpausal stretch. However, this information is obtainable from our annotation as well.

Pauses within speakers' turns were categorized as follows:

- *silent pauses* (Ps): unfilled pause
- *hesitations* (Ph): pause containing a hesitation sound
- *breath pauses* (Pb): pause containing breath intake

The minimum duration of a pause was set to 120 milliseconds; shorter pauses were treated as part of segmental articulation. Pauses that partake in speaker change (i.e. gaps) were not included in this category, see below.

For labelling the turn-taking phenomena, a classification based on [5] was used:

- *gap transitions* (Tg): speakers switch their turns following a gap
- *overlaps* (To): speakers switch by overlapping each other's speech
- *back-channels* (Tbc): intervals of short overlap not resulting in speaker change; often consisting of a single sound or word

It was shown that this classification can cover as much as 96 % of all turn transition phenomena [5].

In the next step, the duration of turns, pauses and turn transitions was measured. Since the duration of transitions or pauses cannot be expected to be normally distributed (the values are only positive and the number of short and long durations is bound to be extremely different), medians instead of arithmetic means are reported. To assess the significance of the results, non-parametrical statistic tests, i.e. Mann-Whitney U test and Kruskal-Wallis one-way ANOVA, were used.

3. Results

3.1. Transitions and overlaps

Gap transitions (Tg) represent the most frequent type of turn-taking in our material. They were over two times more

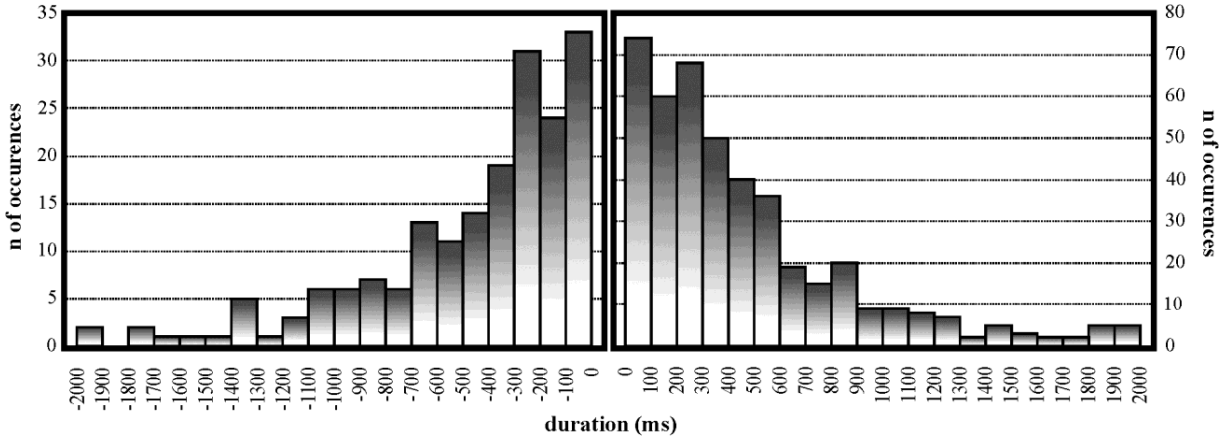

Figure 1: *A histogram of the durations of* OVERLAPS *(on the left) and* GAP TRANSITIONS *(on the right).*

frequent than overlaps (To), and this tendency holds true for individual dialogues as well, although in one of them the ratio amounted almost to 3:1. However, we found a discrepancy between the subjects and the experimenter: the Tg/To ratio was only 1.4 for the subjects, while it was as high as 4.6 for the experimenter (who was instructed not to interrupt the subjects if possible). In terms of percentage, gap transitions constitute 52 % of all turn-taking phenomena, whereas overlaps comprise 22 %.

Figure 1 shows the durational distribution of gap transitions and overlaps. Although both phenomena are inherently different in nature, they display strikingly similar temporal characteristics. The medians for Tg and To are 333 ms and 353 ms, respectively, and both distributions are massively skewed. 57 % of Tg's and 57.5 % of To's are shorter than 400 ms, while 89 % of Tg's and 88 % of To's are shorter than 1 s.

If we pool together gap transitions and overlaps from all speakers, the distributions of Tg × To show no significant difference (Mann-Whitney U test: $p = 0.83$). However, if we divide the transitions between the speakers and assign each to the speaker that follows, we discover that the experimenter and one of the subjects are differentiated in their realization of Tg's and To's – the subject in Dialogue 3 had significantly longer overlaps than gap transitions (Mann-Whitney: $p < 0.05$), while the experimenter had longer Tg's than To's (Mann-Whitney: $p < 0.01$). More importantly, if we compare the duration of overlaps of the subjects with those of the experimenter, the latter are significantly shorter (Mann-Whitney: $p < 0.05$).

Turn transitions in close succession, i.e. those realized with a gap/overlap not exceeding 10 ms (investigated for instance by [6]), constitute 1.7 % of all transitions in our material. According to [22], this boundary can be raised to 120 ms, which is the detection threshold for a no-gap, no-overlap transition in a dialogue. In this respect, smooth or close transitions were realized in 18.5 % of all cases.

3.2. Back-channelling

As expected given the nature of the interview, the back channels (Tbc) were more frequent (1.8 times) with the experimenter than the subjects. Back-channelling can be used as a supportive affirmation and encouragement on part of the experimenter in order to induce subjects to continue speaking. However, there were intra-speaker differences in the experimenter's back-channelling behaviour (see below, section 3.4). The number of back-channels on the part of subjects was too low to permit quantitative analysis.

Out of all turn-taking phenomena, back-channels constitute 26 %, so they occur more often than overlaps (22 %). Interestingly enough, the durational properties of back-channelling are not significantly different from gap transitions or overlaps (Kruskal-Wallis ANOVA: $p > 0.05$). The median duration of back-channels was 384 ms.

3.3. Pauses

The overall duration of within-turn pauses constitutes 16 % of the total duration of the speech material. Since the number of experimenter's pauses was low (due to briefness of her turns), in the following text only pauses of the subjects are reported.

In individual dialogues, breath pauses (Pb) constitute 9-14 % of the duration, while silent pauses (Ps) up to 5 % and hesitation pauses (Ph) only up to 3 % of the subjects' speaking time. Since hesitation pauses were infrequent, differed greatly in manifestation and were problematic in terms of identifying and labelling, we decided to exclude them from further analyses.

Breath pauses were significantly longer than silent pauses (Mann-Whitney: $p < 0.001$), which was the case for all subjects. For three of the subjects the median duration of a breath pause ranged between 425 and 470 ms, while one (D2) was significantly different with 572 ms (Kruskal-Wallis ANOVA: $H(3, n = 894) = 23.2$; $p < 0.001$). Interestingly, the same speaker had the lowest median duration of silent pauses (274 ms), while the other three speakers clustered between 370 and 401 ms.

Working under the paradigm of [1], pauses can be considered *transition relevant places* (TRPs) where the change of speakers does not occur (similarly to [30]). It would therefore be interesting to compare the duration of breath and silent pauses to gap transitions, where the change of speakers takes place.

We discovered a significant difference between the duration of breath pauses and gap transitions – breath pauses were considerably longer (Mann-Whitney: $p < 0.001$). This holds true for all dialogues but one (D1). The case of silent pauses and gap transitions was less clear, as in two dialogues (D1, D2) Tg's were longer than Ps's, whereas in D3 and D4 it was the other way round.

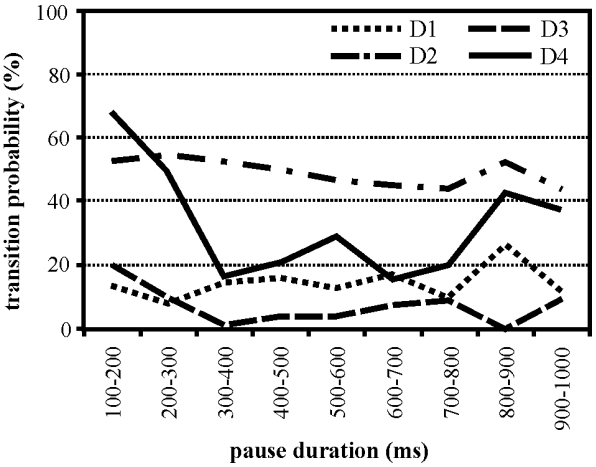

Figure 2: *The probability of turn transition as a function of pause duration. D1-D4 represent individual dialogues.*

We also computed transition probability by determining the percentage of gap transitions in all "silences" (Tg, Ps and Pb). Unlike [4], we did not find any drop in the percentage around 500 ms, nor an increase over 1500 ms. Instead, the percentage curve drops to about 20 % around 300 ms and stays at that level. Figure 2 shows the percentage in steps of 100 ms according to individual dialogues.

It is remarkable that between 300 and 1000 ms (over 1000 ms the number of cases starts to be too low) the percentage of gap transitions stays quite similar and highly dialogue-specific. For D1, gap transitions comprise around 15 % of all silent intervals, D2 has the highest percentage (48 % on average), D3 with only 5 % of Tg's represents the other extreme, and D4 fluctuates around 26 %.

3.4. The experimenter

Since the experimenter was the same in all dialogues, it presents an interesting opportunity to examine changes in her speech behaviour associated with change of dialogue partner.

The frequency of her turns paralleled the speaking behaviour of the subject, resulting in a substantial change in the average values from 1.7 turns per minute (D3) up to 10.5 turns per minute (D2). The duration of turns of the subject and the experimenter also seemed to be in a direct relationship, but the low number of dialogues prevented statistical verification.

Regardless of turn duration or frequency, it is remarkable to see that the experimenter uttered in all cases 58 % of the turns (the exact range was 58.1 to 58.8), leaving the remaining 42 % to the individual subjects. This could be the consequence of the task and of her role as interviewer.

Concerning the experimenter's transition behaviour, it can be seen from the data that her overlap strategy varied. Although in all four dialogues she produces approximately 1/3 of the overlaps, their duration differs significantly (Kruskal-Wallis ANOVA: $H(3, n = 57) = 8.5$; $p < 0.05$). Moreover, the duration and frequency of her back-channels differed as well. While in D3 the back-channels appear only 0.7 times per minute, in D2 it increases to more than three times per minute. This is in inverse relation to the length of the Tbc's – in D3 the back-channels were longest (median 593 ms), in D2 they were shortest (median 322 ms).

4. Discussion

Identical instructions to all participants resulted in a number of similar tendencies in the conversational structure of the dialogues, but several individual differences were also found.

Despite the fact that gap transitions, overlaps and back-channels are phenomena of a different nature and they manifest differently in the flow of speech, their temporal characteristics show remarkable similarities in our speech material.

The most frequent strategy for changing turns seems to be a transition with a silent gap between individual turns. Overlaps occured in our dialogues less often than reported in [6], where they constituted around 40 % of all transitions. We detected 30 % of overlaps; 22 % if back-channelling is also included as a transition phenomenon.

Concerning the findings of [5] and [6], who point out that the principle of minimizing gap and overlap postulated first by [1] may not be the main cause governing transition duration, our results show that although transitions without perceptible gap (that is ±120 ms) do not constitute the majority of transitions (only 18.5 %), the frequency of both gap transitions and overlaps generally does increase as their duration approaches zero.

If we compare the frequency of short transitions (without a perceptible gap), longer transitions and longer overlaps with the findings of [22: 511], our data are well in range of what the author found for 12 different languages. In our data, no-gap, no-overlap transitions constituted 18.5 % of all transitions, longer gap transitions 57.1 %, and longer overlaps 24.3 %. The author also noticed remarkable similarities in the ratio of these categories within language families – but in his material, Slavonic languages were not represented, so more research would be needed to see whether this hypothesis is valid also for them.

Durational characteristics of pauses and their relation to the turn-taking phenomena were also investigated. Gap transitions were significantly shorter than breath pauses. This may suggest that often the communication partner takes the turn before the other finishes breathing in. Despite breath pauses being physiologically conditioned, there also seem to be some idiosyncrasy in their duration. One of our speakers had a significantly longer duration of breath pauses and, interestingly enough, a significantly shorter duration of silent pauses at the same time. It is possible that this represents some kind of unconscious compensation on the part of the speaker. That the duration of pauses may be speaker-dependent and a useful tool for speaker identification has already been pointed out not only by forensic phoneticians (e.g. [11], [32]).

On the other hand, we could not replicate the findings of [4], who observed a marked drop in the probability of transition in pauses around 500 ms of length. We detected no such change in transition probability; however, this probability displayed remarkable and very stable inter-dialogue differences (shown in Figure 2).

In our experimental design, the experimenter received instructions concerning her conversational behaviour. The data suggest that she indeed performed her role as an interviewer – she uttered more turns and of shorter duration than the subjects (around 58 % in each dialogue). Furthermore, she took turns significantly less often by overlapping her communication partner; and, if she did, the overlaps were significantly shorter.

The conspicuous similarity of experimenter's turn percentage in all dialogues could be attributed to the experimental task. In future research we therefore plan to compare it with the controlled interview, which is the other conversational task from the VASST corpus, to see whether the percentage of turns changes. It is also possible to be a characteristics of the experimenter – again, we will examine the same dialogue task performed by other experimenters to verify this hypothesis.

Despite her consistencies mentioned above, the experimenter shows notable changes in her behaviour depending on the dialogue partner. This concerns mainly the duration of overlaps and the duration and frequency of back-channels. The notion of accommodation or entrainment may be evoked in this regard (see e.g. [7]), and these relationships should be investigated further.

The VASST corpus of contemporary Czech with its different speaking styles offers an excellent opportunity to research conversation behaviour in contrast to other speaking styles. In future studies the results will be verified on a larger amount of speech data, and the scope of the research should be enlarged to cover other prosodic phenomena in turn-taking, as well as to discover further individual patterns of speakers' behaviour.

Abstract

The paper reports findings of a study in which Russian speakers without any prior knowledge of Finnish imitated utterances in that language, and, in particular, how they succeeded in imitating segmental duration. The data was analysed using acoustic measurements of segment duration as well as auditory analysis by four judges. The results show that Russian speakers faced difficulties in imitating some aspects of the complicated Finnish quantity system. On the other hand, many of the imitated words were judged as comprehensible.
Index Terms: duration, length, Finnish, imitation, language learning

1. Introduction

There has been a renewed interest in investigating the role of imitation in many fields that study social, cognitive and linguistic activity [1, 2]. To our knowledge, imitation has not been much used as an elicitation method in prosodic research. In this paper, imitation will be studied using a research design in which the participants were asked to imitate sentences of varying length in a language they do not know. We report the results of a pilot study of Russians imitating Finnish utterances, with the aim of focusing on how the participants succeeded in imitating the segment durations. The durational patterns in the imitations were investigated both by acoustic measurements and perceptual analysis. We also present preliminary reflections on the role of first language (L1) in imitating an unknown language and relate our findings to second/foreign language (L2) learning research.

Inspired by Hurme [3], who investigated how native speakers of Russian without any knowledge of Finnish succeeded in mimicking Finnish utterances, the present authors conducted a pilot study [4] where also the connection of the individual's working memory to the imitation ability was investigated. The results of both studies indicated that the success of imitation depended on the length of the utterance as measured in syllables and that the initial and final parts of the utterances were imitated best. In addition, the latter study found a positive correlation between the participants' score in the working memory test and the success of imitation. In this paper we analyse the prosody of the imitated utterances focussing on segmental durations. In contrast with Russian, in Finnish quantity is distinctive which also makes the results interesting from the point of view of second/foreign language learning.

1.1. Quantity in Finnish

Finnish has a complex quantity system. In two-syllable words alone there are eight possible combinations of /short/ and /long/ vowels and consonants [5]: from CVCV to CVVCCVV. Thus, *tule, tulle, tulee, tullee, tuule, tuulle, tuulee, tuullee* are all Finnish words, inflections of the verbs *tulla* (come) and *tuulla* (blow). Word stress is fixed on the first syllable of the word, and the main phonetic correlate of stress is a peak in F0 [6]. All vowels can occur phonemically long and short in all stressed and unstressed syllables [7], e.g. *sika* [sikɑ] (a pig), *siika* [si:kɑ] (a whitefish), *sikaa* [sikɑ:] (a pig, partitive) and *siikaa* [si:kɑ:] (a whitefish, partitive). Most consonants can occur as /long/ or /short/ between vowels too, making a single-double contrast [7] e.g. *muta* [mutɑ] (mud), *mutta* [mut:ɑ] (but). Even words like *muuttaa* [mu:t:ɑ:] (to change) are possible.

However, the phonetic reality of quantity in Finnish is even more complex [e.g. 8, 9, 10]. For instance, in CVVCV and CVCCV structures not only the long segments have longer duration but also the second-syllable vowel is shorter than in CVCV structures, where the second-syllable vowel can be phonetically characterized as long. Indeed, /short/ vowels can vary in duration from [very short] (CVVC*V* *kaato*), [short] (C*V*CV *kato*), [longish] (C*V*CCV *katto*) to [long] CVC*V* *kato*, depending on their position and the quantity pattern of the word [8]. Further, utterance length has an effect on segmental durations: segments tend to be shorter the more syllables the utterance consists of [11]. In recent studies also the tonal patterns in words with different quantity types and the possible role of F0 in maintaining the oppositions have been investigated [6, 12]. The possible role of F0 in perception of the quantity opposition has been shown by O'Dell [11].

1.2. Quantity in Finnish for learners

As quantity is a distinctive feature in Finnish, it is also often mentioned as one of the foremost difficulties of Finnish for L2 learners. However, the complexity and intricacy of the quantity system manifests also in native speakers' slower acquisition. It has been shown that while Finnish children learn to make the difference in the consonantal durations between CVCV/CVCCV patterns at an early age, they do not fully master those differences in the second-syllable vowels that are sub-phonemic but systematic even at the age of six [13].

As studies focussing on learners of Finnish as a foreign language have shown, quantity distinctions are notoriously difficult. Vihanta's [14] study of French learners of Finnish reading Finnish sentences containing minimal pairs showed that they often lengthened the final vowel (as in French) and failed to make the sub-phonemic durational difference in the second-syllable vowel in CVCV vs. CVVCV/CVCCV words. On the whole they tended to exaggerate the distinction between /short/ and /long/, leading to problems in understanding. Toivola [15] who studied the prosodic features and foreign accent in L2 Finnish spoken by Russian learners found out that they often produced either too short or too long segments in word-medial position, and segments that were too long in word-final position. The perception of Finnish quantity

by L2 speakers has been studied by Ylinen and colleagues [16, 17] who learned that the vowel quantity distinction was difficult to perceive even for Russians who had lived in Finland for several years.

In all, while the first extensive experimental acoustic analyses of Finnish quantity in native speakers' speech as well as tests of perception of the quantity distinction were conducted as early as in the 1970s [9], up till now there are few studies that have investigated the topic in L2 Finnish speech. Thus, the current study adds to the understanding of the Finnish quantity system as perceived and produced by non-speakers of Finnish.

1.3. Duration in Russian

In Russian, phoneme length is not distinctive (with the exception of some rare consonantal minimal pairs such as *strany – stranny)*. However, the vowel duration is used for another function, to signal the location of word stress, as stressed vowels are longer than unstressed ones vowels. Being distinctive, word stress can fall on any syllable and its position can differ in various forms of the same word. Proportionately, the durational difference between Finnish stressed long and short vowels is similar as between Russian stressed and unstressed vowels (about 2:1) [18]. However, in Russian the duration of the unstressed vowel depends also on its position relative to the stressed vowel, as there are two degrees of vowel reduction in unstressed vowels. The weak degree occurs in the syllable immediately preceding the stressed syllable, but can also occur in some other positions (e.g. word initial and phrase final positions) and has the duration of 1.25–1.4 times the duration of the other unstressed vowels (with the strong degree of reduction) [19]. The fact that in Russian the duration is one of three cues of word stress (the others being intensity and pitch) whereas in Finnish it mainly signals phonological length offers interesting possibilities for research.

2. Material and Methods

2.1. Material

Data was collected in an imitation task, following the design of [3]. Russian subjects were asked to orally imitate 30 auditory stimuli, each of which they heard only once, in a language they did not know. The stimuli were three-word Finnish utterances (with 4–11 syllables) previously recorded from a female speaker, a native Finnish speaker with a standard Finnish pronunciation. The stimuli aimed at echoing spontaneous utterances in spoken Finnish with a naturalistic prosody in mind. *Tili tuli tänään* (paycheck arrived today) and *yöllä saattaa tuulla* (at night it may rain) are examples. The stimuli were presented to the subjects in two different randomized orders in order to avoid fatigue and learning effects. The responses were recorded with an Edirol by Roland 4-bit Wave/MP3 R-09 digital recorder and a high quality Koss headset (sample rate 44.1 kHz, 16 bit resolution). A practice stimulus was presented before the experiment. Six native speakers of Russian (further R11, R12, R13, R14, R15, R16) were asked to imitate the stimuli. They were all female, aged 20–26, university students from St. Petersburg. Five of them were students of linguistics, and thus, had some phonetic training.

For the present analysis, we chose the stressed vs. non-stressed, short vs. long vowels (and long vs. short consonants) in the following disyllabic words: *päättää*[2] (to decide) – *päätä*[2] (decide, imperative form); *sata*[2] (hundred) – *saattaa*[2] (may); *tuulla*[3] (to blow) – *tulla*[2] (to come); *teetä*[3] (tea, partitive) – *teettää*[3] (to have made), *tili*[1] (pay check) – *tilli*[1] (dill); *tuli*[2] (fire) – *tulli*[2] (customs); *kisaa*[3] (competition, partitive) – *kissaa*[3] (cat, partitive). The numbers refer to the position of the word in the utterance (1=first word, 2=second word, i.e. middle, 3=last word). These words occurred in different utterance positions: the pairs listed above mostly (except for *tulla – tuulla*) occurred in the same sentential position, which makes their comparison possible.

2.2. Methods

First, the imitated utterances were submitted to auditory evaluation by the four authors, all native speakers of Finnish and experts in phonetics. Here, the judges listened to the model utterance and each imitation three times (each judge in a different randomized order) and rated the success of the imitation. The comprehensibility of both the whole utterance and each word were rated on a 1–5 Likert-type scale (0=missing, 1=completely against the model, 2=not completely comprehensible, 3=comprehensible, 4=rather good, 5=near-native). In addition, the judges were asked to submit verbal comments on the segmental and prosodic features that they found particularly disturbing or successful. The judges' numeric ratings ('c' in Figures 2–3) were highly consistent and reliable (Cronbach's alpha .91 at the utterance level, between .86–.92 at the word level).

Second, the acoustic analysis of segment durations were carried out in Praat [20]. First, the comprehensibly imitated words were annotated in the segmental level. The segment onsets and offsets were determined both visually in the spectrogram (as well as in the intensity and F0 curves) and auditorily, and marked manually. Words that were not comprehensibly imitated were discarded. In word-initial plosives the occlusion phase was excluded, but included in the position between the vowels. The durations and auditory ratings were analysed in different word types. The relative segment durations were calculated and expressed as the ratio between segment duration and the mean duration of the [very short vowel], second vowels in CVCCV and CVVCV structures, for each speaker. Due to the small sample size the data is not analysed using statistical tests at this point.

3. Results

3.1. Acoustic analysis of segment duration

First, we present the results of the acoustic analysis of segment duration in a) the first (stressed) syllable and b) the second (unstressed) syllable, further divided into three subgroups (Table 1). Four words were left out of the analysis either because they were not imitated by Russian speakers (*teetä*) or because they were the only occurrence of the particular word type *tuulla* (CVVCCV), *kisaa* (CVCVV), *kissaa* (CVCCVV).

Table 1. *Three categories of second syllable vowel duration following* [10]

Vowel duration	Words	Word type
very short	tulla, tilli, tulli päätä	CVCCV CVVCV
long	sata, tili, tuli	CVCV
very long	päättää, saattaa, teettää	CVVCCVV

Figure 1 shows the mean relative segment durations of the selected words as the proportion of the duration of the mean of the [very short] vowel duration produced by each speaker (see Table 1 for examples). Both Russian speakers and the Finnish native speaker make a distinction between short and long in the first-syllable vowel. However, there are differences in how the Russian subjects and the Finn produce duration in the second syllables, especially in case of the [very long] final vowel, imitated similarly as the [long] final vowel. As for consonants, the difference between /short/ and /long/ consonants is clearer in the speech of the Finnish speaker. The relative segment durations in the speech of the Finnish speaker are similar to those of other Finnish speakers as reported in [10].

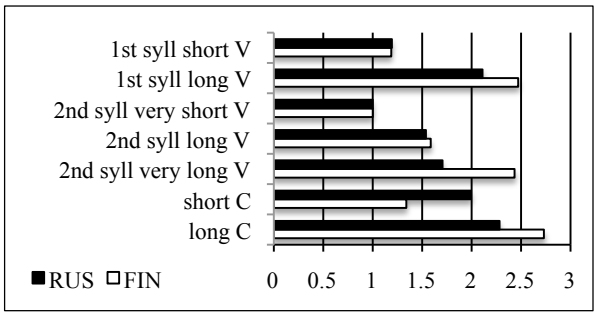

Figure 1: *Relative segment duration*

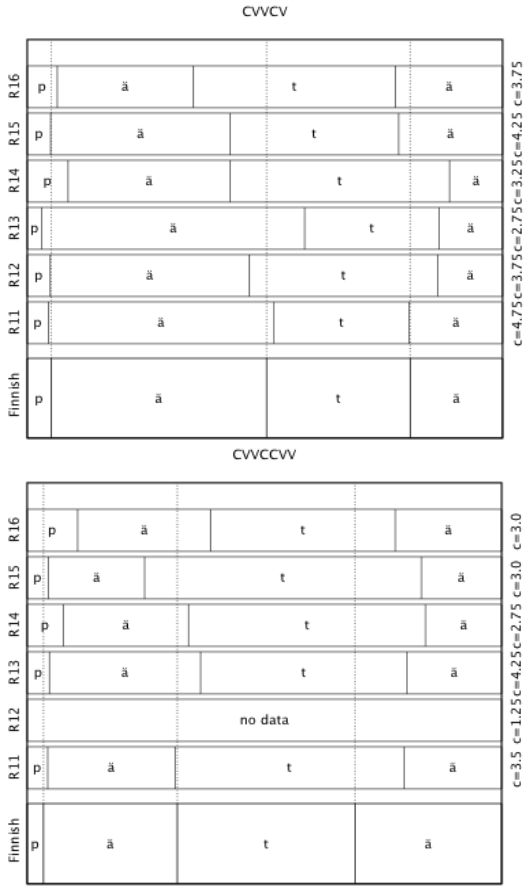

Figure 2: *Relative segment durations of the word päätä (above) and pääättää (below)*

Figure 2 shows the relative segment durations of the words *päätä* and *pääättää* in the Finnish model utterance and its Russian imitations, with time on the x-axis, speakers and comprehensibility ratings (c) on the y-axis. One of the Russian speakers (R11) matches the original durations very closely in her imitation of the word *päätä*. The other productions are less close to the target for all segments in both words, and the word *pääättää* is more difficult to imitate. As Figure 2 shows, the second syllable vowel in *pääättää* is too short in all imitations. However, often the preceding consonant is much longer than in the model. The word *pääättää*, consisting of three consecutive long segments, is structurally foreign to the Russian speakers, but interestingly, the subjects may aim at imitating the length they possibly hear by transferring the feature to the preceding consonant. Thus, Figure 2 confirms the finding illustrated in Figure 1 showing that a [very long] second syllable vowel is difficult to imitate.

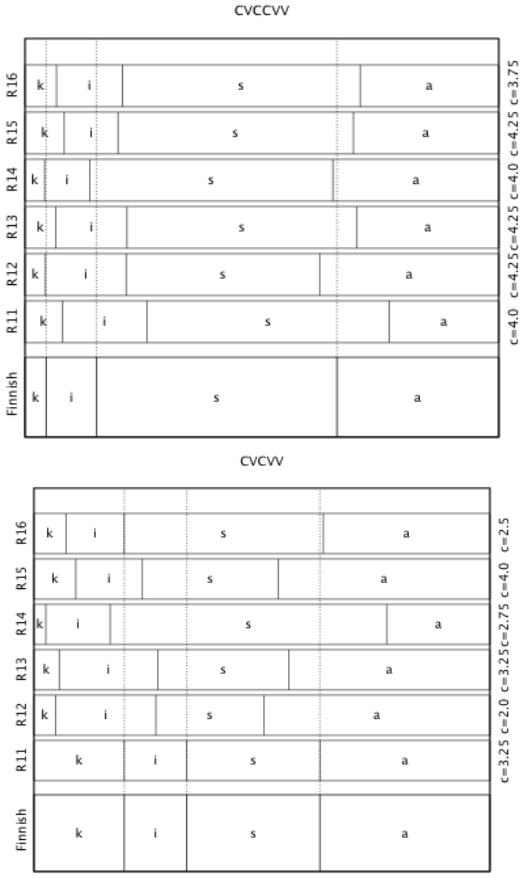

Figure 3: *Relative segment durations of the word kissaa (above) and kisaa (below)*

Next, we will investigate two words that were the only occurrences in their category, *kisaa* and *kissaa* (both in sentence accent position) and thus not included in the previous analysis. Figure 3 shows that some speakers clearly manage to imitate the durational patterns better than others. Speaker R14 matches all segment durations present in the Finnish model in the word *kissaa* and speaker R11 in the word *kisaa*. However, most Russian speakers fail to imitate the duration of the unstressed vowel in the second syllable for both words. This seems to interfere with the relative duration of the other segments in both words, similarly as in the word *pääättää* in

Figure 2. However, one possibility is that vowel duration is more difficult to imitate than that of consonants. In *kisaa* the speakers differ in their imitations: some (R14, R16) exaggerate the duration of the sibilant, others (R12, R13, R15) that of the word final long vowel. Also the duration of the first vowel can be exaggerated (R12, R13). Overall the durational pattern of the word *kissaa* was easier to imitate than *kisaa*, *päätä* or *päättää*, probably because it was pronounced slowly, with a strong sentence accent and some emotionality in the Finnish model. Furthermore, both *kisaa* and *kissaa* were in utterance final position, and thus easier to imitate than *päätä* and *päättää,* which were in utterance medial position, see [4]. Also, it can be speculated that the long fricative in the word *kissaa* may be easier for Russians to perceive and then imitate than the short plosive in *päätä*.

3.2. Perceptual evaluation of the segment duration

Next, we will discuss the perceptual evaluations of the imitations by the four judges. The verbal comments in the perceptual analysis suggest that whenever the judges perceived the participants' productions as recognizable on the whole, also the durational patterns of the model had been closely followed. Although there was some variation – and some poor imitations - the durational patterns in the subjects' productions quite consistently matched the native speakers' intuition of the boundary between /short/ or /long/ quantity. In line with the acoustic analysis, the word-final /long/ vowels were frequently, particularly after a long vowel in the first syllable, perceived as "too short".

Figure 4 shows the comprehensibility ratings (1–5) of the judges in different word types. Overall, most word types got a mean comprehensibility rating of over or near three (3=comprehensible). This means that despite the potential difficulties in the durational patterns discussed above, the speakers' imitations were generally comprehensible. Figure 4 includes all seven word types (see 2.1), although in some of them there is only one word as an example. In line with what was said above concerning Figure 3, the word *kissaa* (CVCCVV) was the easiest to imitate. Other successfully imitated word type was CVVCCVV (e.g. *päättää*). The least successful type CVVCCV was the word *tuulla*, the segmental content of which might be difficult for perception.

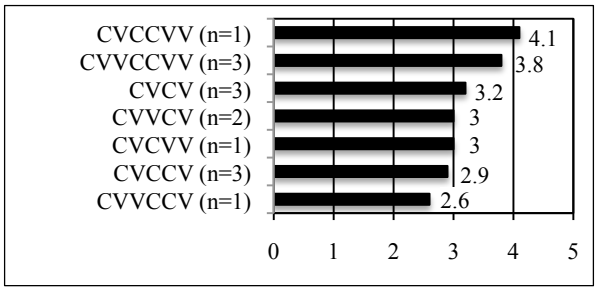

Figure 4: *Mean comprehensibility ratings (1–5) of the imitations according to the word type*

Obviously, the comprehensibility ratings are not based exclusively on successful imitations of durational patterns. Other factors, such as the position of the word within the utterance (see 2.1), the nature of the segments, and sentence stress are likely to influence as well. Nevertheless, it is obvious that a clear violation of the durational pattern is likely to result in low comprehensibility ratings especially when it concerns the first, stressed syllable of the imitated word. This can be seen in Figure 3, in the word *kisaa* where the violation in duration of the first vowel or sibilant appears to be associated with low comprehensibility ratings.

4. Discussion

The paper examined segment duration in imitated Finnish speech by Russians. The results seem to indicate that some features of the Finnish quantity system are indeed difficult to imitate. First, there are large individual differences. Second, there are differences caused by the word type and the position of the word in the utterance. In more particular, our results show that speakers of Russian were not successful in imitating the [very long] vowel in the (unstressed) second syllable, but produced a shorter vowel while prolonging the duration of the preceding consonant (Figures 2 and 3). As such a long vowel does not exist in Russian in similar positions, this is also an example of possible L1 influence. Length patterns in L1 have been shown to have influence on conveying quantity in L2 [21, 22]. Also, previous studies [14, 15] have shown that L2 learners of Finnish tend to produce word-final vowel durations as too long, suggesting that learning can lead to exaggerating the learned category, a phenomenon which is well-known from both L1 and L2 learning of different linguistic skills. Exaggeration of quantity categories in L2 Swedish is reported in [21]. Indeed, the word-final position may be particularly vulnerable for non-nativelike durations as even native speakers do not fully master the durational system by the age of six [13].

The findings indicate that closer examination is needed to study the role of such factors as, e.g., sentence stress, segmental content, tonal patterns [6, 12] and utterance type in the imitation of segment durations. Further, the imitation experiment with its interplay between articulation and perception – and between two languages, Finnish and Russian – offers new insights into cross-language phonetics and learning of L2 pronunciation, e.g. the effect of segments and prosodic features of L1 on L2 and possible differences in the acquisition of segmental and prosodic features.

5. Conclusions

The preliminary results suggest that more research is needed on the interplay between general and language-specific aspects in the ways prosodic features are perceived and articulated. In this experiment, data was elicited that aimed at mapping how subjects cope with the articulation of utterances in a language that is unfamiliar to them, using their auditory perception only. To see how prior knowledge about the language or its writing system exerts influence, new studies will be designed. Further studies will be conducted to examine the presence of L1 transfer in imitated utterances vs. second/foreign language learners' speech. In conclusion, we believe imitation experiments of an unknown language offer an interesting new tool for the study of the role of imitation in language learning and development.

6. Acknowledgements

We thank the students and staff at St. Petersburg State University for participating in and organizing the experiment, especially Dr. Nina Volskaya. We also wish to express our gratitude to the Academy of Finland for a travel grant (n:o 260539) to the first author, which enabled data collection.

Abstract

This paper presents a quantitative analysis of stress in Savosavo (unclassified), an endangered language spoken on Savo Island, (Solomon Islands). Acoustic analyses comprise the measurements of F0, duration, and intensity for each syllable in a dataset carefully selected from elicited speech from one speaker only, aiming to test the effect of increasing morphological complexity on stress realization in a system that displays some variation. Statistically significant variation is found in all correlates between stressed and unstressed syllables, thus fitting with widely attested manifestations of stress cross-linguistically. Findings were further tested with a re-synthesis tool, to confirm our initial hypotheses. Our results demonstrate that the current annotation scheme is a reliable representation of the data, and that the qTA component embedded in PENTAtrainer is effective in modelling F0 contours, even with less controlled data as input. We will argue for the usefulness of instrumental phonetic investigations in describing lesser-known languages, to enhance our understanding of the characterization of the prosodic systems of the world's languages.

Index Terms: prosody, word stress, pitch, duration, Austronesian language, Oceanic language, prosodic typology

1. Introduction

Savosavo is an unclassified, Papuan language spoken on Savo Island (one of the Solomon Islands) by about 2500 people. It does not have any (close) relatives, and has been surrounded by Oceanic languages for at least several hundred years, hence there has been long-standing contact between Savosavo and many of its neighbours. Because of a shift in the younger generations to Pijin and English, Savosavo is an endangered language currently being documented by Wegener [1]. The speech data on which this study is based is part of the documentation of Savosavo, which is thus precious as the sole possible corpus of analysis.

Savosavo is a verb-final language, with postpositions, and adnominal modifiers preceding the head of an NP; it also has a marked-nominative system with case-marking enclitics on syntactic subject noun phrases, but no case-marking on object noun phrases, whereas on verbs only syntactic objects are cross-referenced by means of affixes or stem modification, while syntactic subjects remain unmarked.

In Savosavo, a syllable can either consist of only a vowel nucleus or a vowel nucleus and a consonant onset, i.e. the basic syllable structure is (C)V. Most roots consist of two or three syllables, but roots of four and more syllables also occur. Savosavo has been analysed as a stress language based primarily on auditory impression, with additional qualitative analyses in [1]. Generally, primary stress falls on the penultimate syllable of a root; initial syllables receive a secondary stress if primary stress is on a non-initial syllable. Impressionistically, stressed syllables have been associated with longer duration, clearer pronunciation, higher intensity and sometimes higher pitch. This paper aims to quantify such claims using data extracted from field recordings, however constrained the recording conditions. While lab speech may be desirable and advantageous for such analyses [2], we contend that field-based descriptions are still feasible. The Savosavo data demonstrates a consistency in acoustic correlates sufficient to corroborate its status as a lexical stress language. Its lexical prosody mirrors that of English, a well-studied stress language.

2. Methodology

2.1. Recording

The recordings of Savosavo being analysed are from Wegener (2007-2010), with one male native speaker serving as consultant. Recording took place in a secluded area of the village, though some background noise was unavoidable. The data is extracted from two elicitation sessions lasting about 35 minutes each, in which the subject was prompted by the linguist (using English) to provide a translation for various items, starting from a single word and increasing in morphological complexity e.g. a citation form for a verb, and then various inflections and some negative forms. 207 tokens were analysed in total.

2.2. Annotation and analysis

The initial transcription and annotation was done with ELAN [3] (Sloetjes & Wittenburg, 2008); the 207 selected tokens were converted into Praat [4] textgrid format. The assignment of the stressed syllable was based on the phonological stress assignment rules described above. Syllable boundaries were hand-labeled and glottal pulse data was generated and manually verified for missed or double marked vocal cycles in the wave form. The ProsodyPro script [5] was used to extract all the measurements including mean F0 (based on 10 evenly spaced F0 points from each labelled interval), max F0, duration, and mean intensity, and computed time-normalised F0 contours for each token. The resulting files from ProsodyPro were analysed to investigate the acoustic correlates of lexical prominence.

2.3. Analysis by synthesis

In order to verify the reliability of the stress assignment annotation scheme on which the above analysis is based, the

measurements were re-analysed with PENTAtrainer2 [6], a semiautomatic software package for the analysis and synthesis of speech melody, built upon the Parallel Encoding and Target Approximation model [7] also running on PRAAT [8]. In a preliminary phase, intervals were labeled according to the communicative function tested. The program then extracted the optimal parametric values for the tested communicative function through analysis by synthesis controlled by simulated annealing [6]. The tool assumes three model parameters controlling the F0 movement of each interval (here a syllable), including target slope (*m*), target height (*b*), and strength of target approximation (λ), where *m* and *b* specify the form of the pitch target and λ indicates how rapidly a pitch target is approached.

These results were used to generate F0 contours and compare them with the individual real utterances in the corpus.

In the current annotation scheme, two communicative functions were included, namely Stress condition (stressed (S) vs. unstressed syllable (U)) and Syllable location (Left, Medial, and Right edge of the utterance) as illustrated in Figure 1.

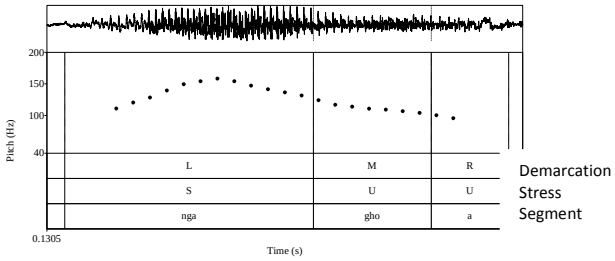

Figure 1. Example of functional annotation of recording for PENTAtrainer2, the top tier indicates the Syllable Location, the 2nd tier its stress condition and the 3rd tier the segmental content.

3. Results

3.1. Acoustic correlates of stress

The acoustic correlates of stress considered in this study are durational (ms.), intensity (dB) and mean F0 which is taken, for our purpose, as the direct correlate of pitch. The results shown in Table 1 indicate that stressed syllables have higher pitch with mean values of 112.06Hz to 96.36 Hz respectively; longer duration, with 212.91 ms to 176.09ms; and greater intensity, with 68.60dB to 64.29dB, than their counterparts. These results are statistically significant for all 3 correlates: F0 ($F=162.299$ (1, 1674) $p<0.001$; intensity ($F=48.933$ (1, 1696) $p<0.001$; duration ($F=146.349$ (1,1696) $p<0.001$.

Table 1. *Acoustic correlates of stress in Savosavo.*

Stress		Mean F0 (Hz)	Duration (ms)	Mean Intensity (dB)
S	Mean	112.06	212.91	68.60
	N	484	484	484
	Std. Deviation	23.50	56.39	9.91
U	Mean	96.36	176.09	64.29
	N	1192	1214	1214
	Std. Deviation	22.61	56.71	12.05

3.2. Analysis by synthesis

Functionally annotated data were fed into PENTAtrainer2, which computed the average parametric value of each interaction of the two functions (i.e. stress condition and syllable location). The results are shown in table 2. The learned values are compatible with our expectations that stressed syllables have a falling underlying target (shown by the negative *m* values) wherever they are located (left, medial or right periphery); these targets are higher than their unstressed counterparts (evident from the greater *b* values) when they are not word-initial. The anomalous Strength value for unstressed syllables at the right edge (100) should be disregarded, as it can be interpreted as a result of missing glottal pulses in the final syllable of some utterances, an artefact of field data commonly observed.

Table 2 *Mean target parameters of the Savosavo data learned through qTA modeling.*

Stress condition	Syllable Location (demarcation)	*Slope m*	*Height b*	*Strength λ*
S	Left	-42.32	1.74	20.15
	Medial	-52.09	-1.86	29.55
	Right	-29.56	4.89	5.34
U	Left	-0.5	2.39	36.86
	Medial	-5.8	-1.66	8.79
	Right	-26.84	-7.27	100

Subsequently, these averaged values were used to resynthesize the F0 contour of each utterance in the corpus. Mean RMSE (Root Mean Square Error is a frequently used measure of the difference between values predicted by a model and the values actually observed from the environment that is being modelled, since the RMSE is a good measure of accuracy, it is ideal if it is small) and Pearson's *r* (Correlation – often measured as a correlation coefficient – indicates the strength and direction of a linear relationship between two variables) of synthesis accuracy were respectively 2.48 and 0.87, these results are comparable to a study of English stress also using PENTAtainer2 [9] who report values of 3.97 ± 0.29 0.478 ± 0.028 for RMSE and R, respectively (for the encoding of the stress function only). The satisfactory accuracy of synthesis, even with only two functions annotated, demonstrates that the current annotation scheme is a reliable representation of the data, and that the qTA component embedded in PENTAtrainer is effective in modelling F0 contours.

4. Discussion

Some limitations due to the field-based nature of our data need be mentioned. First, the data is from only one speaker, and we are aware that in the context of a lab-based study, data from a lone speaker would not be deemed sufficient for a quantitative analysis; in our context it may indeed be a source of confounding factors such as speaker specific speaking style. Second, the male consultant in question uses a low mean F0 (100.7 Hz average across all utterances analysed), often close to his own pitch floor. As a result, some syllables were produced in non-modal phonation, hence did not contain glottal pulses. Third, where glottal pulses are not present, the duration of the syllable in question is determined by the annotator based on auditory

impression. The aforementioned limitations thus need to be taken into account when interpreting our results; nonetheless, we maintain that the acoustical correlates reported in the present paper serve as strong evidence to establish that Savosavo has stress, comparable to English, and unlike other languages, like Urdu, where lexical stress is marked by a lower F0 instead [10]. Further research will also investigate the acoustic difference between primary and secondary stress in Savosavo. Existing literature [1] has postulated the existence of secondary stress within the language, despite the claim of 'no or little [auditory] difference in realisation' between syllables carrying primary versus those with secondary stress. A possible avenue for future research would be to annotate for perceive primary and secondary stress and conduct descriptive statistics between these subgroups. An obvious limitation to this suggestion might be that the learning accuracy of the re-synthesis tool would be biased towards a system that distinguishes between three variables (Stressed, Unstressed and Secondarily Stressed) rather than one which uses two (as in this paper), rendering it incomparable with our above presented annotation scheme.

Finally, expanding from the word domain, continuing analyses will test how the encoding of lexical stress may interplay with sentential prosodic functions, such as modality and focus.

5. Conclusion

In this paper, we have provided quantitative evidence for the marking of lexical prominence in Savosavo through stress to complement previous qualitative analyses. We demonstrate that, even under adverse recording conditions, it is possible to carry out analyses using tools usually reserved for lab speech.

It is important to restate that this study forms the basis of further descriptive work on the prosodic system of Savosavo, so that after establishing the foundation for stress, we can define with more accuracy the nature of its syllable by analysing phonological processes such as syllable fusion. This description, in turn, will contribute to the ongoing areal research aiming to establish whether a historical change took place from a moraic to a syllabic system [11]. These findings will also be the basis for further investigations that will examine, for example, the interplay of word stress and sentence stress.

This paper argues for the usefulness of instrumental phonetic investigations in describing lesser-known languages. Our results demonstrate that the current annotation scheme is a reliable representation of the data, and that the qTA component embedded in PENTAtrainer2 is effective in modelling F0 contours. Finally, this paper also illustrates the usefulness of tools such as ProsodyPro for acoustic measurements, and PentaTrainer2 for hypothesis testing, tools that will eventually make a contribution towards our greater understanding of the characterization of the prosodic systems of the world's languages.

6. Acknowledgements

The authors would like to thank the Savosavo speakers for their continuing efforts to document their language and to make the recordings available for linguistic research. The present study is funded by DoBeS (Volkswagen Foundation) as part of the project 'Discourse and prosody across language family boundaries: two corpus based case studies on contact induced syntactic and prosodic convergence in the encoding of information structure'.

Abstract

In a previous production experiment, post-focus compression (PFC) of F_0 and intensity were found to be present in Persian. It was also shown that F_0 and duration were the main correlates of prosodic focus in Persian. However, the perceptual relevance of PFC in Persian was not yet clear. The present paper reports the findings of an experiment on focus perception in Persian. Native speakers of Persian listened to sentences produced with focus in different positions as well as the neutral-focus sentence, and judged the presence and location of focus. Results show that final focus is identified much less well than other types of focus, and most of its confusion is with neutral focus. This shows that the presence of PFC is a main factor in recognizing prosodic focus in Persian.

Index Terms: prosodic focus, PFC, perception, post-focus, pre-focus, on-focus, F_0, intensity, Persian.

1. Introduction

There are different strategies to catch the attention of a listener to a particular portion of an utterance, i.e., to mark focus. This can be done both by syntactic and morphological means and by prosodic devices. Prosodically, many languages use phonetic variation in F_0, duration and intensity to mark focus. In particular, prosodic focus is realized not only by increasing F_0, duration and intensity of the on-focus component itself, but also by compressing the pitch range and intensity of the post-focus elements [5, 7, 16, 27, 28, 31]. There is also increasing evidence that post-focus compression as a perceptual cue plays a pivotal role in focus perception [11, 29]. It has been reported that if there are no F_0 peaks after an earlier peak in a sentence, it would be easier for listeners to perceive a non-final focus; otherwise listeners are prone to hear an additional late focus or no focus [15, 18]. It is also shown that when focus is not utterance-final, i.e., when PFC is applicable, its perceptual recognition is much easier, whereas final focus is often confused with neutral focus [3, 5, 13, 18]. Hence, findings from focus perception seem to lend further support to the importance of PFC [29]. However, the perceptual importance of PFC is not widely accepted, and much of the research on focus perception is still mainly concentrating on the focused words only [e.g., 20, 25]. There is therefore a need to explore further evidence for the importance of PFC in focus perception. In this paper, we present data of a perception experiment on Persian, for which PFC has been found in a recent study [22]. Before probing the perceptual effectiveness of PFC, a brief background of Persian prosody is provided in the next section.

2. Persian prosody

Persian, an SOV language with fairly free word order, is an Iranian language within the Indo-Iranian branch of the Indo-European family. Regionally, Persian has three major varieties: (1) the Persian of Iran (2) the Persian of Afghanistan, now called Dari and (3) the Persian spoken in Tajikistan in Central Asia. The variant used in this study is Iranian Persian, the official language of Iran and the mother tongue of about 60% (42 million) of Iran's population. It is worth noting that bilingualism and multilingualism are widely found in Iran [6].

There have been three central issues about Persian prosody. The first concerns word prosody. Persian has traditionally been described as a stress language. Abolhasanizade et al [1] recently found no marked phonetic difference between stressed and unstressed syllables independently of the presence of intonational pitch accents. The authors conclude that Persian word prosody involves a lexically-sensitive pitch accent assignment system that is more like Tokyo Japanese, which has no stress in the phonetic sense, than West Germanic, where stressed and unstressed syllables differ in durational and spectral properties.

The second issue relates to sentence prosody. Initial works, mostly based on the British tradition, have carefully documented the intonational patterns for various sentence types [24, 23]. In more recent literature, there has been a tendency toward the framework of autosegmental-metrical and intonational phonology [8, 14, 19]. A remarkable development to emerge from these studies concerns the issue of main stress in the sentence, generally referred to as the nuclear stress. Eslami [8] and Kahnemuyipour [12] have proposed a number of syntax-based rules to identify the location of the main stress within sentence.

The notion of syntax-based sentence stress, however, is contrasted by the findings related to the third issue, which concerns prosodic focus [1, 10, 19, 21]. According to these findings, any constituent in Persian can be contrastively focused, the only constraint being that focused elements cannot appear post-verbally. The phonetic properties of focus has been addressed in a number of experimental studies. The evidence provided by Sadat-Tehrani [19] points to greater pitch excursion and longer duration of focused elements. In a more detailed experiment, Abolhasanizade et al [1] show that focus has no significant durational and spectral effect and is expressed only by the differences in F_0. That the effect of duration and intensity is negligible is also maintained by Hosseini [10], who claims that F_0 is the only robust acoustic correlate of focus. As for the post-focal region, Abolhasanizade et al [1] provide evidence for PFC of F_0 and intensity. According to these authors, while the pitch range of the post-focal elements is phonetically reduced, the pitch accents are not deleted after the focus. This contradicts earlier report of complete post-focal de-accentuation [19, 21, 10]. The

existence of PFC in Persian is also found by Taheri-Ardali and Xu [22], who showed that focus not only increased the F_0 and duration of words under focus, but also decreased F_0 and intensity of post-focus words. In contrast, they did not find significant changes in on-focus intensity or post-focus duration.

Previous research has therefore established the existence of PFC in Persian. But there have been no empirical studies on the importance of PFC in the perception of focus in Persian, a gap the present study aims to fill.

3. Method

3.1. Stimuli

The sentence used in the perception experiment, as shown in Table 1, was taken from the previous production experiment [22]. The key words in the sentences consisted of mostly sonorant sounds to make sure that the F_0 contours were as smooth and connected as possible. The sentences were produced by five male speakers, who repeated each of the sentences five times in blocked random order. There were a total of 30 utterances from each speaker.

Table 1. *The target sentence of the experiment*

W1	W2	W3	W4	W5
Maha	baba-ye	nili-ro	lændæn	didim
we-PL	father-EZ	Nili-DO	London	see.PST-1PL

To elicit focus on a specific word in the production experiment, the target sentence was preceded by a sentence in parentheses. This focus cueing sentence was the same as the target sentence except the focused word, the verb and the ending word 'but' (Table 2).

Table 2. *The focus cueing sentences*

Focus	Focus cueing sentence (plus 'but')
W1	**They** didn't see Nili's father in London
W2	We didn't see Nili's **uncle** in London
W3	We didn't see **Amini's** father in London
W4	We didn't see Nili's father in **Tehran**
W5	We didn't **take** Nili's father to London

The stimuli for the current perceptual study were selected using mean standard deviation of F_0 across all repetitions of each speaker as arbitrary criteria, a method previously used in [5]. Speakers with minimum, maximum and median standard deviations were chosen. Then all tokens from these three speakers were used stimuli. In total, there were 6 foci x 5 repetitions x 3 speakers = 90 tokens.

3.2. Subjects

Five males and five females participated as subjects. All were native speakers of Persian with average age of 26.1 which is comparable to the age range of those who took part in production experiment. Each subject was paid in exchange for his/her participation in the test. They have also reported no hearing or speech disorders.

3.3. Listening Procedure

The experiment was conducted using ExperimentMFC in Praat software [2]. The listeners were instructed on how to choose the emphasized word. They listened to the stimuli once and then judged which word was focused. They were also told if none of the words was focused, the neutral focus choice must be selected. Before the start of the experimental trials, listeners had five practice trials without any feedback on the correctness of the answers.

3.4. Results

Figure 1 shows focus recognition rates of all six focus conditions, in percentage of correct identification. The overall rate of focus identification is fairly high. Compared to each other, the identification rate for the final focus (last word) is much lower than other focus conditions.

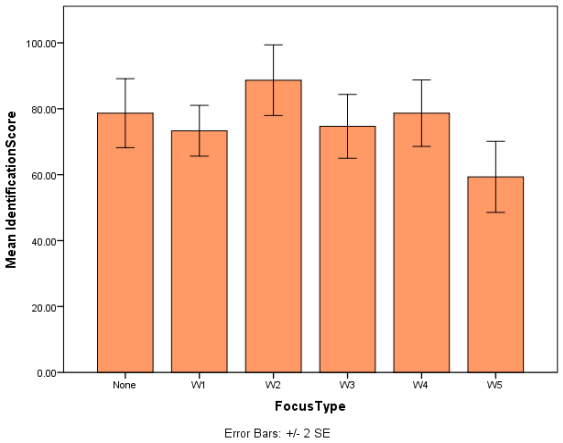

Figure 1. *Percentage of correct identification of neutral focus and focus on word 1-5. The error bars represent standard errors.*

Table 3 shows a confusion matrix of the focus perception experiment. It can be seen that when listeners identified focus location wrongly, they were prone to hearing no focus in the utterance. For example, 29.3% of the final foci that the listeners heard wrongly were heard as neutral focus. In contrast, there were almost no wrongly identified cases that were recognized as final focus.

Table 3. *Confusion matrix of focus perception (percent). Bold face indicates correct focus identification.*

heard as / original	none	W1	W2	W3	W4	W5
none	**78.6**	9.3	4.6	3.3	4	0
W1	24	**73.3**	2	0	0.6	0
W2	6.6	4	**88.6**	0.6	0	0
W3	16.6	2	4.6	**74.6**	2	0
W4	16	0.6	2	2	**78.6**	0.6
W5	29.3	2.6	0.6	3.3	4.6	**59.3**

Table 4 shows results of post-hoc pairwise comparisons between the focus conditions with Bonferroni adjustments. It can be seen that focus on Word 5 has significantly worse recognition rate than neutral, focus on Word 2 and focus on Word 4. In contrast, there is no significant difference between any other two focus conditions.

Table 4. *Results of post-hoc pairwise comparisons. The mean difference is significant at the .05 level.*

Focus Type (I)	Focus Type (J)	Mean Difference (I-J)	Sig.
None	W1	5.334	1.000
	W2	-10.000	.713

	W5	15.334	.258
W4	W5	19.336*	**.015**

4. Discussion

Results from Table 3 show that recognition rates of all focus positions were high except for final focus. That the lowest recognition rate is for final focus is in line with many other studies where the final focus had the lowest rate of identification compared to other positions [3]. The most likely reason is that the lack of PFC impedes the easy recognition of focus in this position [13]. This is supported by Figure 2, which displays time-normalized mean F_0 contours of the three speakers whose utterances were used as the perception stimuli in the present study. It can be seen that the F_0 increase by final focus relative to neutral focus is just as substantial as in other focus positions. The only thing missing compared to the non-final focus is the compressed F_0 (and intensity) after the focused word, since there are no words following the final word. The second word has the highest rate of focus identification, followed by the fourth word and neutral focus.

The high recognition rate of focus on the second word can be explained from a syntactic perspective. The basic pattern of Persian sentence prosody is that every major class word receives an accent. From the neutral-focus contour in Figure 2 we can see that all words are accented except the second word, i.e. *babaye* 'father-EZ'. Generally speaking, under some discourse conditions, the head noun of a definite noun phrase may be unaccented when post-modified, as is the case with the head noun *babaye* inside the noun phrase *babaye nili* 'Nili's father' [19]. This usual lack of pitch accent on the second word apparently had a consequence on the focus perception. That is, when asked to put focus on the second word, speakers in fact accented a constituent that would receive no accent in the neutral pronunciation of the sentence. Thus, the focus on the second word involves one extra structural manipulation (i.e. accenting a structurally unaccented word) compared to that on the other words in the sentence which are structurally accented words. This may have made the second word even more salient than the other focused words, and so helped the subjects to more efficiently identify focus on this word.

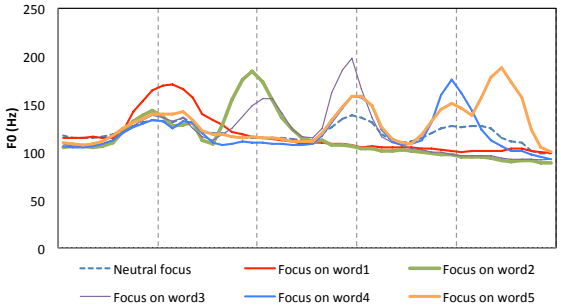

Figure 2. *Time-normalized mean F_0 contours of all the sentences uttered by speakers with* minimum*, maximum and median standard deviations. Each curve is an average of 25 repetitions.*

In Persian, like Uygur [26], initial focus was mostly confused with neutral focus (24%). But in terms of confusion of final focus with neutral focus, with 29.3% wrong identification, Persian acts like Beijing Mandarin [5].

Speakers of Iranian and Turkic languages (both PFC languages) have been in contact since pre-Islamic times [17]. However, to compare with each other, phonetic realization of prosodic focus in Persian and Turkish as two exemplars of Iranian and Turkic languages is not similar in pre-, on- and post-focus regions. To name a few, contrary to Persian, Turkish does not show significant changes in F_0 in on-focus region. And it was also observed that in Turkish pre-focus region is raised in F_0 while in Persian there is no change in mean F_0 in this region. Furthermore, in Turkish, unlike Persian, the acoustic differences in the three above-mentioned regions are not independent of the position of focus. It is worth noting that Azeri language as a Turkic language which is also spoken in Iran is heavily influenced by Persian as an Iranian language. Thus, since Azeri has a common proto language with Turkish, on the one hand, and its close contact with Persian on the other hand, the prosodic focus of Azeri and its cross-comparison with Persian and Turkish are worth investigating.

In addition, since Persian has been in close contact with Arabic and even some part of the population (2%) in Iran is Arab, findings from the study of prosodic focus for Arab-speaking areas and its comparison with Persian and the other dialects of Arabic like Hijazi, Lebanese [4] and Egyptian [9] might reveal further implications.

5. Conclusions

Considering the results of the present perception experiment, it can be concluded that post-focus compression of F_0 and intensity is a highly important acoustic cue for the recognition of prosodic focus in Persian [30]. Its presence in non-final position leads to an average of over 78% focus recognition, whereas its absence in final position leads to less than 60% of focus recognition. Therefore, the overall recognition rate is 75% somewhere between the PFC languages like Beijing

Mandarin [5] and Uygur [26] with 90%, and languages without PFC like Taiwanese with 60% [5]. This perception experiment thus provides another piece of evidence that Persian, like English, Beijing Mandarin, Japanese, Turkish and Tibetan, can be categorized as a PFC language. This finding therefore adds yet another piece to the overall picture of focus typology.

Interpreting Final Rises: Task and Role Factors

Catherine Lai

Centre for Speech Technology Research,
School of Informatics, University of Edinburgh, United Kingdom
clai@inf.ed.ac.uk

Abstract

This paper examines the distribution of utterance final pitch rises in dialogues with different task structures. More specifically, we examine map-task and topical conversation dialogues of Southern Standard British English speakers in the IViE corpus. Overall, we find that the map-task dialogues contain more rising features, where these mainly arise from instructions and affirmatives. While rise features were somewhat predictive of turn-changes, these effects were swamped by task and role effects. Final rises were not predictive of affirmative responses. These findings indicate that while rises can be interpreted as indicating some sort of contingency, it is with respect to the higher level discourse structure rather than the specific utterance bearing the rise. We explore the relationship between rises and the need for co-ordination in dialogue, and hypothesize that the more speakers have to co-ordinate in a dialogue, the more rising features we will see on non-question utterances. In general, these sorts of contextual conditions need to be taken into account when we collect and analyze intonational data, and when we link them to speaker states such as uncertainty or submissiveness.

Index Terms: Intonation, task-oriented dialogue, rises.

1. Introduction

The question of what prosody contributes to meaning is a key problem for both automated spoken language understanding and theories of semantics and pragmatics. In particular, a good number of studies have investigated how utterance final pitch rises and falls relate to epistemic and affectual states of speakers and how this relates to tasks such as dialogue move detection. Such studies generally examine how prosody affects the interpretation of the carrier utterance in the immediate context, e.g. whether a cue word is interpreted as a backchannel or not. While the local context clearly has a large effect on how prosody is interpreted, we would also like to know what impact higher level features such as task and role have as well.

One reason we expect higher level features to affect the interpretation of prosody follows from the incongruence of findings based on single dialogue types. For example, a correlation between rises and backchannels has been reported in map task dialogues in Bari Italian [1], Swedish [2], and Dutch [3], as well as in other game corpora in English [4, 5, 6]. However, these sorts of results are absent from studies of more free-form conversational dialogues in English [7, 8, 9] and Hindi [10]. We would like to know whether the differences in rise distributions from these backchannel studies extend to other sorts of dialogue moves, and if so, why.

To examine this, we look at the IViE (Intonational Variation in English) corpus [11]. The corpus contains speech of various styles including isolated read sentences as well as spontaneous conversational and task-oriented dialogues (the map task) from speakers of urban regions of the United Kingdom. In this paper we look at the boundary intonation of speakers from Cambridge (i.e. Standard Southern British English) in these different modes of speech. The motivation for looking at this dialect in particular is that out of those included in the corpus the intonation pattern for this region's declarative statements has been found to be the most pervasively falling or low at the boundary in read speech. Thus, rises are more likely to be seen as deviations from the canonical. When we observe rises, we expect them to mean something more than just a phonological boundary. So, looking at this data enables us to look at the effects of task and role on the frequency of rises, as well as giving as a more general view on how task-oriented and conversational dialogue differ.

2. Background

Direct comparisons of conversational and task-oriented speech have mainly focused on the greater need for affectual/emotional modelling in the former [12, 13]. While automatic role recognition has received more attention recently [14, 15], studies have not generally investigated in any detail how prosody varies with different role/move categories. However, some investigations of this type have been carried out with the goal of improving expressive speech synthesis. For example, [16] find that 'Assess' moves in the AMI corpus were produced with tenser voice quality, while project managers had higher average F0 and vocal effort. Dominant participants exhibited 'louder' voice quality features in [17]. While these studies provide broad descriptions for specific roles, they don't look at the contribution of intonation features like terminal rises in any detail.

Theoretical studies have analyzed rises as expressing uncertainty [18, 19, 20] or submissiveness [21, 22]. So, we might expect to find more rises in the productions of participants in socially submissive roles rather than leader type roles. However, empirical studies suggests that the distribution of rises depends heavily on situational and cultural conventions. For example, in a qualitative analysis of sorority speech, rises were used by senior members to take and hold the floor in monologues, while they were perceived as expressing uncertainty in narratives by uninitiated members of the group [23]. Similarly, in a comparison of several dialogue types, rises were found to be more prevalent in dialogues where one person has a socially dominant role, e.g. academic supervision versus informal office conversations [24] . Moreover, it was the socially dominant participant who produced the rises.

The latter study doesn't conditionalize over different move types, so it's not clear whether the more one-sided conversations simply involve more questions. In particular we would like to know when rises occur on sentence types that are canon-

ically falling in the dialect we are examining, e.g. declarative statements (informing moves) and imperatives (instructions) [25, 11]. Rises have also been analyzed in terms of contingency [26, 27], hearer dependence [28] about the rise carrying utterance. So, we would like to know whether the distribution of rises in a dialogue can be explained in terms of whether moves need explicit ratification or not. This would predict a higher number of affirmatives following rising moves. More generally, we would like to know if the distribution of rises can be adduced from the turn-taking structure of the dialogues, i.e. whether rises give or hold the floor.

3. Experimental Setup

3.1. Data

The IViE corpus was developed to systematically study differences across regions, speakers, and styles [11]. As mentioned previously, we look at data from Cambridge speakers as the most consistently 'falling' dialect in the collection. Twelve speakers (6 male, 6 female) from each region were recorded between 1997-2000. The speakers were 16 years old at the time of recording and had been born in and grown up in the region. The recordings include a mixture of read and spontaneous speech, of which we use the following:

- *Map task (map):* Each participant was given a map of a small town. Participants took one of two roles: Instruction *giver* and *follower*. The goal was for the giver to explain a pre-defined route around town on their map to the follower, who traced it out on their own map. The task ended when the route was completed to the satisfaction of both participants. Maps differed in place names and locations of landmarks, so speakers had to work to establish common ground. Speakers were separated by screens so they could not see each other. More details about this task can be found in [29].
- *Free conversation (conv):* Participants discussed smoking, face-to-face. Speakers had the same role, which was simply a *participant*

3.2. Segmentation and Annotations

Only short portions from four speakers were transcribed and annotated at sentence type level for each of these dialogue types in the official IViE release, so additional annotation was undertaken. The dialogues were manually segmented into utterances corresponding to whole meaning units rather than phonological phrases (cf. [30]). This was done as a conservative measure of the frequency of rises. Sentential segmentation delimited whole propositions including any embedding. Similarly, imperative utterances mapped to one action (i.e. one segment of the route). A number of sub-sentential clauses also formed separate utterances, e.g. an NP or VP as an answer or a modifier separated by an affirmative, which were as marked as XPs. Utterances were labelled with sentence (syntactic) and move types:

- Sentence type: Declarative (dec), Imperative (imp), Polar question (yno), Wh-question (whq), Tag (tag) question, Affirmative (affirm), Negative (neg), Cue word (cw), If antecedent (IFA), XP (XP).
- Broad dialogue moves: Affirm, Neg, Contra (direct contradictions), CW (cue words), Inform, Instruct, Q (non-syntactically marked question), YNQ (polar question), WhQ (wh-question), Tag (Tag-question), sync (synchronize).

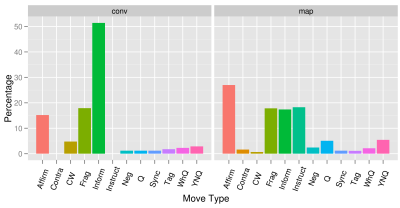

Figure 1: *Proportions of moves:* $N_{conv} = 430$, $N_{map} = 1287$.

The rationale for using such broad move types was to keep the annotation in terms of easily identifiable categories which could be refined in the future. In many cases, one sentence type dominated a move type (e.g. wh-questions). The main points of variation were in the declaratives which we see as instructions, informing moves, and questions, amongst other moves. Similarly, instructions, while primarily imperative in form, were also expressed as declaratives, polar questions or if-antecendents ('If you could go to the church'). The *sync* category captured utterances in the map task like 'You should be at the Anne's Arms' which were not quite questions, instructions or inform moves. A backchannel category was not included as it was not clearthat the distinction could be reliably made [31]. Moreover, it did not seem that any of the affirmatives in the map task could be clearly classified as simple signals of attention. In the investigations to follow we will concentrate on the most populous and easy to identify categories: Affirmative, Instructions and Inform moves. Utterance segmentation of the dialogues resulted in 430 and 1287 utterances for the conversational and map task sets respectively. The distribution of moves is shown in Figure 1.

3.3. Boundary pitch features

The target area for analysis was the stretch of speech from the last prominence rather than the last word. Extension away from the last word was generally due simply to stress assignment in compounds (e.g. *bowling* alley) or deaccenting of pronouns, (e.g. *about* it). Utterances with speaker overlap at the target were excluded from the prosodic analysis (3% conv, 4% map).

The F0 contour data on target segments was extracted using the Praat autocorrelation method. Parameter settings were automatically determined using the method described in [32]. Utterances which produced less than 5 F0 points were discarded. The F0 data was normalized into semitones relative to the median F0 value (Hz) for each speaker using data produced in all IViE tasks including read speech [11]. F0 contours were smoothed using a Butterworth filter and contours were approximated using Legendre polynomial decomposition of order 4 (cf. [33]). Instead of making categorical judgements about shape, we will instead look at first three coefficients where LC1 increases with overall pitch *height*, LC2 increases with positive contour slope (or *tilt*), and LC3 with *convexity*. Positive LC2 and LC3 indicate a fall-rise contour with an overall rising trend, negative LC2 and LC3 indicate a rise-fall contour, while values close to the origin indicate a flat contour. Previous work has described the relationship between these features and ToBI perceptual labels [34].

4. Results

4.1. Rises across dialogue types

Figure 2 shows the distribution of values for LC2 ad LC3 by move type. Overall, the map-task data can be characterized as

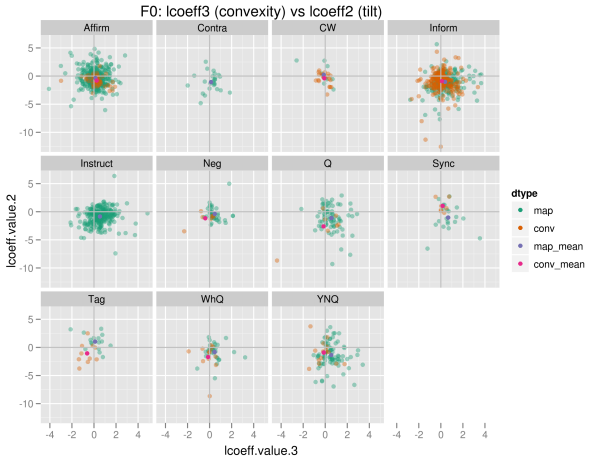

Figure 2: *Tilt (LC2) and Convexity (LC3), by move type, with means.*

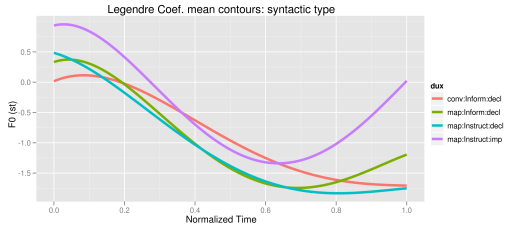

Figure 3: *Mean contours Instruct and Inform moves based on Legendre coefficients grouped by syntactic type.*

having more rising features, with these mainly coming from instructions and affirmatives. We see that Instruct moves are mostly situated in the positive LC3 space, indicating a fall-rise contour. The distribution of affirmatives in the map task extends into the positive LC2 space, indicating rising tilt.

Inform and Instruct moves make up 44% of the utterances in the map task, while 66% of conversation moves were Informs. These moves provide most of the 'new' content in the dialogue and are canonically falling in Southern Standard British English [25]. So, this subset of moves are good indicators that task affects the distribution of rising features. Figure 3 shows mean contours for Inform and Instruct moves which are declaratives, as well as the imperatives for comparison. Within the Instruct moves, syntactic imperatives are particularly rising compared to declarative instructions. We see that, on average, Inform declaratives are more rising in the map task than in conversational speech.

In order to quantify this we model the relationship between Legendre polynomial coefficients and dialogue factors (role, move, and syntactic type).[1] We fit (non-nested) multilevel linear models predicting values of LC1, LC2 and LC3. The model parameters were estimated using the package `lmer` in `R`. We only see significant effects for role when we look at convexity (LC3). The effect estimates and confidence intervals shown in Figure 4 indicates that being an instruction giver (1) increases convexity, while simply being a conversational participant (3) decreases it. In terms of moves, there is a signficant positive effect on convexity for imperatives (i.e. fall-rise). The effect of

[1]Note: Role encodes the task.

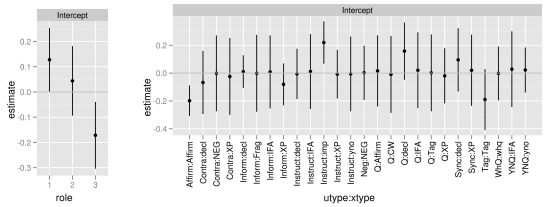

Figure 4: *F0 convexity (LC3) parameter estimates.*

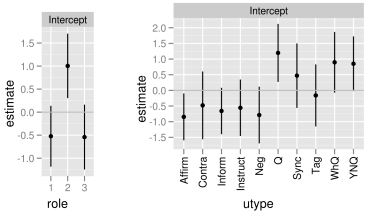

Figure 5: *Speaker change parameter estimates: 1=giver, 2=follower, 3=conversational participant.*

Affirm moves was negative on convexity, but positive on height and tilt, with a positive value for the instruction follower. This again points to there being more rising affirmatives in the task-oriented dialogue. Interestingly, yes/no and declarative questions have a negative relationship with tilt. This suggest that the specific questioning use of rises is less in play in these sorts of dialogues.

4.2. Turn-taking

Since Cambridge imperatives and declaratives are usually described falling at the boundary we would like to know whether the rises we see in the map task data can be attributed to other discourse factors like turn-taking. To do this, we fit parameters for multilevel logistic regression models (stay=0, switch=1). We compare a model containing speaker, role and move factors with one extended with Legendre coefficients as predictors (adding syntactic indicators did not improve the model fit).

Looking at the parameter estimates in Figure 5, we see that being the instruction follower (role 2) increases the probability of a switch by 25%. The trend for the other two roles is to hold the floor. In terms of move type, we see that the broad class of question moves increase the probability of switching, while content adding moves decrease it, although we saw previously that these generally had a falling tilt. With respect to move-role interaction, affirmatives produced by the instruction giver are likely to result in stays. That is, instruction givers seem to use affirmatives as a ready signal. The effects of the other move-role combinations are quite small in comparison.

Figure 6 shows significant positive effects for LC2 and LC3 (estimated coefficients: 0.12 and 0.2 respectively.) However, the magnitudes of these effects are relatively small compared to the effects of role and move. For example, when LC2 equals 1 we get an approximate 3% increase in probability of a switch, where the 95% interval of values in the observed data for LC2 is $(-4.15, 2.30)$ (LC3: $(-1.39, 2.12)$). So it seems that having higher tilt or convexity nudges up the probability of a speaker switch, but the contribution is not as strong as that of move or role. As we would expect, question type moves are generally turn giving irrespective of whether the utterance has a rising or falling boundary. To see whether rising features have different

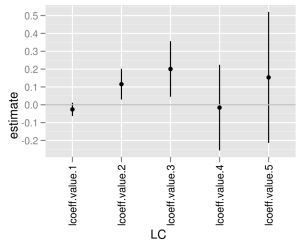

Figure 6: *Turn-taking: LC data as individual level predictors.*

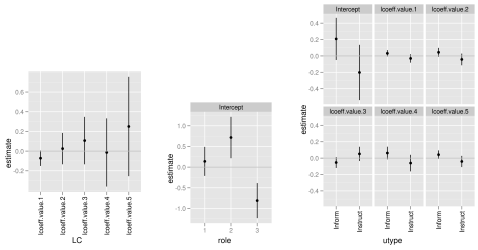

Figure 7: *Predicting Affirmatives after Inform/Instruct moves with LC features as individual level predictors and predictors on the move group.*

effects on different move types for turn-taking we extend the model to allow coefficients for the LC values to vary by move type. However, the difference between the previous two models is very small: DIC decreases from 1809 to 1802 where the new model adds many more parameters. So, it does not appear that rising features have much of a role to play in determining who takes the floor.

4.3. Eliciting Affirmatives

To check whether rising features signal a need for explicit ratification/agreement, we fit a multilevel logistic model predicting whether or not Inform or Instruct moves are followed by Affirm moves with the same predictors as above but coding an Affirm response as 1, and other responses as 0. If rises do signal a need for ratification we would expect to see that the probability of an affirmative increase with LC2 and LC3. After controlling for the higher level dialogue features, we see that the effects of the contour shape features to be, again, dwarfed by the effect of role. Estimated coefficients for the pitch features are around ± 0.05 at the move level, resulting in about a $\pm 1\%$ change in the likelihood of an affirmative response for every LC coefficient unit (cf. Figure 7). The effects are similarly close to zero at the individual level. On the other hand, being the map task follower, again, increases the probability of the next move being an affirmative by about 18%. In general, we don't see that pitch shape features on content moves are predictive of whether or not that move will be explicitly ratified.

5. Discussion

Our goal was to find out if higher level effects like task, role and move type had an effect of whether an utterance was produced with rising features. Looking at the Cambridge IViE data, it seems that we do get more rising features in the task-oriented speech than the free conversation, mostly with respect to instructions and affirmatives. While we saw that significant positive effects of tilt and convexity coefficients for speaker changes and production of affirmatives, we also saw that these effects were dwarfed by the effect of role. So, whatever the rising features are doing on these turns, it does not seem that their main role is to manage turn-taking. Instead, turn-taking strategy seems mostly dictated by the higher level, task structure of the dialogue.

How do our results fit with other analyses of rises? It is hard to reconcile the data with accounts that link rises to *propositional* attitudes (i.e. attitudes about the content bearing the rise). For example, we wouldn't want to associate rising features with how we usually think of epistemic uncertainty (contra [18]'s Maxim of Pitch), nor would be want to associate them with social submissiveness [21] or lack of speaker commitment [28], since these features are predominantly used by by the instruction giver, i.e. the situationally dominant speaker. In fact, if the instruction giver is uncertain about anything, it's not about the actual route. Instead it seems to be about whether the follower can or will carry out the task, i.e. discourse structural uncertainty. Similarly, the instruction giver is at the mercy of the follower in terms of task completion. So, at a glance we might say that the map-task shows more rising features because it just has more contingent elements (cf. [27, 26]. However, we saw that rises don't seem to elicit ratification in terms of explicit affirmative responses. So, if rises do signal contigency it is not necessarily about the current utterance.

An alternative is that the speaker deploys rising features because it is important to attend to whether a task is open or closed, since each subtask is dependent on the subtask before it. That is, we get more rises because there is a more well defined subtask structure (cf. [30]) and participants need a high level of common ground co-ordination in order to reach the end-goal of the dialogue. The need for co-ordination is much less pressing in conversational speech where participants are basically voicing opinions. So, the notion of contingency we are dealing with is at a higher level than accepting single instructions. From this point of view, explicit affirmation (rise or not) is a good strategy for the map-task follower, but rises primarily signal that there is more to come [35]. Thus we expect to see more rises in dialogues where greater quality of co-ordination is required.

6. Conclusion and Future Work

In this paper we saw that that higher level discourse factors, like task and role, have an effect on whether an utterance is produced with rising features or not. Overall, we found that content providing utterances in map-task dialogues had greater convexity than those from the conversational dialogue. Most of this seemed to come from instruction moves which often had a distinct fall-rise shape. While the rate of Affirmative moves was higher in the map task, we didn't find any strong link between rising features – higher LC2 and LC3 – and affirmative responses, or more generally speaker switches or stays. This state of affairs sits best with discourse structural analyses of rises, rather than notions like submissiveness or uncertainty. It appears that the more speakers have to co-ordinate through verbal signals, the more rising features we expect to see. So, these sorts of contextual conditions need to be taken into account when we collect and analyze intonational data.

Further work looking at the relationship between frequency of rises and the overall quality of task-completion, as well as comparision to other dialects, especially default rising ones such as Belfast English, and styles, will help complete the picture of where intonation fits into semantic/pragmatic theories.

Spontaneous speech corpus data validates prosodic constraints

Philippe Martin

philippe.martin@linguist.univ-paris-diderot.fr

Abstract

In the Autosegmental-Metrical model, the prosodic structure is defined as a hierarchy of Accent Phrases (AP). Groups of AP form intermediate prosodic phrases ip, which in turn are grouped into Intonation Phrases IP, and finally sequences of IP form the sentence intonation unit. In this hierarchy several constraints affect the prosodic structure, such as the AP 7 syllables rule, the stress clash conditions, eurhythmicity and syntactic clash.

These constraints have been established essentially from read sentences data. They lead to an experimental justification in the observed synchronization of AP's syllabic chunking by Delta brain waves.

This paper investigates the validity of the prosodic structure constraints on spontaneous speech data in French, as well as the adequacy of the Delta waves characteristics to synchronize AP data.

Index Terms: prosodic structure, accent phrase, spontaneous speech, Delta waves, eurhythmy.

1. Introduction

In the classical Autosegmental-metrical approach, the prosodic structure is defined as a hierarchical organization of minimal prosodic units, the Accent Phrases (AP, aka prosodic words, rhythmic groups, etc.), a sequence of syllables which contain one lexical stress (or a metrically strong syllable). Groups of AP's form intermediate prosodic phrases ip, groups of ip form Intonation Phrases IP, and groups of IP form the complete sentence intonation. In this hierarchy, the whole sentence intonation can eventually be reduced to one single IP, which may contain a single ip, which itself may include a single AP.

Furthermore, the prosodic structure is constrained by a set of rules [8]:

a) AP 7 syllables rule;
b) Stress clash;
c) Eurhythmy;
d) Syntactic clash.

The maximum number of 7 syllables per AP was already mentioned by Meigret [12]. Stress clash pertains to avoidance of two consecutive stressed vowels in sentence realizations [12]. Eurhythmy ([3], [8], [14]) determines the tendency to either balance the number of syllables in successive IP's (or possibly ip's), or compensate the duration of enunciation of successive IP's containing an unbalance number of syllables. Finally, syntactic clash defines AP's allowed alignments with sequences of grammatical categories, which for instance cannot group a Verb followed by a determinant (something like *which for the* or *followed by a* in a single AP). In these examples, in the syntactic structure, syntactic units (words) are dominated immediately by nodes that group (i.e. are fathers) units which do not belong to the same AP.

Another characteristic pertains to the composition of AP, assumed to contain a single lexical word (Verb, Noun, Adjective or Adverb) possibly accompanied by grammatical words (Pronoun, Conjunction…) [2]. The validity of the rule will be evaluated as well.

2. Testing the hypotheses

The prosodic structure constraints originate mostly from observations pertaining to read sentences built by linguists. The goal of this paper is to evaluate the validity of these constraints for spontaneous speech, and also test a hypothetical cognitive explanation for each of the constraints.

Briefly stated, the cognitive hypothesis assumes that Delta brain waves are synchronized by stressed syllables (ending accent phrases in French) much as syllabic perception is synchronized by Theta waves [5],]6]. This synchronization would operate even if stressed syllables are not in final position.

Delta waves frequency varies from 1 Hz to 4 Hz, i.e. their periods vary from 250 ms to 1000 ms. This suggests that Delta waves are responsible for the conversion of sequences of syllables stored in short-time memory into a higher level linguistic unit, corresponding to AP's [6], [12]. This process timing is limited by the extreme values of Delta periods, whereas minimal period of Theta waves, which synchronize the perception of syllables, is about 100 ms (10 Hz).

The Delta wave hypothesis would be validated for constraints a) and b) if the observed AP longest and shortest duration would not exceed the Delta wave period values, whereas eurhythmicity would be explained if a compression effect would affect AP syllable duration, the shortest AP containing longest syllables, and the longest AP the shortest syllables.

Finally, the syntactic clash constraint could be validated by the total absence of realizations violating this alignment condition in the corpus. In addition, the validity of the AP composition with lexical words will be questioned, as occasionally some examples show AP containing only grammatical words.

These hypotheses are central in the prosodic incremental storage concatenation process proposed in [11]. In this model, acoustically and phonologically differentiated prosodic events trigger various transfer in the listener memory: a) transfer of syllables into another part of memory synchronized by Theta brain wave, b) transfer of syllabic chunks (correspond to AP's) into another short term memory synchronized by Delta waves, and c) concatenation of these sequences of partial processing into an interpretation module synchronized by differentiated prosodic events (various melodic contours).

3. Data analysis

To test the prosodic structure constraints, French data were selected as the absence of lexical stress in French may a priori

lead to more variations in AP number of syllables, as one single Accent Phrase can contain more than one lexical word, as in *le bilan des ventes* "the stock sales" pronounced rapidly, with two nouns *bilan* and *ventes* belonging to the same AP.

Analyzed data were taken from the C-PROM corpus [16]. C-PROM is a transcribed, aligned and annotated corpus, developed among other applications, to evaluate syllabic prominences in French. It includes 24 recordings belonging to 6 different speech styles of francophone speakers originated from Belgium, France and Switzerland. Only French speakers were retained in this study. Details and transcription formats can be viewed on line.

Primary data were then transferred to WinPitch [17], whose routines allow a direct analysis into an Excel sheet of results, giving automatically in one single mouse click (Fig. 1 and Fig. 2):

a) The number of syllables in each AP;
b) The overall AP duration in ms;
c) The average syllabic duration in a given AP;
d) The AP stressed vowel duration;
e) The API vowel transcription;
f) The AP transcription in API;
g) The AP orthographic transcription;
h) Time references of the events.

Figure 2. Example of Excel sheet of primary results (*nar-fr speaker*)

The speech styles of the corpus are:

lec-fr: oral reading;
cnf-fr: university conference;
nar-fr: narrative, life story;
pol-fr: political discourse;
jpa-fr: radio news.

The iti-fr itinerary style of the corpus was not retained as recordings were considered too short, whereas the lec-fr recording are kept for comparison with the non-read styles.

Since French has no lexical stress, only boundary tones (in AM terminology) are observed. Their effective realization is sometimes difficult to establish as linked to the effective stressed characteristics of given syllables [10], but the error rate can be estimated at less than 5 %.

The original labelling of stressed syllable into two degrees of stress, noted p and P, were carefully revised. As few occurrences were found questionable, informal perception tests were conducted for possible corrections and adjustments.

An example of AP stress syllable revision is given below.

In cnf-fr, a segment was originally transcribed as:
de deux cent soixante-cinq phrases, dədøsãswasãtsœ̃fʁaz*
with seven syllables pronounced in 1491 ms. But listening more carefully two AP were actually realized :
De deux cent dədøsã* and *soixante-cing phrases* swasãtsœ̃fʁaz (« of two hundred sixty five sentences") with two accent phrases, of respectively 3 and 4 syllables.

The AP's duration are taken from the right boundary of the syllable vowel to the next stressed vowel right boundary. When the stressed syllable is preceded by a pause, the end of the pause is retained as the starting time reference to measure the duration of the current AP ended by the next stressed syllable.

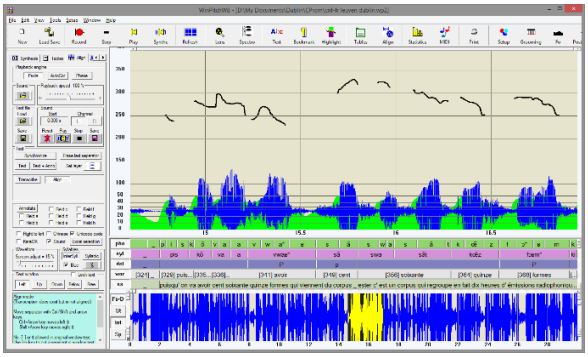

Figure 1. Example of WinPitch display [17]. The second transcription tier displays the syllables in API, with perceived prominence indicated by a star (*cnf-fr speaker*)

4. Results

Table 1 gives the following results pertaining to the hypotheses to be tested:

a) Longest AP duration;
b) Shortest AP duration;

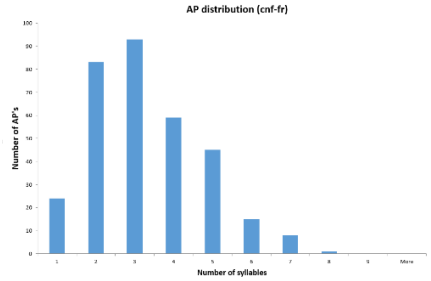
c) Number of stress clash violation.

These values were computed for each recording styles individually, in order to evaluate the possible influence of speech styles on the results.

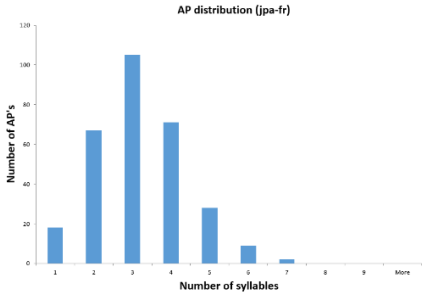
Table 1. Longest and shortest AP duration (in ms) and AP duration vs. number of syntactic clash violation for five speech styles.

Duration	Lec	Cnf	Nar	Pol	Jpa
AP Max	1260	1134	1058	975	1258
AP Min	435	277	354	438	241
Synclash	0	0	0	0	0

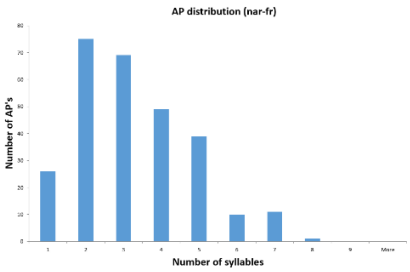
Histograms giving the distribution of the number of syllables per accent phrase are given Fig. 3. They are very similar for the five styles retained.



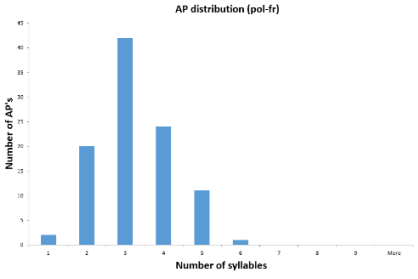
Distribution of cnf-fr number of syllables in AP's



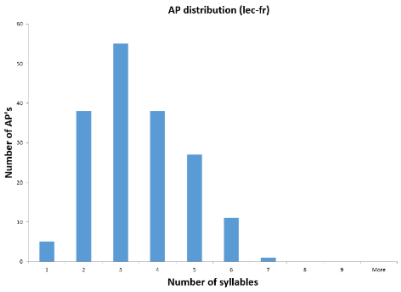
Distribution of jpa-fr number of syllables in AP's



Distribution of nar-fr number of syllables in AP's



Distribution of cpol-fr number of syllables in AP's



Distribution of lec-fr number of syllables in AP's

Fig. 3. Distribution of the number of syllables for the C-PROM styles retained

The only noticeable difference pertains to pol-fr (political speech), which uses a more restrained distribution of AP number of syllables similar to lec-fr, i.e. 3-4 vs 1-7 or 1-8 for the other styles. This suggests that pol-fr style was, at least partially, read speech.

Fig. 4 and Fig. 5 give the corresponding distributions of shortest and longest AP duration in function of the five styles considered.

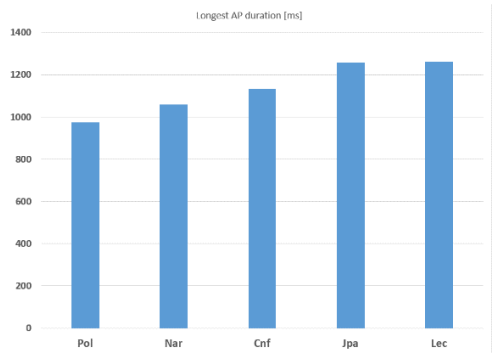


Fig. 4. Longest AP duration in ms

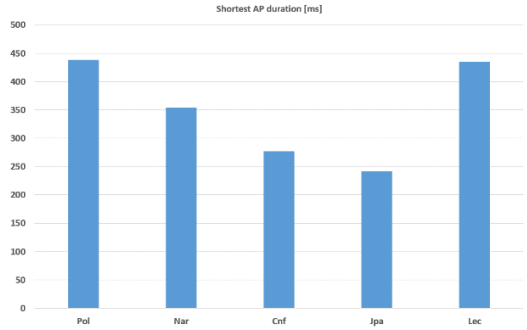

Fig. 5. Shortest AP duration in ms

These distributions show that the spoken news style uses the shortest AP's, whereas the reading and political recordings favor longer minimal AP duration.

The regression line of Fig. 6 demonstrate the compression of AP's duration in function of their number of syllables. When this number increases, the average duration of syllables is reduced allowing a single AP to contain up to about 7 syllables.

The regression lines of the other styles are not shown, as being similar to the one presented (cnf-fr).

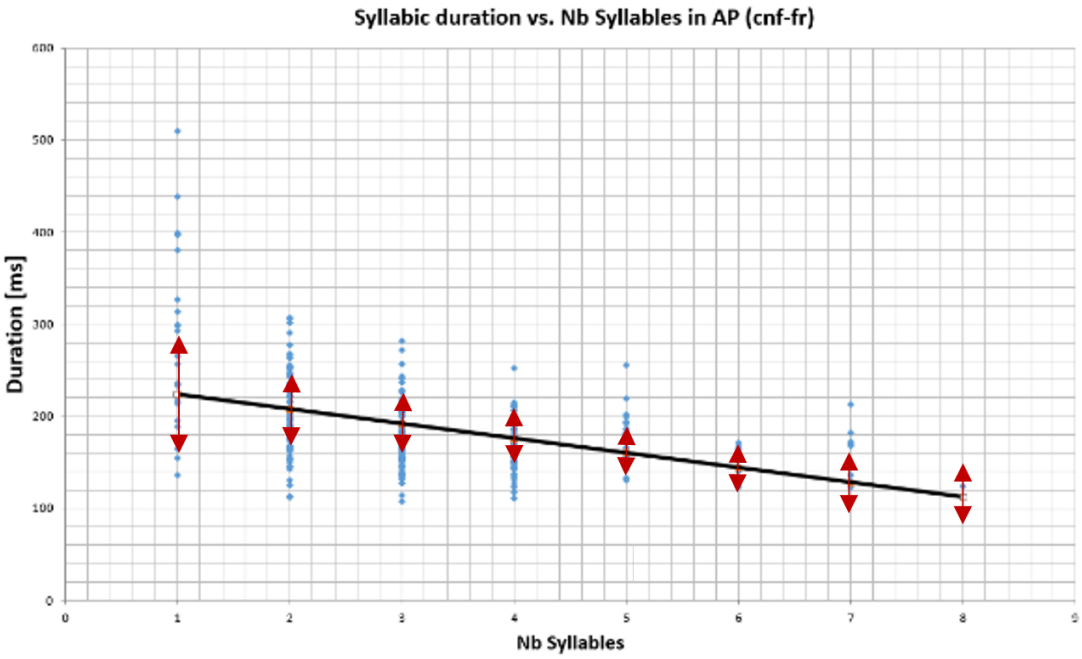

Figure 6. Syllabic duration in function of the number of syllables in AP regression line (*nar-fr*). Standard deviation is indicated by double arrows.

These regression lines correspond to the results given in [12] and [1], the longest the AP duration, the shortest are the syllables they contain.

5. Interpretation of results

1.1 Maximum and minimum values of AP's duration

Table 1 and the following figures suggest that Delta brain waves synchronization hypothesis is validated, as the minimum and maximum values do correspond convincingly to the maximal and minimal values of AP duration values.

1.2 Eurhythmy

Fig. 6 shows that eurhythmy is obtained by compression of the syllabic duration for long AP's.

1.3 AP's grammatical words

Table 2. Number of AP's containing only closed class words (Conjunctions, determinants, etc.) over the total number of AP's in each recording.

	Lec	Cnf	Nar	Pol	Jpa
Cases	**4/175**	**18/223**	**2/290**	**0/100**	**11/300**
	2%	**8%**	**0.6%**	**0%**	**3.6%**

This table shows clearly that the hypothesis pertaining to the AP content is invalidated. Not only can an AP contain more than one open class word in French, but spontaneous speech data include a relatively large number of occurrences of AP's with only grammatical words.

6. Conclusion

The analyzed data on various styles of spontaneous speech data validate the proposed explanation for prosodic structure constrains, namely:

a) The maximum number of syllables in a given AP is indeed of the order of 7 to 8, but the actual limit is given by the largest possible Delta wave period, about 1200 ms. Examples of AP containing up to 12 syllables in are found for example in [7], but even in this fast speech rate case their duration is below the Delta brain wave limit of 1200 ms;

b) Successive stressed syllables are found ("stress clash", corresponding in French to one single syllable AP following the first AP) but there is a minimal amount of time between two consecutive stressed syllables (actually between two consecutive stressed vowels). This observation confirms the hypothesis about Delta brain waves synchronizing the perception of AP, in the case at a maximum frequency, i.e. a minimal period of about 250 ms.

c) Cases where eurhythmy is obtained at the expense of congruence of the prosodic structure with syntax are rare so the eurhythmic compensation is done by compressing the syllabic duration in AP with many vowels. This was already observed empirically in [4], [8], [15] and more recently in [1]. One of the reason why balancing of the number of syllables is not frequent in spontaneous data may pertain to the fact that such balancing requires preplanning essentially possible for read speech (cf. the

read phrasing [*Marie adore*] [*les chocolats*] vs. the spontaneous [*Marie*] [*adore les chocolats*]). It seems that speakers realize eurhythmic phrasing when the syntactic constraint is weak or absent, i.e. for enumeration, short read sentences, etc.

d) No cases of syntactic clash were observed;

e) However, occurrences of AP containing no lexical words and only grammatical word are not infrequent.

The next step in this research would concern other Romance languages with lexical stress, and later tone languages such as Mandarin with no lexical stress.

Romance languages other than French may show the coexistence of a lexical stress and a tone boundary sometimes combines on the same AP final syllable (in Italian for example). These two prosodic events may play the same role (or complement each other) in the storage concatenation process proposed by [11].

Hearing the Structure of Math: Use and Limits of Prosodic Disambiguation for Mathematical Stimuli

Michael Phelan

Department of Linguistics, The Ohio State University, USA
phelan@ling.osu.edu

Abstract

Listeners use the prosodic cues of an utterance to help determine its syntactic structure, but how does this process happen in the specialized domain of mathematics? Mathematical expressions can contain deeply embedded structures, and listeners encounter read mathematical expressions (RMEs) far less frequently than other potentially ambiguous utterances. How does experience with listening to math affect our ability to hear the structure of an RME via its prosody? Are there limits to the amount of structure we can pull out of the prosody of an utterance?

A perception experiment was conducted with subjects aged 7-59 to help answer these questions. Participants heard recordings of RMEs and attempted to determine which of two or more mathematical structures the reader intended. When subjects chose between two options for phrases like *nine times A minus two*, they chose the mathematical expression that had bracketing matching the prosody of the utterance. However, for more complex phrases like *the square root of sixteen over A plus twelve*, results were at chance. Age played a surprising role: subjects' performance increased dramatically from age 7 to 16, but adults' performance varied widely. This is attributed to variation in exposure to read mathematics.

Index Terms: speech perception, acquisition of prosody, prosody of mathematics

1. Introduction

If you have just heard someone say *two plus three squared*, should you be thinking of 11 or 25? The present study shows that the answer largely depends on the prosody of the utterance. Speakers use prosodic manipulations to communicate the intended grouping of words and phrases in their everyday English utterances, and listeners make use of these manipulations when determining which of several possible syntactic structures the speaker intended [1][2]. This paper extends these findings to the domain of read mathematical expressions (RMEs) and explores variations in the way listeners of different ages interpret certain prosodic phrasing. Finally, limitations on the use of prosodic phrasing for disambiguation are investigated with the use of complex RMEs that could correspond to more than two possible mathematical structures.

Read mathematical expressions provide and ideal test case for investigations of prosodic disambiguation for several reasons. First, the written form of a mathematical expression unambiguously shows the structural relationships between terms of the expression at a glance, while the utterance used to describe the mathematical expression can be ambiguous between two (1) or more (2) structures.

(1) Nine times A minus two: $(9 \cdot A) - 2$ $9 \cdot (A - 2)$

(2) The square root of sixteen over A plus twelve:

$$\frac{\sqrt{16}}{A+12} \qquad \frac{\sqrt{16}}{A}+12 \qquad \sqrt{\frac{16}{A}+12}$$

$$\sqrt{\frac{16}{A+12}} \qquad \sqrt{\frac{16}{A}+12}$$

Unlike everyday English stimuli, none of the mathematical structures corresponding to RMEs are inherently more or less plausible, and frequency effects are unlikely to bias listeners towards one selection or another.

Importantly for the purposes of this paper, readers in the same speech community have widely varying levels of experience with mathematical stimuli. Children who have long since attained adult-like levels of proficiency in using prosodic cues to disambiguate everyday English utterances may not yet have come across mathematical expressions like (2), and adults who do not work in education or math-heavy fields may not have dealt with such expressions in many years. On the other hand, older children and teenagers frequently encounter such expressions in the classroom, and thus may have an easier time disambiguating utterances of these expressions.

Finally, research to date on listeners' use of prosody for disambiguation has largely focused on whether a phrase should be interpreted with high or low attachment to previous parts of of the sentence. Comparatively little work has been done on prosodic disambiguation of utterances with many possible interpretations. The ease of generating such complex stimuli with mathematical utterances such as (2) can thus shed some light on the limitations of what listeners are able to disambiguate when forced to rely on prosodic cues alone.

2. Background and Assumptions

2.1. Previous research

Study of the prosodic disambiguation of syntactic ambiguities in non-mathematical speech goes back many years. Speakers have been shown to use lengthening and pausing to mark the intended structures of sentences with prepositional phrase and relative clause attachment ambiguities, complex noun phrase coordination ambiguities, and many others [3][4]. Listeners have likewise been shown to be sensitive to these

manipulations, at least when the interpretations differed in their syntactic bracketing [1][2].

A few previous studies investigated prosodic disambiguation of mathematical stimuli. Streeter [5] and Wagner [6][7] used simple mathematical stimuli like (3) and found that both speakers and listeners use the same prosodic disambiguation strategies as with non-mathematical stimuli.

(3) a. $A + (E \cdot O)$
b. $(A + E) \cdot O$

Only a few authors have used more complex mathematical stimuli, and all did so only in production. [8] and [9] both found longer pauses at locations likely to be marked with parentheses, though the only prosodic events coded by [8] were pauses over 300ms in length and [9] used a single speaker who consciously tried to prosodically disambiguate very complex stimuli.

In a production experiment with both simple (1) and complex (2) stimuli, [10] found that speakers produced RMEs using four distinct prosodic patterns. When intending structures like (3a), speakers most often used a strong prosodic break early in the utterance to group later terms together. When intending structures like (3b), speakers used a late prosodic break to group early terms together. Because the prosodic structure of these two sorts of utterances matched their syntactic structure, [10] referred to these utterances as having "cooperating prosody". In a few cases, speakers did the opposite, producing RMEs where the placement of breaks in prosodic structure grouped terms contrary to their grouping in syntactic structure, which [10] referred to as "conflicting prosody". Finally, many speakers produced evenly sized prosodic breaks throughout the utterance. Though the prosodic structure in these utterances did not necessarily group terms together in any particular way, different prosodically flat structures were used in different ways by speakers. When flat prosodic structures were used to indicate structures like (3b), the prosodic breaks were significantly more likely to be large, either all intonational phrase (IP) breaks or all intermediate (ip) phrase breaks. When flat prosody was used with structures like (3a), the breaks tended to be small (∅, or prosodic word-level breaks). [10] referred to these prosodic patterns as "big flat" and "little flat". The current study uses stimuli from [10] to determine whether these four distinct prosodic patterns are interpreted by listeners the same way they are apparently intended by speakers, and whether age and the complexity of the mathematical expression affects listeners' ability to determine the structure the speaker intended.

2.2. Assumptions about prosodic processing

Accounts of the processing of prosodic breaks fall into two main camps: those assuming the Strict Layering Hypothesis of [11], and those like [12] that allow for recursion in the prosodic description of an utterance. Data from experiments like the one presented here can bear on this question, allowing investigators to test the limitations on what sorts of utterances can be reliably disambiguated via prosody. Both sorts of theories would agree that utterances of phrases like (1) should be easily disambiguated by listeners, while more complex phrases like (2) could quickly reach the limit of the number of psychologically distinct levels of prosodic phrases in theories that assume the Strict Layer Hypothesis. The number of prosodic layers available to the speaker should set a hard limit on the degree to which multiply-embedded mathematical phrases could be reliably disambiguated. Under theories like [12] that are not subject to this restriction, speakers and listeners attempting to disambiguate utterances of phrases like (2) could make use of continuously varying relative differences in boundary strength. Drop-offs in perception accuracy for these more complex utterances would need to be explained by limitations on working memory capacity, and thus should be more gradual.

3. Experiment

To answer the questions raised above, a perception experiment was conducted with 29 subjects recruited from a local science museum. Subjects ranged in age from 7 to 59 (mean 25.2, sd 14.9) and participated in the experiment in groups of two to seven. None reported hearing problems, and all subjects whose data are presented here were native English speakers.

3.1. Stimuli

Three sets of mathematical stimuli were used. Two sets were selected from the recordings made for [10], in which naïve college students were asked to read twelve pairs of expressions like (4) and (5) with similar structures but different numbers.

(4) a. $9 \cdot (A - 2)$
b. $(10 \cdot A) - 2$

(5) a. $\sqrt{\frac{16}{A+12}}$
b. $\sqrt{\frac{81}{A}+72}$

Speakers in [10] were asked to avoid using terms like *the quantity, parentheses,* and *all of that,* and were told not to rearrange the terms of the expression, but were not told of the possible ambiguity in their speech. The two members of each pair (4a, b; 5a, b) were separated by at least four expressions with different structures, to prevent intentionally contrastive readings.

The first set of stimuli were chosen from pairs where one speaker produced cooperating prosody on both RMEs in a pair. The second set were chosen from pairs where a speaker produced cooperating prosody on one member of the pair and conflicting prosody on the other. A third set of stimuli were used in which one member of each pair was produced with IP breaks after each number or variable (called big flat, as in [10]) and the other member had only prosodic word level breaks throughout (little flat). Since such pairs were rarely produced by the same speaker in [10], these stimuli were recorded for this study by the experimenter.

There were 66 total mathematical items, 44 of which allowed only two structures as in (1), and 22 of which allowed either three or five possible structures, as in (2). All three sets

of stimuli were intermixed, such that the same expression was never repeated without at least five others expressions in between. The 44 "easy" items appeared first, followed by the 22 "hard" items.

A fourth set of stimuli consisted of eight non-mathematical English sentences like (6), which contained ambiguities due to prepositional phrase attachment, relative clause attachment, or complex NP conjunction.

(6) Leslie photographed the manager with the iPad.

English stimuli were recorded by prosodically trained speakers unaffiliated with the study, who were told to disambiguate by putting an IP break either after the verb (for low attachment) or before the preposition (for high attachment) in PP attachment ambiguities and similarly for other ambiguity types. These eight non-mathematical English stimuli were given at the end to assess subjects' understanding of the general pattern of prosodic disambiguation in English.

3.2. Procedure

Subjects were given paper packets showing the possible mathematical structures that corresponded to each utterance. They were told they would hear people reading math problems and were to circle which problem they thought the subject meant, or, for the non-mathematical stimuli, which of two paraphrases they thought the subject intended. Stimuli were played back to groups of subjects via a laptop situated in front of the group, at a volume comfortable for all participants. There was a brief pause after each item to allow subjects to make their selections: six seconds following "easy" items, twelve seconds for "hard" items, and ten seconds for non-mathematical items.

4. Results

4.1. Mathematical results – Easy trials

Over all trials in which the subjects had a choice between exactly two mathematical structures, if the prosodic structure grouped two terms together, subjects were significantly more likely to pick the mathematical structure that grouped those terms together. Trials with cooperating prosody, where the grouping of terms in prosodic structure matched the grouping in syntactic structure, saw subjects selecting the intended mathematical expression on 67% of trials, significantly higher than chance (binomial test, $p < 0.001$). On trials in which the utterance was produced with conflicting prosody, where the prosody did not match the syntactic grouping the speaker intended to convey, subjects followed the prosody, choosing the mathematical expression that matched the prosody on 59% of trials (binomial, $p < 0.05$).

For the easy subset of problems with flat prosodic structures, listeners were significantly more likely to interpret "big flat" utterances containing IP breaks between each term as indicating left-branching syntactic structures (as in (3b)) than right-branching syntactic structures, doing so on over 80% of trials (binomial, $p < 0.001$). "Little flat" structures, however, were not consistently seen as marking one type of mathematical structure. Subjects selected left-branching and right-branching mathematical structures at essentially the same rate (binomial, $p > 0.3$) on these trials.

4.2. Mathematical results – Hard trials

On trials where subjects were asked to pick between more than two answer choices, there was an significant difference in performance between problems that allowed for multiply-embedded constituents and those that did not. When subjects did not have to consider multiply-embedded structures, accuracy resembled that of easy problems, with choices following prosodic structure on over 60% of trials. However, when the utterance was consistent with multiply-embedded structures, as in (2) and (5), subjects were no better than chance at selecting the expression the reader had intended to convey (binomial, $p > 0.4$).

4.3. Non-mathematical trials

Overall accuracy on the eight non-mathematical items was reasonably high at 79%, significantly better than chance (binomial, $p < 0.001$). However 10 of the 28 subjects did score at or slightly below chance on these eight items, showing that understanding of the general English prosody-syntax correspondence rules is not universal. There was no significant correlation between age and accuracy on the non-mathematical items ($t = 1.717$, $p > 0.09$), though the two youngest subjects were the least successful on these questions.

In general, subjects who were most successful on the non-mathematical trials were also more successful on the mathematical trials ($t = 3.470$, $r = 0.56$, $p < 0.005$).

4.4. Interaction with age

There was an overall trend for accuracy in selecting the intended mathematical expression to improve with age ($t = 2.073$, $r = .37$, $p < 0.05$), though figure 1 shows that there is more going on than a simple trend to get better with age. Subjects improve dramatically from age 7 to 16, while adults are scattered all over the range. On non-mathematical trials adults did significantly better than children (64.4% vs 57.5%, $t = 2.234$, $p < 0.05$).

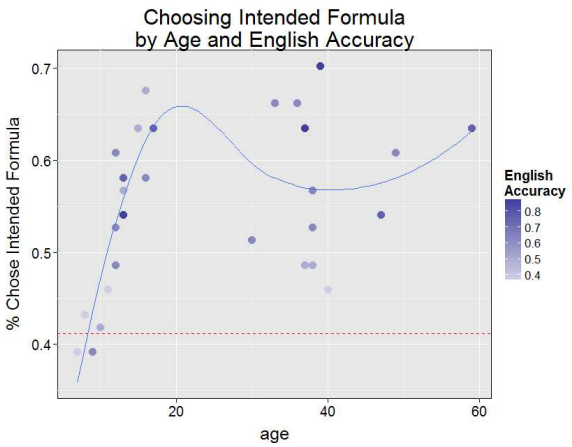

Figure 1. Effects of age and non-mathematical English trials accuracy in selecting intended form. Line of best fit is decidedly non-linear. Dashed line shows chance performance.

5. Discussion

In a listening experiment where they were asked to choose which of two or more possible mathematical expressions a speaker had intended to convey, subjects assumed that a larger prosodic break early in an utterance was meant to group later terms together, whereas a larger prosodic break later in an utterance was intended to group earlier terms together, as has been shown to be the case when listeners use prosody to disambiguate non-mathematical utterances.

Listeners correctly chose the intended mathematical form when there were only two options, or when there were more than two options but answers did not involve multiply-embedded phrasings. For trials where multiply-embedded structures were possible, listeners performed at chance. Under theories that follow the Strict Layer Hypothesis, this poor performance on complex problems could be attributed to listeners only have a small fixed number of psychologically distinct levels of prosodic phrasing. When the number of levels of embedding exceeds the number of prosodic phrasing levels available, disambiguation becomes difficult or impossible. Theories that reject the Strict Layer Hypothesis and allow recursion in prosodic phrasing would have to assume that this drop off in performance was due to higher memory load requirements for these complex mathematical expressions. The role of working memory in prosodic disambiguation could be tested by adding distractor tasks that increase memory load independent of the prosodic disambiguation task.

The striking effects of age evident in figure 1 suggests that familiarity with listening to or working with algebraic expressions like those used in the experiment has a strong impact on a listener's ability to use prosodic cues to disambiguate read mathematical expressions. The youngest subjects, just seven and eight years old, performed at or below chance. This was not surprising, given that these subjects were unlikely to have ever encountered expressions as complex as (4a,b), let alone (5a,b). [13] found that five to seven year olds could use prosodic breaks to choose between two different groupings in phrases like *pink and green and white,* but only when the pauses were quite pronounced (680ms), much longer than almost all pauses in stimuli here. Likewise unsurprising was the increase in performance for older children, who have had more experience with algebra and with prosodic disambiguation in general. What jumps out is the widely varying ability of adults in figure 1. While the results of the non-mathematical English trials clearly show that adults are able to use prosodic cues to disambiguate utterances, the presence of mathematical expressions seems to have greatly impacted adults' ability to apply the rules of prosody-syntax correspondence. Syntactically, the utterances used in the non-mathematical English trials are very similar or identical to those used in the mathematical trials, so differences between these two sets of results must be due to the fact that the stimuli were mathematical. It is unlikely that adults did not understand the structure of the mathematical expressions they were choosing between, since spacing, parentheses and other conventions of written mathematics indicate the grouping of terms quite clearly. It may be the case that adults, who generally do not have much exposure to algebraic expressions after graduating high school, are out of practice in applying known rules of prosody-syntax correspondence to the mathematical domain. There are few if any previous studies showing this sensitivity to a particular domain for prosodic disambiguation, and follow-up studies are underway with adult math teachers and college students majoring in math and engineering, who have much more exposure to mathematical expressions in their daily life.

Abstract

This paper presents an efficient pitch estimation algorithm for noisy speech signal using ensemble empirical mode decomposition (EEMD) based time domain filtering. The dominant harmonic of noisy speech is enhanced to make pitch period more prominent. The normalized autocorrelation function (NACF) of the modified signal is then decomposed into time varying subband signals using EEMD. In contrast to the ordinary EMD, it does not introduce any mode mixing during decomposition. The subbands containing pitch component are selected and separated yielding partially reconstructed signal. The pitch period is determined from thus separated signals. The experimental results show that the proposed algorithm performs better compared to other recently reported algorithms in noisy environment.

Index Terms: ensemble empirical mode decomposition, filtering, pitch estimation

1. Introduction

Pitch information is an important prosodic feature which is used in many speech processing applications including speech enhancement, automatic speech recognition, analysis and modeling of speech prosody, low-bit-rate speech coding [1]. Although there are many pitch estimation algorithms (PEAs), the development of an efficient PEA is still demanding.

Some PEAs implemented in time domain contained poor accuracy of pitch estimation [2]-[5]. Autocorrelation Function (ACF) based algorithm is introduced in [2]-[3]. The performance of ACF method is basically depended on pitch peak in the autocorrelation domain which may be quite difficult to perform against noise, quasi-periodic nature of the speech signals [6]-[7]. Normalized autocorrelation function (NACF) based algorithm has been presented in [2] which provides better results than ACF but suffer from robustness. A weighted autocorrelation (WAC) based method has been presented in [3]. It is easy to enhance pitch peak by dividing ACF with the AMDF in a lower portion than succeeding peaks but this leads the algorithm to cause a serious problem called double pitch error. Signal reshaping technique with the improvement of specific harmonic is presented in [6]-[7]. The dominant harmonic (DH) of the noisy speech signals is determined by using a DFT based method and boosted the amplitude of DH in the analyzing signal which is called dominant harmonic modification (DHM). This technique also fails to perform under noisy environment. The data adaptive techniques of pitch estimation are introduced in [8]-[11] using EMD [12, 13]. The ordinary EMD suffers from the 'mode mixing' effect decreases pitch estimation performance. To overcome the mode mixing problem, Wu and Huang [14] proposed a modification to the EMD algorithm what is termed as EEMD.

In this paper, a novel pitch estimation algorithm is proposed using the combination of DHM and EEMD. DHM plays an important role to overcome the double pitch error while EEMD acts as data adaptive time domain filtering to separate the signal containing only the pitch information which minimizes the pitch estimation error.

2. Pitch Estimation Algorithm

The noticeable improvement of the EMD based PEA is possible by overcoming the mode mixing problem. At first, conventional low-pas filtering is performed on the noisy speech signal. If $s(n)$ and $v(n)$ denote the speech and additive noise signals respectively, the observed speech signal $x(n)$ can be represented as: $x(n) = s(n) + v(n)$.

The noise effect can be reduced significantly by pre-filtering the observed signal $x(n)$ in the Fourier domain. As the pitch range of speech signal is well known to be 50-500Hz, a significant portion of the high frequency components is filtered out in frequency domain. The resultant signal is termed as pre-filtered speech (PFS) and represented as $\psi(n)$ which contains less noise. In the second phase of pre-processing, the DHM is applied to the PFS signal which is described in the following subsection.

2.1. Dominant harmonic enhancement

The dominant harmonic (DH) can be estimated as the one which has the largest amplitude in the Fourier domain [6].

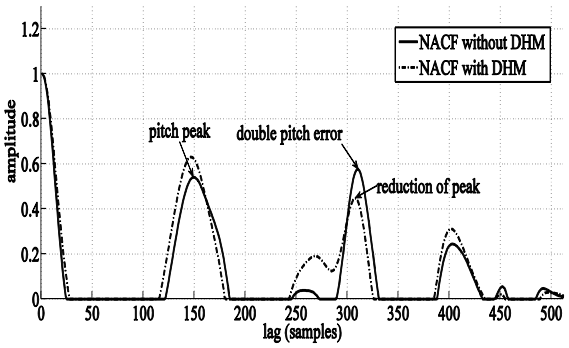

Figure 1: *Pitch peak enhancement using DHM for a voiced frame of a female speaker with 0dB SNR. NACF causes double pitch error but DHM resolves that problem. The true pitch is 151 in samples.*

Let $y_{dh}(n)$ denotes the DH present in the PFS signal $\psi(n)$. The signal after dominant harmonic enhancement denoted by $y(n)$ is then given by:

$$y(n) = \psi(n) + \bar{y}_{dh}(n) \quad (1)$$

where,

$$\bar{y}_{dh}(n) = \rho[y_{dh}(n) - |y_{dh}(n)|] \quad (2)$$

and

$$y_{dh}(n) = \theta_{dh}\cos(\omega_{dh}n + \delta_{dh}) \quad (3)$$

where, θ_{dh}, ω_{dh}, δ_{dh} are amplitude, frequency and phase of the dominant harmonic respectively, ρ is an arbitrary constant, and |.| denotes the absolute value. The parameter ρ controls the mixing ratio to be chosen appropriately. Figure 1 demonstrates the effects of the DHM which shows that the conventional NACF of $\psi(n)$ causes double pitch error while the use of DHM to $\psi(n)$ overcomes such error.

2.2. EEMD in pitch detection

EMD suffers from mode mixing effect which indicates that the oscillations of different time scales coexist in a given IMF, or that oscillations with the same time scale have been assigned to different IMFs [14]. Due to this problem, EMD does not guarantee the accurate frequency scale separation and pitch information can be mixed between two successive IMFs which degrades the pitch detection accuracy. EEMD utilizes the scale separation principle of the EMD. The principle of the EEMD is to add white noise into the signal with many trials. The noise in each trial is different, and the added noise can be canceled out on average, if the number of trials is sufficient. Let $\phi(n)$ is the NACF of $y(n)$. For signal $\phi(n)$, original EMD is defined as [12]:

$$\phi(n) = \sum_{k=1}^{N} c_k(n) \quad (4)$$

where $c_k(n)$ is the k^{th} IMF. EEMD decomposes $\phi(n)$ by first construction an ensemble of signal samples $\phi_m(n)$ by adding to $\phi(n)$, M independent copies of finite amplitude white-noise $\eta_m(n)$, i.e.,

$$\phi_m(n) = \phi(n) + \eta_m(n), \ (m=1, 2, \ldots, M), \quad (5)$$

Applying EMD to $\phi_m(n)$ and repeat until the trial number with different added white noise series of the same power at each time, the new IMF combination $c_k^{(m)}$ is obtained, where k is the iteration number and m is the IMF scale.

$$\phi_m(n) = \sum_{k=1}^{N} c_k^{(m)}(n), \qquad (m=1, 2, \ldots, M), \quad (6)$$

where, N is the trial number.

The ensemble means is calculated as:

$$\tilde{c}_k(n) = \frac{1}{M}\sum_{m=1}^{M} c_k^{(m)}(n), \qquad (k=1, 2, 3\ldots), \quad (7)$$

A large number (M) of samples and white noise of finite amplitude are required to force the ensemble to exhaust all possibilities in the sifting process. In this way, possible mode mixing is effectively removed, and components of different time scales embodied in the original signal are well collated in proper IMFs, whose frequency bands essentially approximate those dictated by the dyadic filter banks [14]. The effect of the added white noise should decrease following the well-established statistical rule:

$$\beta_n = \frac{\beta}{\sqrt{M}} \quad (8)$$

or

$$\ln \varepsilon_n + \frac{\varepsilon}{2}\ln M = 0 \quad (8)$$

where, M is the number of ensemble members, β is the amplitude of the added noise and β_n is the final standard deviation of error, which is defined as the difference between the input signal and the corresponding IMF(s) [14].

Mode mixing problem is illustrated in the left column of Figure 2, where a clean speech segment of 100 ms length is decomposed by EMD. The three IMFs with higher energy are shown. The appearance of oscillations of dramatically disparate scales in IMF_3 is clear. Another example can be seen in IMF_4, where two oscillations are marked with circles. These oscillations are very similar to those on IMF 5. On the right side of Figure3, in IMF_4 and IMF_5 there is no mode mixing, where $M=50$ and $\beta=0.1$ were used for generating the resulting IMFs decomposed by EEMD.

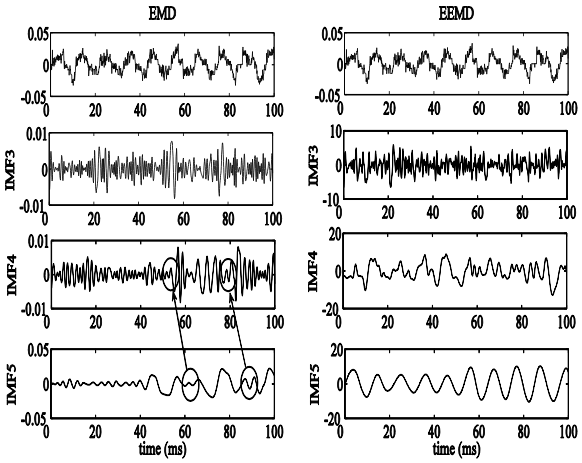

Figure 2: *A clean speech segment analyzed by EMD (left col-umn) and EEMD (right column). The corresponding IMFs 3 to 5 are shown. In IMF4 and IMF5of EMD where "mode mixing" occurs are marked with circles.*

The pitch detection performance using DHM method often reduced especially for low SNR speech signals [6]-[7]. To mitigate this shortcoming effects, EEMD based data adaptive time domain filtering is applied to the NACF of the DH modified signal $y(n)$ (equation-2) and a partial reconstruction is made from the EEMD domain to calculate the actual pitch period. The reconstructed signal $\lambda(n)$ is

obtained as $\lambda(n) = \sum \tilde{c}_j(n)$, where $\tilde{c}_j(n)$ are the IMFs and its fundamental periods are within the pitch range 50-500Hz. Let *ξ(n)* is the NACF of *y(n)*. The NACF *ξ(n)* and its corresponding partially reconstructed signal *λ(n)* are shown in Figure 3. It is observed that the pitch peak is more prominent in *λ(n)* and overcomes double pitch error.

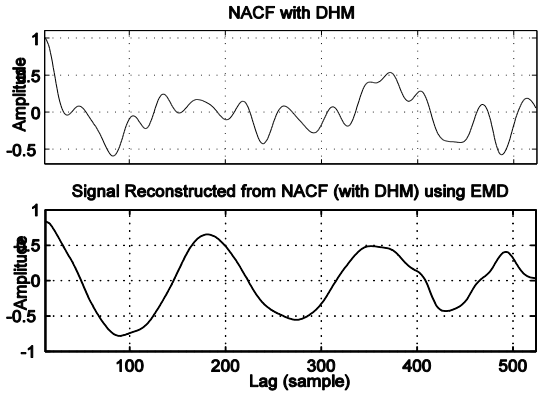

Figure 3: *NACF of the signal after performing the DH enhancement (above), the partially reconstructed signal from NACF with DHM using EMD (bellow). The double pitch error is eliminated (bellow).*

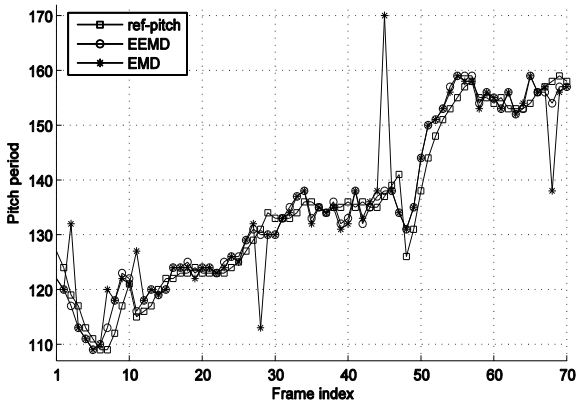

Figure 4: *Performance Comparison of pitch period estimated by EEMD (proposed) and EMD method with the reference pitch for female speech. The proposed EEMD based method performs better than EMD.*

2.3. Proposed pitch detection algorithm

The proposed algorithm for pitch estimation can be summarized as:

- Apply pre-filtering to the noisy speech signal to remove a significant portion beyond the pitch range 50-500Hz.
- Perform signal modification using DHM on PFS and then apply NACF to the modified signal.
- Apply EEMD to the obtained NACF.
- Sum up the IMFs with fundamental period lies within the specified pitch range for partial.
- Take the right half of the reconstructed signal.
- The amplitude at zero-lag is selected as the starting index of the pitch period.
- Find the next highest peak from the right half of the reconstructed signal.
- Calculate the pitch period from the difference between the starting index and the next highest peak index.

The detected pitch response based on the proposed algorithm has shown in Figure 4.

3. Experimental Results and Discussion

The performance of the proposed method is tested using the Keele pitch extraction reference database obtained from ftp://ftp.cs.keele.ac.uk/pub/pitch/ which contains the sampling frequency of 20 kHz with 16-bit resolution. Note that the value of the parameter ρ in Eq. (3) was set to 0.5. Both male (M2~M3) and female (F2~F3) mature speakers' speech are used here. There are 2650 'clearly voiced' male frames and 3227 'clearly voiced' female frames that is a total of 5877 analysis frames are used for experiment. White Gaussian noise and babble noise are used to corrupt the test signal to investigate the robustness. In the experiment, each 25.6 msec analysis frame is weighted by a 512-point rectangular and 10 msec is used as frame shift to generate the reference pitch values given in the database. If the estimated pitch for a frame deviates from the reference by >20%, we recognize the error as a gross pitch error (GPE).

The performance of the proposed EEMD based algorithm is compared with recent four PEAs - EMD based method [11], DHM based method [6], and conventional NACF method [2] and WAC [3] in presence of white noise as shown in Table I. It is observed that the proposed EEMD based algorithm performs better and closer to the original reference pitch (as shown in Figure 4) than all the mentioned PEAs for a wide range of SNRs(-5dB to 30dB). Figure 5 shows the average %GPE for male and female speakers respectively from which we see that the proposed PEA improves pitch estimation accuracy in noisy environment especially with low SNRs.

Table 1. *Performance comparison of EEMD algorithm with recently reported PEAs for male and female data. White noise is used to corrupt the speech signal.*

SNR(dB)		**-5**	**0**	**10**	**20**	**30**
M2	EEMD	6.72	5.51	2.02	1.54	1.53
	EMD	13.78	7.69	4.13	2.92	2.67
	DHM	14.26	7.45	2.99	2.26	1.94
	NACF	22.36	14.74	6.96	5.26	4.94
	WAC	25.20	15.23	7.37	6.17	6.07
M3	EEMD	3.12	0.99	0.21	0.14	0.07
	EMD	7.77	2.40	0.35	0.14	0.14
	DHM	12.28	4.73	1.12	0.56	0.35
	NACF	23.37	11.51	3.38	1.69	1.27
	WAC	24.29	12.07	3.38	1.20	0.98
F2	EEMD	5.51	1.98	0.93	0.88	0.55
	EMD	10.98	5.85	1.32	1.05	0.72
	DHM	10.97	6.39	1.93	1.15	0.93
	NACF	21.48	11.91	4.24	2.04	1.70
	WAC	23.05	11.58	3.97	1.93	1.59
F3	EEMD	5.51	2.97	0.98	0.28	0.21
	EMD	11.67	5.37	1.49	0.50	0.49
	DHM	11.38	6.01	2.05	0.70	0.49
	NACF	21.49	12.16	4.73	2.19	1.69
	WAC	21.78	7.85	4.38	1.64	1.62

In the second phase of experiment, we evaluate and compare the pitch detection performances of the proposed PEA with EMD [11, 15] and DHM [6] in noisy environment with bubble noise as illustrated in Table II. The proposed EEMD method provides better results than EMD and DHM based methods for the whole range of SNRs (-5dB to 30dB). The average performance comparison for this experiment has been shown in Figure 6 and it is clearly observed that the proposed PEA exhibits better performance than EMD and DHM based approach.

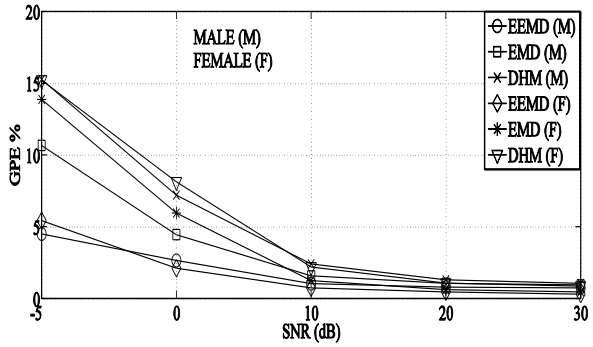

Figure 5: *Average performance results in terms of %GPE for white noise ('M' and 'F' denote male and female, respectively).*

Table 2. *Performance comparison of EEMD algorithm with recently reported PEAs for male and female data. Babble noise is used to corrupt the speech signal*

SNR(dB)		-5	0	10	20	30
M2	EEMD	20.65	10.93	5.26	2.26	1.54
	EMD	24.71	18.15	5.26	2.76	2.75
	DHM	52.83	32.98	9.64	3.81	3.08
M3	EEMD	21.66	14.74	2.04	0.56	0.07
	EMD	29.52	19.49	4.02	0.71	0.28
	DHM	57.98	38.42	8.55	1.06	0.35
F2	EEMD	13.18	5.62	1.48	1.10	0.56
	EMD	58.30	32.98	5.63	1.49	0.93
	DHM	73.08	47.21	9.82	2.31	0.94
F3	EEMD	8.69	5.23	1.06	0.35	0.28
	EMD	63.72	41.02	9.12	2.75	0.49
	DHM	67.05	38.76	6.44	1.98	0.78

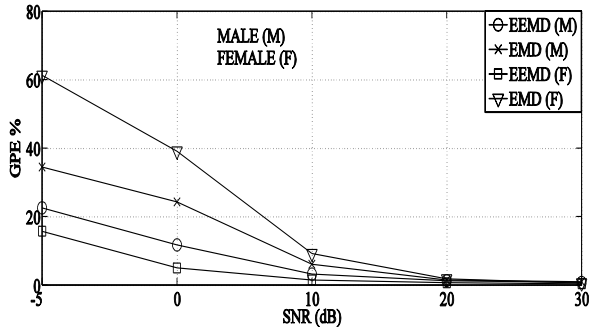

Figure 6: *Average performance results in terms of %GPE for babble noise ('M' and 'F' denote male and female, respectively).*

4. Conclusions

It is observed that the proposed method provides better performance in terms of % GPE than other recently reported PEAs in bubble and white noise environment for a wide range of SNRs(-5dB to 30dB). The EEMD based filtering efficiently extracts the signal components containing pitch information. Then pitch period is determined from partially reconstructed signal of EEMD domain. The pitch peaks become more prominent in the reconstructed signal. The EEMD is being free of mode mixing problem, pitch period does not overlap between any two IMFs and in most cases the detected pitch responses are almost closer to the original reference pitch. This strategy proves the superioty of the proposed algorithm. Also its performance in low SNRs is extremely better than EMD, DHM, NACF and WAC based PEAs. Finally, all sorts of experimental results prove the advantages of the proposed algorithm.

Abstract

Several grammar theories relate information structure and prosody, highlighting a major correspondence between theme and rheme, and intonation patterns. Although these theories have been successfully exploited in some specific speech synthesis applications, they are mainly based on short default-order sentences, which limits their expressiveness for real discourse with longer sentences and complex structures. This paper revises these theories, identifying cases in which they are valid, and providing a new proposal for cases in which a more complex model is needed. Specifically, our experiments performed on real discourse from the Wall Street Journal corpus show that we need a model that: (1) foresees a hierarchical theme/rheme structure, and (2) introduces, apart from the traditional theme and rheme, a new element—the specifier.

Index Terms: information structure, thematicity, theme, rheme, prosody, ToBI.

1. Introduction

The influence of the information structure on intonation is widely reported in literature [1, 2, 3] under the heading of the "semantics-syntax-intonation language interface" [4, 5, 1, 6, 7]. Steedman [1] proposes a grammar theory that relates three different fields: syntax, semantics and intonation. Based on the theory stated by Beckman and Pierrehumbert [8] on intonation and information structure, Steedman establishes a main and recurrent correspondence between theme and rheme on the one side and intonation patterns on the other side. This correspondence has already been exploited experimentally in speech synthesis applications that serve as front ends in dialogue engines [9, 10]. However, it is not obvious that the experience gained in these applications can be transferred to, for instance, monologue generation: works such as [1] are based on rather short sentences with a simple structure and a default word order (SVO for English), which are not common for the genre of monologues. If we want to generate natural speech based on real discourse information, the hypotheses put forward in these works must be applicable to long sentences with complex syntactic structures as well. There are no descriptive studies on real data that provide evidence for their applicability or offer sound arguments that help revising these theories.

The aim of this paper is to test these theories at a small scale with a two-fold objective: (i) to validate them and, in case discrepancies between their proposed thematicity–intonation correlation and the observed correlation are identified, to determine when and why these discrepancies occur; and (ii) to propose a model that has the potential to capture better the thematicity–intonation correlation, especially in the case of complex linguistic constructions. Achieving this objective will also be instrumental for the establishment of a valid methodology for dealing with large corpora for the description of prosody at a deep structure level. To this end, this paper draws upon real discourse extracted from the Wall Street Journal and recorded in a professional setting.

The structure of this paper unfolds as follows. In Section 2, the theoretical background related to the annotation of both information structure and prosody is briefly explained. Section 3 presents the study in which we relate information structure and intonation patterns in the spirit of the "classical" theories, as well as the most outstanding findings in this respect. Section 4 suggests how at least some of the challenges encountered in the previous section can be met by drawing upon a more elaborated notion of information structure. The summary of our experiments and the conclusions we draw from them are sketched in Section 5.

2. Theoretical background

In what follows, we briefly introduce the notions of information structure and the information structure–prosody interface.

2.1. Information structure

The Information Structure (IS) (also known as Topic-Focus Articulation, TFA [11] in the Prague School [12], and Communicative Structure, CommStr, in the Meaning-Text Theory [6]) determines the "communicative" segmentation of the meaning of an utterance. This makes it central to the semantics–syntax–intonation interface [4, 5, 1, 6, 7] and therefore also to Natural Language Processing (NLP).

Steedman's work (which will be referred to in this paper as "the classical approach") is based on the interpretation of IS as a two-partite *thematicity* structure, with *theme* (that part of an utterance which connects it to the rest of the discourse) and *rheme* (what the utterance contributes to that theme) [1, p.655]. According to Steedman, it is also possible to have discontinuous themes and rhemes and all-rhematic sentences.[1] Consider an example of theme (Th)/rheme (Rh) distribution taken from [1]:[2]

(1) *Q: I know what Marcel SOLD to HARRY.*

[1]In fact, for Steedman, "the majority of themes in everyday utterances are null themes" [1, p.678], i.e., the majority of sentences are all–rhematic.

[2]For theme/rheme determination in a sentence, Steedman pictures, as is common in the field, the sentence in question as an answer to a hypothetical question.

But what did he GIVE to FRED?
A: (Marcel GAVE)$_{Th}$ (a BOOK)$_{Rh}$ (to FRED.)$_{Th}$

Mel'čuk [6] proposes a more complex thematicity structure. Thus, on the one hand, he distinguishes, apart from the traditional theme and rheme (whose definition, in general terms, coincides with Steedman's), a specifier element (SP), which sets up the context of the utterance; and, on the other hand, he defines thematicity over propositions rather than over sentences. The second feature implies that thematicity is *per se* a hierarchical structure: if a proposition is embedded, its thematicity partition will be embedded as well. In sentences containing coordinated propositions, there is a parallel thematicity structure (one partition by proposition)[3].

In further contrast to Steedman, Mel'čuk assumes that apart from existential and zero-argument propositions, which are all-rhematic, any proposition has at least theme and rheme. Consider an example of theme (T)/rheme (R)/specifier (SP) distribution in the sense of Mel'čuk:

(2) $\{$*[Years ago]$_{SP}$, [he]$_{T}$ [collaborated with the new music gurus Peter Serkin and Fred Sherry in the very countercultural chamber group Tashi,* $\{$*[which]$_{T(P2)}$ [won audiences over to dreaded contemporary scores like Messiaen's Quartet for the End of Time]$_{R(P2)}\}_{P2}]_{R}\}_{P1}$

2.2. The classic information structure–prosody interface

Although all three elements of prosody (intonation, rhythm and stress) are equally important from a theoretical point of view, intonation is the most relevant feature for speech synthesis applications, since its correct prediction helps to obtain naturalness and variability in the generated speech [13]. As has been argued by many authors, among them by Beckman and Pierrehumbert [8] and Steedman [1], intonation is also directly correlated with IS. Beckman and Pierrehumbert identified six pitch accents and classified them as theme-rheme markers (see Table 1).

Table 1: *Pitch markers of theme and rheme (stated by [8]).*

	patterns
theme	L+H*, L*+H
rheme	H*, L*, H*+L, H+L*

As far as pitch accents are concerned, Beckman and Pierrehumbert suggest that the characteristic bitonals for theme and rheme are L*+H and H+L* respectively. Steedman [1] builds upon this theory and hypothezises on complete pitch accent/boundary tone (PABT) patterns, claiming that:

> *the intonational phrase L+H* LH%* [a clearly increasing Low-High pattern] *(among others) is associated with the theme, whereas the H*L% and H*LL%* [clearly decreasing High-Low] *tunes (among others) are associated with the rheme*; cf. [15, p.275, 16, p.28, 17].

Accordingly, Steedman correlates the theme/rheme in example (1) with intonation patterns (IP) as follows:

(3) *Q: I know what Marcel SOLD to HARRY.*
But what did he GIVE to FRED?
A: (Marcel GAVE) (a BOOK) (to FRED.)
L+H LH% H* L L+H* LH%*

In order to test Steedman's theme/rheme-IP correlation hypotheses, we have grouped together ToBI patterns resulting from automatic labeling and a further reduction process into three cathegories according to their final intonation curve typology, i.e. 'falling', 'rising' and 'flat'. We assume that our automatic labeling [20], based upon one main pitch accent within each intonational phrase, may not always coincide with detailed manual labeling accounting for all intonation events occurring along the pitch contour line, such that a need for broader categories arises in order to establish a comparable ground between our automatic labeling and traditional theories. Table 2 summarizes the collection of patterns we used in this experiment.

Table 2: *Intonation patterns classified according to their final intonation curve type.*

	patterns
falling	H*L%, L*+HL%, H*+LL%
rising	L*H%, L*+HH%, H*+LH%, H+L*H%
flat	L*L%, H*H%, H+L*L%

3. Validating the classic interface

In order to validate the classic information structure–prosody interface defined in terms of the correlation between theme/rheme of a sentence and its prosodic patterns, we carried out a number of experiments. In the context of these experiments, a non-expert native speaker of standard American English was instructed to read 109 sentences from the corpus annotated with information structure (composed of around 450 sentences from the Penn TreeBank).[4] The selection of those 109 sentences was based on the variation and complexity of their deep-linguistic (and thus also information) structures, making them prosodically interesting and useful for our study. The speaker was recorded in a professional recording studio to guarantee the quality of the sound signal. In a first stage, those sentences were annotated prosodically. In a second stage, the prosodic and theme/rheme patterns of these 109 utterances were assessed and contrasted with the patterns as prognosticated by Steedman's proposal.

3.1. Prosody annotation

Among several prosody annotations models, ToBI (Tone and Break Indices) [17] is the most widely used for annotating and adapting a markup language for open-source speech synthesizers such as Festival [18]. In our experiments, intonation patterns have also been annotated following the ToBI annotation convention. ToBI labels account for pitch accents (PA) within the intonational phrase (IP) and significant boundary tones (BT) within the sentence, which perfectly suits the purpose of these experiments. However, in contrast to most annotation exercises, which use a manual ToBI annotation,[5] we developed an own au-

[3]The hierarchical relations in a given thematicity segmentation are in practice controlled by parentheses (e.g. 'T(T)' will stand for "theme within the theme" and 'R(T)' for "rheme within theme". In coordinations and subordinations, each proposition is pointed out, e.g. T(P2) stands for the theme of the second proposition.

[4]The Penn Treebank was chosen as corpus base because it already contains the annotation at different linguistic levels (semantic and syntactic). Thus, we just added the information structure level to obtain all the information we need.

[5]The manual ToBI annotation has the advantage of being reliable and highly descriptive, but on the other hand it is subjective and very time consuming.

tomatic annotation interface that is based on AuToBi as initial labeling stage [19]. Since AuToBI only labels sentences word by word and our aim is to describe intonation patterns within intonational phrases (see [20] for details), we have processed the data automatically in a second stage to obtain a single ToBI pattern that is *a posteriori* manually validated and matched to the corresponding IP in the utterance. The advantage of working at the IP level is that we can correlate it with other layers, especially with IS.

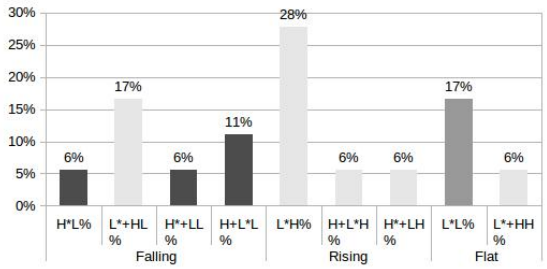
3.2. Assessment of the IS–prosody correlation

As already mentioned above, in the scope of our IS–prosody correlation assessment, we aimed to observe to what extent the classical proposals on the information structure–prosody interface can be applied to general (monologue) discourse with its rather complex sentential (and thus also thematic and prosodic) structures.

We analyzed pitch accents within the intonational phrase and complete intonation patterns (PABT — the combination of a pitch accent and a boundary tone). The analyzed themes include the set of patterns shown in Figure 1. All IPs are taken into account for calculating the percentages, regardless their position. It can be observed that rising PABT patterns together with L*+H tones represent a reasonable amount of the total (63%).[6]

(4) shows an example where the short theme, "Mister Kuehn", matches the pattern L*+H as expected by [1]; the same can be observed in (5), where the non-subjectival theme, "for some players", also matches the L*+H pattern.

Figure 1: *Theme ToBI Patterns.*



That is, as Steedman [1] claims there is indeed a tendency in themes to contain a rising pattern, at least in our recording, which includes only one speaker performing a reading task—although somewhat less than 40% of themes do not reflect the intonation pattern suggested in [1].

(4) *"Mister Kuehn, the company said, will retain the rest of the current management team".*

T	**Mister Kuehn**			
	H+L*H%			
R	**the company said**	**will retain the rest**	**of the current**	**management team**
	L*L%	L*+HL%	L*L%	L*L%

(5) *"For some players the lure is money up to fifteen thousand dollars a month".*

T	**For some players**			
	L*+HL%			
R	**the lure**	**is money**	**up to fifteen thousand**	**dollars a month**
	L*H%	L*H%	L*+HL%	L*L%

[6] It obviously remains to be proved that this tendency is kept in a big recorded corpus with several speakers and different registers, such as spontaneous speech.

However, in both (4) and (5), the rhemes do not show the expected pattern. In (4), there is no explanation for the L*L% pattern of the IP "the company said" and in (5), there is no explanation for any of the rising patterns found in the rheme span. Consequently, these two examples suggest that [1]'s approach to include everything, apart from theme, into a flat rheme span lacks the prediction accuracy we would need for speech synthesis applications.

4. Towards a more accurate IS–prosody interface

[1] is based on a linear dimension of thematicity. However, the study of our recorded material suggests that if we apply a hierarchical three-partite thematicity structure in the sense of Mel'čuk, we may be able (i) to find a justification for the discrepancies we saw in (4) and (5) between the prognosticated and the observed rheme patterns; (ii) propose a more accurate modelization of the intonation–thematicity correlation for the about 40% of non-coincident patterns within the theme span captured in Figure 1. Consider in (6) and (7) the sentences already cited in the examples in (4, 5), with a thematicity annotation as suggested by Mel'čuk.

(6) *"Mister Kuehn, the company said, will retain the rest of the current management team".*

T1	**Mister Kuehn**			
	H+L*H%			
SP1	**the company said**			
	L*L%			
R1	**will retain the rest**	**of the current**	**management team**	
	L*+HL%	L*L%	L*L%	

(7) *"For some players the lure is money up to fifteen thousand dollars a month".*

T1	**For some players**		
	L*+HL%		
T1(R1)	**the lure**		
	L*H%		
R1(R1)	**is money**	**up to fifteen thousand**	**dollars a month**
	L*H%	L*+HL%	L*L%

As already pointed out in Section 2.1, the notion of thematicity in the sense of Mel'čuk's includes, apart from theme and rheme, specifier elements. We have observed in our corpus that the identification of specifier elements provides very stable intonation patterns, being L*L% the commonest pattern, especially in reported speech. The IP "the company said" is a specifier (SP) and indeed carries this pattern. Another example in (8) also shows that the specifier element introduced in our information structure-prosody interface can be intonationally characterized as a separate entity from theme and rheme. This observation reinforces the tripartite division proposed by Mel'čuk.

(8) *"There is a large market out there hungry for hybrid seeds, he said".*

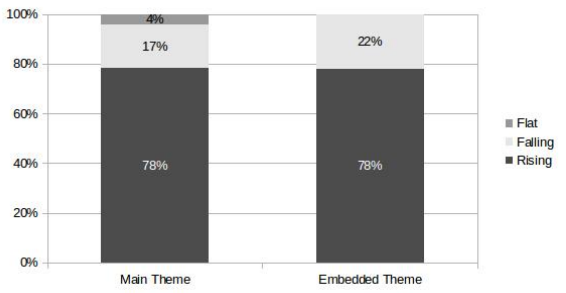
R1	**There is a large market out there**	**hungry**	**for hybrid seeds**
	L*+HL%	L*H%	L*L%
SP1	**he said**		
	L*L%		

In (7), the rheme element of (5) is hierarchically decomposed into an embedded theme/rheme structure. "The lure" becomes an embedded theme of the rheme and "is money up to fifteen thousand dollars a month" becomes the rheme of the rheme. As a consequence, we can at least explain why "the lure" carries a rising pattern: it is theme.

Going back to the results presented in Figure 1, a deeper analysis has been carried out to shed some light on the 40% of patterns within the theme span that do not coincide with the L*+H pattern in that they are either flat or falling and thus subsumed by the category Steedman called "among others". These diverging patterns are mostly found in complex structures, i.e., long themes containing more than one IP, coordinated sentences, subordinated clauses, etc. Consequently, an information structure model that can cater for complex utterances may be suitable to target this linguistic reality.

In order to test whether Mel'čuk's proposal of thematicity can be used as such a model, another experiment has been carried out. Thematicity, in accordance with Mel'čuk's definition, has been labeled in our selected corpus of 109 sentences following the guidelines outlined in [21]. Taking into account only theme spans which are prosodically marked up, we have classified their intonation patterns into rising, falling and flat, as shown in Table 2. The pattern L*+H L% is included into the rising pattern classification due to the fact that the state of the art considers this rising PA as characteristic of theme tunes. As a result, we have found that both main and embedded themes contain rising intonation patterns at equal rates of 78%. Consequently, we can affirm that embedded themes behave as main themes in terms of intonation when they are prosodically marked up. If we take into account the total of spans analyzed, main themes containing a rising pattern will characterize 34%, and when we add embedded themes we reach 50%. Therefore, we can conclude that a hierarchical approach to thematicity has the potential to provide more clues than traditional approaches when attempting to predict intonation patterns under complex communicative conditions.

Figure 2: *Comparison between main and embedded theme spans.*



In Section 3, we have already shown several examples where both main and embedded themes are characterized by rising tunes. The fact that data from a broader selection of utterances at an intra-speaker level also show this tendency sets a sound ground for further insight into the characterization of diverging intonation patterns based upon a hierarchical IS-prosody interface.

However, despite these advances in the explanation of the IS-prosody correlation there is still a substantial amount of cases that call for further investigation. These are, first of all, cases where a whole theme is not intonationally marked: 19% of primary themes and 49% of embedded themes. The example in (9) shows a sentence where the theme is a deaccented subject pronoun ("he") that, intonationally, forms part of the first IP of the rheme.

(9) *"Nevertheless he said he is negotiating with plant genetic to acquire the technology to try breeding hybrid cotton".*

SP1	**Nevertheless**				
	H*L%				
SP2	**he said**

The characterization of this kind of thematicity is also worthwhile to be born in mind, and further experiments will aim to find out if there is a characteristic IP in those cases. So far, we have observed that IPs containing a deaccented theme tend to bear a rising pattern, but the tendency is not so clear, and it seems that more layers interact at this level. Therefore, further research needs to be carried out, also including more speakers of the same dialect in order to test inter-speaker consistency and thus be able to draw more definite conclusions.

5. Conclusions

We have presented results of a descriptive study on a limited set of sentences from a wider corpus, attempting to determine which intonation patterns better characterize thematicity in real utterances, with the ultimate goal to build a model suitable for use in speech synthesis applications. We have observed that classical theories on IS–prosody interface are partially applicable in that themes of a specific (simple) nature have been proved to be characterized by a rising tune. On the other hand, the flat theme/rheme interpretation prevailing in these theories fails to explain complex linguistic structures. Drawing upon more advanced proposals on information structure, we have shown that further descriptive work needs to be done in order to accurately and concisely describe the IS–prosody correlation. Complex and hierarchical thematicity structures as well as the introduction of specifiers into the thematicity structure are bound to render positive results. Furthermore, the tri-partite division and the possibility of hierarchy are features of thematicity that facilitate a fine-grained communicative partition of complex utterances and thus a more detailed projection between the different layers of the semantics–syntax–intonation interface (or, more especifically, a more accurate description of the prosodic patterns related to each span). Our work can also be considered as detailing Steedman's proposal where he remains vague, stating that the patterns he identifies are only a few "among others".

The ultimate goal of developing a model combining prosodic and communicative structures for speech synthesis requires a deeper insight into descriptive studies on how these two linguistic layers interact. A good understanding of the structure and sequence of intonation patterns, as well as rare and/or exceptional cases will hopefully provide clues to more efficient NLP.

Prosody is in the hands of the speaker

Abstract

It has been suggested that speech and hand gestures could form a single system of communication that facilitates the interaction between the speaker and the listener. What kind of information do gestures carry? In the present study, we tested the possibility that spontaneous gestures accompanying speech carry prosodic information. Results show that gestures provide prosodic information as adults are able to perceive the congruency between a low-pass filtered – thus unintelligible - speech stream and the gestures of the speaker. These results suggest that prosody is not a modality specific phenomenon and can be perceived in spontaneous gestures that accompany speech.

Index Terms: prosody, hand gestures, speech perception.

1. Introduction

Human language is a multimodal experience: it is perceived through both the ears and the eyes. Adults automatically integrate auditory and visual information as evidenced by the McGurk effect [1], and seeing someone talking improves performances on speech intelligibility tasks [2]. This visual information involved in speech is not limited to the lips and the mouth but includes also the movements of the head [3, 4]. Other regions of the body could also give information about speech. Indeed, when interacting with others, people usually also produce spontaneous gestures while talking. What is exactly the role of these gestures that accompany speech? A line of research evidenced that gestures accompanying speech ease the speaker's cognitive load and gesturing help solving diverse tasks in mathematics and spatial problems [5, 6]. Gestures are also believed to aid the conceptual planning of messages as well as facilitate lexical access [7, 8]. This suggests that gestures and speech go 'hand-in-hand' from the earliest stages of cognitive development. In this view, gestures should carry the same structure as spoken language. One way to test this possibility is to look at prosody, an essential aspect of language.

In the auditory modality, prosody is characterized by changes in duration, intensity and pitch [9]. Interestingly, some part of the grammatical structure of human language is automatically mapped onto prosodic structure during speech production [10]. An interesting issue is whether prosody is modality specific or not. Since it has been shown to characterize sign languages as well [11], prosody cannot be restricted to the oral modality. It is therefore possible that the grammatical structure of language is not only automatically mapped to the acoustic speech signal but also to the spontaneous gestures accompanying speech.

Adult listeners use prosodic cues for various tasks that range from segmenting speech, to constraining lexical access [12], to disambiguating sentences that have more than one meaning (e.g., [bad] [boys and girls] vs. [bad boys] [and girls]) [10]. If some elements of grammatical structure are automatically mapped also to the spontaneous gestures accompanying speech, we should ask whether listeners use these gestures while processing the speech signal.

Thus, while there is evidence suggesting a direct link between the prosody of the speech signal and the spontaneous gestures that accompany speech, it is unclear whether listeners can use these cues provided by gestures when perceiving speech audio-visually. In the present study, we investigate the role of gestures as prosodic cues in speech perception.

2. Method

2.1. Experiment 1

In this first experiment, we explored whether gestures carry prosodic information. We tested Italian-speaking participants in their ability to discriminate audio-visual presentations of lowpass filtered Italian utterances where the gestures either matched or mismatched the auditory stimuli. While low-pass filtering renders speech unintelligible, it preserves the prosody of the acoustic signal [13]. This guaranteed that only prosodic information was available to the listeners.

2.1.1. Participants

We recruited 20 native speakers of Italian (15 females, mean age 24 ± 5) from the subject pool of SISSA – International School of Advanced Studies (Trieste, Italy). Participants reported no auditory, vision, or language related problems. They received a monetary compensation.

2.1.2. Stimuli

We used sentences that contain the same sequence of words and that can be disambiguated using prosodic cues from one of two different levels of the prosodic hierarchy. The disambiguation could take place at the Intonational Phrase (IP) level – the higher of these two constituents, coextensive with intonational contours – signaled through final lengthening and pitch resetting [10]. For example, in Italian, *Quando Giacomo chiama suo fratello è sempre felice* is ambiguous because depending on the Intonational Phrase boundary *è sempre felice* (*is always happy*) could refer to either *Giacomo* or *suo fratello* (*his brother*): (1) [Quando Giacomo chiama]IP [suo fratello è felice]IP (*When Giacomo calls him his brother is always happy*); or (2) [Quando Giacomo chiama suo fratello]IP [è felice]IP (*When Giacomo calls his brother he is always happy)*. Alternatively, the disambiguation could take place at the Phonological Phrase (PP) level where phrase boundaries are signaled through final lengthening. The Phonological Phrase extends from the left edge of a phrase to the right edge of its head in head-complement languages (e.g. Italian and English); and from the left edge of a head to the left edge of its phrase in complement-head languages (e.g. Japanese and Turkish) [10]. An example of a phrase with two possible meanings is *mappe di città vecchie* that is ambiguous in Italian because depending on the location of the PP boundaries, the adjective *vecchie* (*old*) could refer to either *città* (towns) or

mappe (maps): (1) [mappe di città]PP [vecchie]PP (old *maps of towns*); or (2) [mappe]PP [di città vecchie]PP (*maps of old towns*). The presentation of the two types of sentences – those ambiguous at the IP level and those ambiguous at the PP level - was randomized across subjects. We video recorded two native speakers of Italian – a male and a female – uttering ten different ambiguous Italian sentences (see Table 1). The speakers were unaware of the purpose or the specifics of the experiments. The speakers were asked to convey to an Italian listener the different meanings of the sentences using spontaneous gestures. The videos of the speakers were framed so that only the top of their body, from their shoulders to their waist, was visible (see Figure 1). Thus the mouth – i.e. the verbal articulation of the sentences – was not visible. Two categories of videos were created from these recordings using the Sony Vegas 9.0 software. One category corresponded to the 'matched videos' in which the speakers' gestures and their speech matched and the second category corresponded to the 'mismatched videos' in which the gestures were associated with the speech sound of the same sequence of words, but with the alternative meaning. A total of 80 videos were created (each of the sentences was uttered twice). We ensured that, in the mismatched audio-visual presentations, gestures and speech were temporally aligned so that the beginning and the end of the gestures were aligned with the beginning and the end of the speech act. To remove the intelligibility of speech but to preserve prosodic information, the speech sounds were low-pass filtered using the Praat software with the Haan band filter (0-400 Hz). As a result it was impossible to detect from speech which of the two meanings of a sentence was intended. The resulting stimuli had the same loudness of 70 dB.

Table 1. *Example of a sentence with two different meanings depending on its prosody.*

Sentence	**Meaning 1**	**Meaning 2**
Quando Giacomo chiama suo fratello è sempre felice.	Giacomo è felice.	Suo fratello è felice.
When Giacomo calls his brother is always happy.	*Giacomo is happy.*	*His brother is happy.*

Figure 1: *Examples of the stimuli presented.*

2.1.3. Procedure

Participants were tested in a soundproof room and the stimuli were presented through headphones. They were instructed to watch the videos and answer – by pressing a key on a keyboard – whether what they saw matched or mismatched what they heard (i.e., [S] = yes or [N] = no). A final debriefing ensured that none of the participants understood the meaning of the sentences.

2.1.4. Results

The results show that participants correctly identified the videos in which hand gestures and speech matched (M=81.9, SD=11.03: t-test against chance with equal variance not assumed $t(19)=12.93$, p<.0001) and those in which they did not match (M=69.3, SD=10.17; $t(19)=8.41$, $p<.0001$). A repeated measures ANOVA with condition (Match, Mismatch) and type of prosodic contour (Intonational and Phonological Phrase) was performed on the mean percentage. The ANOVA only revealed a significant main effect for condition ($F(1,19)=12.81$, $p=.002$, $\acute{\eta}^2 = 0.4$), but neither for type of prosodic contour ($F(1,19)=1.20$, $p=.287$, $\acute{\eta}^2 = 0.06$) nor for an interaction of type and condition ($F(1,19)=3.52$, $p=.076$, $\acute{\eta}^2 = 0.16$). The results show that adult listeners detect the congruency between hand gestures and the acoustic speech signal even when only the prosodic cues are preserved in the acoustic signal. The spontaneous gestures that accompany speech must therefore be aligned with the speech signal, suggesting a tight link between the motor-programs responsible for producing both speech and the spontaneous gestures that accompany it. The results of Experiment 1 thus also show that adult listeners are sensitive to the temporal alignment of speech and the gestures that speakers spontaneously produce when they speak. We thus asked whether the prosodic cues that adult listeners use for understanding spoken language may automatically be mapped to gestures.

3. Discussion

Our findings show that when presented with acoustic stimuli that contain only prosodic information (i.e., low-pass filtered speech), participants are highly proficient in detecting whether speech sounds and gestures match. The prosodic information of spoken language must therefore be tightly connected to gestures in speech production that are exploited in speech perception. The syntactic structure and the meaning of utterances are therefore not necessary for the perceiver to align gestures and prosody. As opposed to the visual perception of speech in the speakers' face, where the movements of the mouth, the lips, but also the eyebrows [14] are unavoidable in the production of spoken language, the gestures that accompany speech belong to a different category that is avoidable in speech production. Our results suggest that prosody is a domain-specific phenomenon (i.e., characteristic of language) that extends from the auditory modality to the visual one in speech perception. This link between speech and gestures is congruent with neuropsychological evidence for a strong correlation between the severity of aphasia and the severity of impairment in gesturing [15]. While further studies are clearly needed to identify the specific aspects of spontaneous gestures that are coordinated with speech acts, our results demonstrate that part of speech perception includes the anticipation that bodily behaviors, such as gestures, be coordinated with speech acts.

Rising pitch and quoted speech in everyday American English

Joseph Tyler[1]

[1] Department of English Literature and Linguistics, Qatar University, Doha, Qatar
josephctyler@gmail.com

Abstract

Phonetic variation in rising pitch has been analyzed for how it correlates with contextual factors like speaker gender, utterance type (questions vs. statements) and turn position (turn-medial vs. turn-final). This paper analyzes variation in terminal rising pitch between quoted and non-quoted speech, using data from the Santa Barbara Corpus of Spoken American English. Results show rises in quoted speech start and end higher, rise more overall, have steeper slopes but are no different in duration. These results are gender-dependent, however, for while women produce 65% of all rises in the corpus sample, they produce 100% (n=23) of the quoted speech rises.

Index Terms: rising pitch, intonation, quoted speech, reported speech, gender, uptalk, HRT, corpus analysis

1. Introduction

Terminal rising pitch, also known as uptalk or the High Rising Terminal, has received attention for its semantic and pragmatic meanings [1, 2], its social meanings [3, 4], its perception effects [5, 6] and its production patterns [4, 7-10]. Production studies have used corpora to explore phonetic variation in rises and how such variation correlates with contextual factors like gender, utterance type (questions vs. statements) and turn position (turn-medial vs. turn-final) [11, 12]. Most of these studies used speech from a corpus of map task data [13]. This study makes two novel contributions: first, it uses everyday conversational American English; second, it looks at how rises in quoted speech differ from rises in other contexts.

1.1. Literature Review

Corpus studies of rising pitch in speech production have shown systematic correlations between phonetic dimensions of those rises and contextual factors. The rises have been analyzed phonetically for their starting pitch, ending pitch, rise onset position, rise span, and pitch dynamism [4, 11, 12]. Some studies code phonological representations of a rising pitch contour [14], using a transcription system like ToBI [15], and other studies combine both phonetic and phonological analyses.

This variation in rise form has been correlated with a range of contextual factors, e.g. speaker gender, utterance type (statement vs. question) and turn position (turn-medial vs. turn-final). Results show systematic differences in rise production between men and women: women have been found to produce more rises [4, 9], to start their rises later [3, 4], and to use more pitch dynamism [12]. In addition, results for speakers in Southern California, London and New Zealand suggest that women produce bigger rises than men [3, 4, 9, 12]. This result persists even when using the ERB scale, a scale designed to control for physiologically-determined differences [12].

In addition to gender effects, rises have been found to vary by utterance type, turn position, dialect, age, and a rise's position in the discourse [4]. Other corpus work using different measures of intonation have examined pitch variation by speech register [14] or speech situation [16]. What has not received as much attention is how rises vary by the stylistic implementation of the speech by the speaker. Rampton [17] describes stylization as "reflexive communicative action in which speakers produce specially marked and often exaggerated representations of languages, dialects, and styles that lie outside their own habitual repertoire (at least as this is perceived within the situation at hand)". One such type of stylization may be the performance of quoted speech, especially in the recounting of a narrative.

Quoted speech, also known as direct reported speech, has been studied from a number of perspectives. The intonation of quoted speech was analyzed many years ago by Bolinger [18], who argued that the goal of the speaker in such situations is to "re-enact the original intonation," though the achievement of this goal may be more or less successful. Klewitz and Couper-Kuhlen [19] discuss how quoted speech is sometimes set apart intonationally from the discourse around it, e.g. with prosodic changes at the boundaries between quoted and non-quoted speech. But more often, they report, intonation may mark reported speech but not exactly at the boundaries, serving as a more indirect cue to what is quoted. In addition, a variety of discourse types and data sources have been used to show quoted speech is produced with wider pitch range than non-quoted speech [20-22].

From this work on intonation and quoted speech, it remains unclear how terminal rises are produced in quoted speech compared to rises in other contexts, though the fact that quoted speech often has wider pitch range suggests rises may be larger in quoted speech than elsewhere. The data for many of the corpus studies discussed above have been elicited through map tasks [4, 9, 11, 23, 24], leaving open the question of how such behavior generalizes to more everyday speech contexts. In this study, phonetic features of rises in everyday conversational English are examined and compared in both quoted and non-quoted speech. The results can tell us something about how the quoted speech is realized in rises and how those rises compare to rises more generally.

2. A Corpus Analysis

The spoken data analyzed in this study come from Disc 1 of the Santa Barbara Corpus of Spoken American Spoken English (henceforth SBC). The SBC includes conversations from different regions of the United States, discussing a variety of topics in everyday settings. Some conversations are dyadic and some are multi-party (up to 9 speakers). This corpus sample contains 51 unique speakers across 14 different conversations; except for two speakers who were in two conversations, all speakers were in only one conversation. Recordings lasted an average of 67 minutes, with the shortest and longest being 28 minutes and 120 minutes respectively. They took place in a range of settings, including private settings (living room, kitchen, bedroom, dining room) but also professional contexts (an office, a classroom or a bank).

Speakers' home states were around the US, with more common states being California, Indiana and Illinois, but also Alabama, Montana and Texas. Thirty-one speakers lived in their home state, ten were listed as living in a different state than their home state, and ten had this information missing.

In addition to the naturalness of the data in this corpus, a second important benefit of the SBC is the transcription system used. All conversations have been transcribed into time-stamped intonation units with terminal pitch marked as either rising (marked with a "?"), flat (marked with a ",") or falling (marked with a "."). A simple search for intonation units marked with a "?" reveals hundreds of rises. In addition to the relative ease of identifying the rises, it also supplies a sample of *perceived* rises, regardless of their specific phonetic characteristics.

All rises that the transcript suggested were phonetically analyzable were annotated to a TextGrid in Praat [25]. Cases where the transcript indicated that environmental noise or overlapping speech masked the rising pitch were excluded. This resulted in a set of 636 tokens from Disc 1 of the SBC that were then subjected to phonetic analysis.

The rises were analyzed phonetically using a pitch window of 50-500Hz. The rise domain was annotated from the start of the rise to the end. The rise start was determined impressionistically, though guided by the phonetic trough and with a slight buffer after the syllable onset to reduce segmental effects. The rise start usually occurred on the last stressed syllable of the intonation unit. The rise end was the phonetic peak, i.e. the point at the end of the rise with the highest Hz value.

All tokens were analyzed with a Praat script that extracted the rise-start pitch (in Hz) and the rise-end pitch (in Hz), as well as rise duration information. During the original TextGrid annotation, some tokens did not exhibit a pitch value or showed an unreliable pitch value (e.g. apparent halving or doubling errors). Because these instances were going to result in unreliable output from the Praat script, they were marked for follow-up manual analysis.

The tokens marked for manual measurement were then analyzed individually. During manual measurement, the pitch settings were adjusted according to the author's discretion to control for halving or doubling errors. For some rises, the script outputted Hz values of zero; these tokens were analyzed individually. Outliers were also examined manually; outliers were identified as values at the extremes (<75Hz, >400Hz, and with a span that was >200Hz or negative) or those that were more than two standard deviations away from a speaker's mean. Following the manual analyses, (5%) of the 636 total tokens ended up being excluded because they were unmeasurable. The remaining 603 tokens served as the basis of the corpus analysis. These tokens were produced by 39 unique speakers (see Table 1 for the distributions across speakers). In addition to rise-start and rise-end, variables were also defined for rise-span, defined as rise-end minus rise-start, and rise-slope, defined as rise-span(Hz) divided by duration(seconds).

While the original phonetic measurements were taken on the linear Hz scale, they were converted in two ways for analysis: 1) log-transformation, and 2) conversion to the ERB (Equivalent Rectangular Bandwidth) scale. The log transformations resulted in a more normal distribution. The ERB scale was developed using psychoacoustic tests to track changes in Hz to perceived changes in prominence, and has been argued to be more appropriate for the analysis of intonation [26]. It has been argued to better correspond to listeners' perceived pitch scale. It has also been used in other research on rising pitch [3]. Duration measures were log-transformed to increase the normality of the distribution.

In addition to the phonetic measurements, each rise was coded for various contextual factors, including quoted speech, speaker gender, utterance type (question vs. statement) and turn position (turn-medial vs. turn-final). While part of a larger project, this paper focuses on rises in quoted and non-quoted speech. For this study, quoted speech was coded exclusively as direct reported speech, i.e. where the speech was presented as said exactly as it was said in the past. In each of the following examples, the reported speech ("oh you mean adults" and "oh so you're going to host them are you") is presented as a word-for-word representation of what was said in the original speech context. The original transcription format of the SBC is maintained.

(1) PAMELA: (H) she said,
oh you mean,
... adults=?

(2) ALINA: And I said,
oh.
.. So you're going to host them are you?

As is visible in these two examples, the quoted speech is introduced with the quotative "to say". In this corpus sample, all 23 tokens of quoted speech were introduced with a quotative, 17 with the verb to say (e.g. (1) and (2)), 6 with "to go" (e.g. (3)).

(3) CAROLYN: And they look at] you and they go,
... <Q the what Q>?

While it is not the focus of this study, quotative use has been examined for its systematic variability, e.g. in the context of narrating a life story [27] as well as in language change [28].

Table 1 lists the number of rises and quoted rises by speaker, showing that all quoted speech tokens were produced by women. Therefore, all results are gender-dependent, for while women produce 65% of all rises in the corpus sample, they produce 100% (n=23) of the quoted speech rises. Moreover, while eight different women in the corpus sample produced measurable rises in quoted speech contexts, a single woman (speaker 16) produced a majority (52%).

2.1. Results

Table 2 shows the distribution of untransformed values for rise-start, rise-end, rise-span, rise-duration, and rise-slope (risespan/duration) in quoted and non-quoted speech.

Table 2. *Descriptive statistics for rise measurements.*

Quoted	N	Rise-start (Hz)	Rise-end (Hz)	Rise-span (Hz)	Rise-dur (sec)	Rise-slope
Min	23	121	160	6	0.105	27
Max	23	361	745	425	0.634	1139
Mean	23	215	320	105	0.290	404
SD	23	56	127	101	0.145	358
Non-Quoted						
Min	580	79	91	-24	0.047	-113
Max	580	350	636	352	1.716	1724
Mean	580	174	224	50	0.333	189
SD	580	48	79	51	0.228	204

The distribution suggests quoted speech rises tend to start higher, end higher, rise more and be steeper. In this table, minimum and maximum rise-span may not correspond to the difference between rise-end and rise-start because they could be the values for different tokens.

In order to test whether quoted speech rises are produced differently from non-quoted rises, mixed models were used, which have been found to have advantages over other models [29]. Random effects for speaker and conversation (the sound file from which each speaker's data are drawn) were included in order to control for variation due to speaker- or conversation-specific differences. The predictor variable was a binary variable for quoted vs. non-quoted speech. The dependent variables were the rise-start, rise-end, rise-span, and rise-slope values on both log(Hz) and ERB scales. Also included was a dependent variable for rise duration (in seconds, log-transformed). These models were implemented using the `lmer` function in R [30]. Because the `lmer` function does not output a p-value, p-values were retrieved with the `pvals.fnc` function.

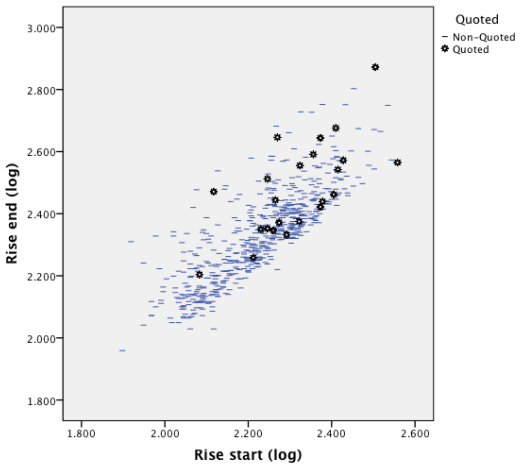
Results in Table 3 show that quoted speech has higher rise-start pitch, rise-end pitch, rise-span, and rise-slope in both Hz and ERBs. No difference was found for rise durations. These results indicate that rises in quoted speech start higher, end higher, rise more and more steeply in this corpus sample. They do not, however, rise for a longer duration. In order to test whether the pitch results depend on duration differences, the same models were run for rise-start, rise-end, and rise-span but with log(rise-duration) as a covariate. In these models, quoted speech remained a significant predictor for all pitch measures, with rise-duration also significantly predicting the rise-end and rise-span measures, but not the rise-start measures. And when data from male speakers are excluded, significant effects for the quoted speech variable remain.

Table 3. *Quoted vs. non-quoted speech rises.*

	Quoted vs. non-quoted speech
Rise-start (log(Hz))	ß=.074, SE=.016, t=4.56, pMCMC<.001
Rise-start (ERB)	ß=.003, SE=.001, t=4.56, pMCMC<.001
Rise-end (log(Hz))	ß=.117, SE=.024, t=4.93, pMCMC<.001
Rise-end (ERB)	ß=.005, SE=.001, t=4.93, pMCMC<.001
Rise-span (log(Hz))	ß=.087, SE=.026, t=3.33, pMCMC=.001
Rise-span (ERB)	ß=.002, SE=.001, t=2.382, pMCMC=.021
Rise-slope (risespan(log) /duration)	ß=.234, SE=.097, t=2.43, pMCMC=.014
Rise-slope (risespanERB /duration)	ß=.007, SE=.003, t=2.073, pMCMC=.042
Rise duration (log(seconds))	ß=-.024, SE=.059, t=-.40, pMCMC=.690

Figure 1 presents results for quoted and non-quoted rise-starts and rise-ends.

Figure 1: *Scatterplot for quoted and non-quoted rises*



While there is overlap in the distributions, this plot shows that quoted speech rises tends to start and end higher in pitch.

Among the rises in quoted speech, some tokens reach the extremes of pitch excursion. For example, on the word "balcony" in the excerpt in (4), the speaker reaches almost 800Hz. The pitch contour for this rise is plotted in Figure 2.

(4) ALINA: of course I said,
.. <VOX ~Cassandra,
... you wanna play one [bounce off the] balcony VOX>?

The domain of the rise is marked in Figure 2 as the portion between the two vertical dotted lines and corresponds to the nucleus of the first syllable to the nucleus of the last syllable

of the word "balcony". This remarkable rise is in the context of narrating a story about someone who was jumping. The narrator is annoyed, and quotes her own speech in a dramatic and excited manner. The speaker's excitement in the story may have resulted in extremely high pitch on the final rise.

Figure 2: *Pitch contour for the utterance "wanna play one bounce off the balcony?" produced by speaker 16 (Alina), with the rise domain indicated by vertical dotted lines.*

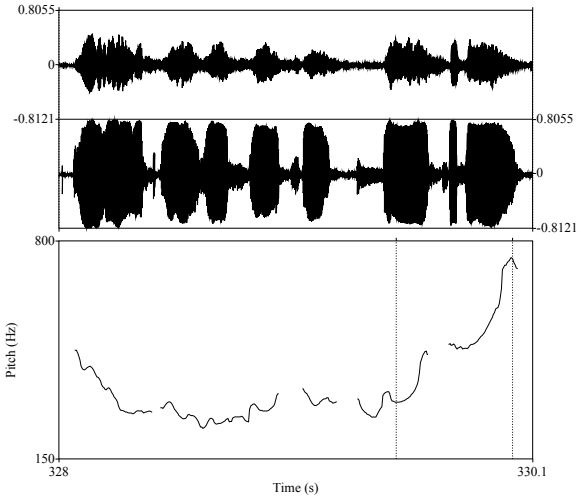


Figure 3: *Pitch contour for the utterance "oh you mean… adults?" produced by speaker 15 (Pamela), with the rise domain indicated by vertical dotted lines.*

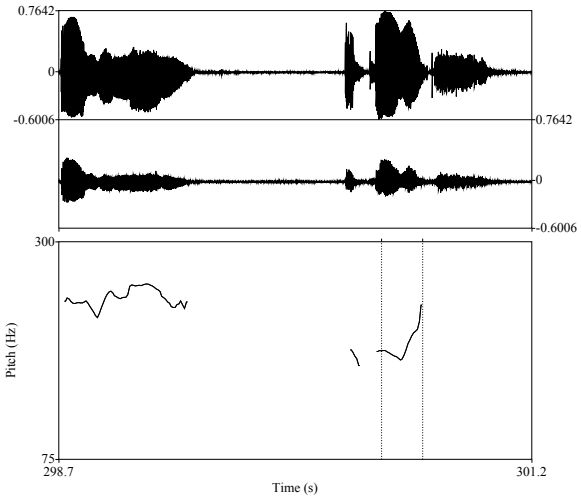

Another speaker seemed to exploit pre-rise pauses as part of her repertoire. For example,

(5) PAMELA: (H) she said,
oh you mean,
... adults=?

The domain of the rise covers the onset through the end of the word "adults". As is visible in Figure 3, there is a sizeable pause (794ms) between the words "mean" and "adults". The pitch contour also shows that the speaker drops in pitch before starting the rise. This study has not explored the relationship between the pitch of terminal rises and pre-rise pitch, but (5) suggests that that relationship may display meaningful variation.

While this paper has not specifically addressed distinctions between types of rises other than being quoted or not, one popular contrast is between rises in polar questions and uptalk (often defined as rises on declarative syntax that are not questioning [31]). Uptalk has been derided in popular media [32] and studied in scholarly work [5]. Statistical models were run again with variables for rise duration, questioning speech act and interrogative syntax as covariates (to control for the factors of uptalk). In all of these models, the effects of quoted speech on the pitch measures remain significant. Therefore, the findings reported here for quoted speech are not reducible to an uptalk effect.

3. Discussion

The results discussed above suggest that in the context of quoted speech, (female) speakers produce rises that start higher, end higher, rise more overall and have a steeper rise. These results complement existing research that has determined quoted speech in general to be characterized by higher than average pitch [20-22]. One possible explanation for this is that the act of quoting, i.e. of representing speech from another time, is generally dramatic. Rendering speech from outside the immediate context is a kind of performance. The nature of that performance includes higher, larger and steeper than average rises.

The findings that quoted speech rises are produced with different intonation from non-quoted speech rises may contribute to ongoing discussions on the nature of speech stylization. Given Rampton's [17] definition of stylization referenced above, quoted speech may itself be a case of stylization, where the speech is marked and exaggerated, lying outside the speaker's habitual repertoire. Notably, the speaker could be quoting themselves, as in (4) above. While the original production that the speaker is quoting is not available for comparison, it seems likely the original did not end in a rise that reached almost 800 Hz (if, in fact, she said these words at all). Therefore, her goal may not necessarily be to most accurately reproduce the original speech, as Bolinger [18] had claimed. Instead, the special circumstances of quoting, even when the one being quoted is oneself, can lead a speaker to mark the quoted speech as other. One of the mechanisms by which speakers can mark quoted speech as other is through distinctive intonation. The results discussed above suggest that the size and slope of a rise, in addition to wider pitch range [20-22], can help stylize quoted speech as marked speech.

Fine temporal structure of Finnish sign language

Abstract

Signs can be divided to syllables and further into transitions and nuclei based on the sign flow of the handshapes. Here, a mixed effects linear regression model is used to describe the variation in the duration of the syllable nuclei in a data set of 341 signs (474 syllables) produced by five native FinSL signers during a map task. The phonetic fixed variables are the duration of the adjacent transitions and syllable nuclei; phonological fixed variables are the syllabic length of the sign, the syllable position within the sign, and the sign type (functional or content bearing). Both preceding and following nucleus had a significant effect on the nucleus duration, while an asymmetric effect was found for the transitions: only the postnuclear transition had a significant effect. The syllable structure had no effect. However, the nuclei were shorter in function signs. These results suggest that signs are produced in two stages where the first stage, preparatory transition, is merged with the production of the previous syllable, and the second stage consists of executing the sign.

Index Terms: Finnish sign language, spontaneous signing, mixed effects model

1. Introduction

Introduction is divided into three subsections, which address different aspects of sign language research respectively. Signs in a sign language correspond to words in a spoken language, and thus they are the basic carriers of meaning in the particular language. The sign flow divides into individual signs and further into syllables. However, the notion of a syllable is under a debate within sign linguistics community. Nevertheless, it is accepted that signs divide temporo-spatially to segments/gestures. In the current work we study the impact of lexical and segmental factors to the duration of signed syllable nuclei.

1.1. Temporal organization of signed languages and prosody

Previous studies have shown that facial expressions can switch the function of a signed utterance from a statement to a question [1]. Facial expressions are markers for linguistic stress as well [2], but as Wilbur et Nolen discovered, it does not increase the duration of the signs as such but manifests in faster movement and larger displacement instead [3].

Temporal structure and prosodic features of signed language have been studied mainly in relation to the linguistic scope [4], [5] while this study concentrates on the articulatory issues related to sign flow *per se*.

Kröger et al. [6] compare the principles of syllable structures in relation to articulatory phonology. This study concentrates on the precise syllable-internal structures and their durations. The current project compiles the approach by Kröger et al. in comparing sign data to articulatory phonology principles, and the approach by Wilbur et Nolen [3] in studying syllable durations.

Signs within a sign language are further divided into articulatory gestures. These alternate temporally within sign stream, so that the stream has salient movements and motionless moments called holds. Holds and movements represent the sequential organisation of a sign flow. It also forms the basis for our definition of a signed syllable.

Recent sign language research has concentrated on rhythm in connection with signed poetry, but some of the phenomena found are not present in ordinary signed discourse [7]. Studies on sign coarticulation have suggested that the index finger has a dominant role in governing the rate and speed of both coarticulatory and interarticulatory phenomena [8]. The intertwining rhythms in sign are found within manual and facial elements. One of the key facial elements in signed discourse are the headnods [9]. Sign language prosody is also expressed in facial expressions, however, they are not in scope in this study. The twofold structure of prosody is similar to spoken language prosody division between segmental and suprasegmental features.

In a previous study [10] we showed that syllable durations change in terms of sentence position and sign type. The data showed a reduction of duration in polysyllabic signs and it would suggest that spatial relations have a special role in timing of signed languages. Now we want to take the study questions one step further and look if there are differences according to the syllable type (nucleus vs. transition), and what type of interaction between sign types (function vs. content sign) can be found. Function signs, such as pronouns and conjunctions, denote grammatical functions whereas content signs account for the meaning in the sentence. The position of the sign in a signed utterance affects its duration but not its linguistic stress.

1.2. Coarticulation, signing rate, and segmental factors

Just like isolated words differ from the words spoken in their context because of coarticulatory patterns and phenomena, the signs produced in isolation, i.e. in their dictionary form, are also different from those produced within their context. In signed languages, the coarticulatory patterns differ in several dimensions, as not only the signs in succession within one hand influence each other, but the hands also interact together to form another layer of coarticulatory patterns. This is sometimes called interarticulation. For example, the hands slow down when they are nearer to each other [8], [11]: p. 23.

The two main models of sign language phonology share the goal of segmenting an on-going sign stream, but approach it from different perspectives. The segmental models, includ-

ing HM (hold and movement) model, [3], [12], [4] and the latest contemporary model [13], derive from a more linguistic perspective, while the gesture model takes a more physiology based approach to the problem, and bases the segmentation principles on the general principles of human movement: the alternation of more and less active segments during the signed utterance [14] . This results in a different type of segments within the sign stream. In speech production theories the derivatives of articulatory phonology [15] and motor theory of speech production [16] most resemble the above-mentioned. In this study we reflect on our data in the light of these two types of theories, segmental and gestural theories.

Human action is often a combination of many intertwining rhythms, be it basic human actions, such as walking or eating [17], or something more complex, such as speaking or playing an instrument. The rhythms we use are highly individual. Speech rhythm is one of the key features we observe when trying to identify a speaker [18] – the individual "figure of speech".

Lindblom, Mauk et Moon [19] study both sign and speech in equal terms based on the dynamics of the production in a sequence. Here too, the motor equilibrum theory with the human movement principles forms the basis for the analysis. According to Lindblom et al. we should not concentrate on the distinct categories *per se*, but on the interpolation between categories. They ask: if perception likes change, why is phonetic specification built mainly around steady-state attributes?

1.3. Mental lexicon and dictionary forms

The articulatory gestures in spontaneous signing are formed by hands (elbows, wrists, metacarpals and phalanges) in relation to the body (face, chest and shoulders). The particular geometric form taken by bones distal to wrists is called the handshape. Often, the handshapes are static, but fingers might move to create a dynamic handshape. Signs in a sign dictionary are categorised by handshapes, even though handshapes are one of the most difficult parts of the sign, and one of the last elements to be learned by sign acquiring children [18].

As stated earlier, individual signs are the basic building blocks of sign language and as such, they are also the meaning-carriers. In addition, signs are collected into sign language dictionaries, similar to dictionaries of spoken languages. However, unlike spoken languages, signed languages do not have written forms, so a sign language dictionary is based on static pictures or videos. Dictionary forms present normative versions of signs and they also guide the language teachers in their teaching, similarly to how spoken language teachers use dictionaries in their teaching [20].

These dictionary forms are thought to be the basic, prototypical representations in our mental lexicon as well. These mental images or soundscapes of words, signs and sentences are adjusted according to the person we are communicating with. This is done based on so-called perceptual anchors, such as greeting words. In English the word that is often used is "Hello". This gives the acoustic guidelines to the speaker's vocal tract. Similarly in signed language a hand wave is used to greet. This gives many clues to the use of physical space anchors, such as size of hand, positioning of hand in relation to face etc. [21].

For the reasons stated above, the dictionary forms found in Finnish Sign Language online dictionary Suvi (http://suvi.viittomat.net) were used as the main reference guide where applicable to the syllabification processing of the spontaneous signed data. After the syllabification, the signs were labelled as monosyllabic or polysyllabic, and as function or content signs. Syllables were further categorised as nuclei or transitions.

In this study, sign language prosody is in focus, in particular the temporal variation within the constituents of the signs in spontaneous Finnish Sign Language (FinSL). Both phonetic (duration of adjacent constituent) and linguistic factors will be considered. We concentrate on the fine temporal structure of Finnish Sign Language based on the movement patterns of the dominant hand. The purpose of the article is to investigate if lexical factors can affect the duration of the syllables.

2. Methods

2.1. Subjects and data recording

The recording was done in a well-lit office. No spotlights were used but lighting was kept constant by shutting the blinds and curtains to prevent possible glare from outside. The camera was on a tripod 2 metres from the subject facing the subject directly. The subject was facing the camera and was sitting on a sofa to prevent the obstruction of signing space by armrests on one hand and to make the situation more comfortable for the subject at the same time. The equal positioning of the camera and the subjects was ensured by using tape markings on the floor for the camera tripod and the subject's feet position. The background was a light brick wall with solid colouring. Five native signers of FinSL were recorded with 24 Hz frame rate during a map task. The task elicited free signing from a map with a starting point, a path, and an end-point. A more detailed description of the gathering procedure and the data can be found in [18]: pp. 77-78, 85-86. Here, a subset of the data is further analysed.

2.2. Sign flow segmentation

The sign flow of the dominant hand was segmented and labelled. The hand a signer uses to sign one-handed signs is called the dominant hand. Most people use their right hand but there are left-handed signers as well. A labelled sign was compared to the dictionary form. Thereafter, the sign was classified either as a function or a content sign. The data contained a total of 335 signs out of which 95 were function signs (28%).

The signs were divided into smaller constituents. We used a phonetic definition of a syllable although there is no generally accepted definition for a signed syllable. The signs were divided into syllables according to the following rules:

1. Each sign consists of at least one syllable.
2. If the sign can be decomposed to temporal segments each constituting an independent sign, then the sign is called a compound sign with each component being composed of at least one syllable; otherwise the sign is simple.
3. If the movement in the handshape flow is cyclic inside a simple sign or compound sign component then each cycle contains at least one syllable.
4. Every signed segment of an utterance belongs to at least one syllable.

The syllable boundaries were defined following the definition of a syllable. The boundaries of the signs were always syllable boundaries and the beginning of the new cycle (even if it remained incomplete) defined a syllable boundary. Only when two consecutive signs overlapped, the syllables could overlap. This could be a result of the two hands articulating different signs simultaneously or when the hand dominance switched temporarily to the other hand.

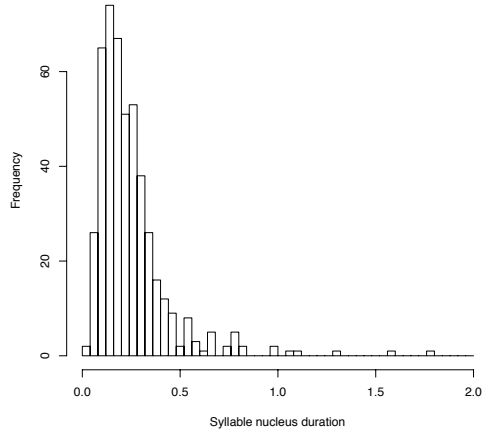

Figure 1: *A histogram of the syllable nucleus durations. The distribution is unimodal with mean 0.24 s, standard deviation 0.20 s, and median 0.21 s.*

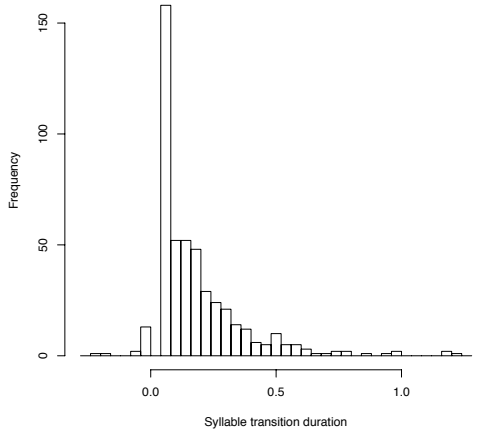

Figure 2: *A histogram of the syllable transition durations. The distribution is unimodal with mean 0.17 s, standard deviation 0.19 s, and median 0.13 s.*

The monosyllabic signs were most common (235 signs; 70% of the signs). In addition, there were 70 disyllabic signs (21%), 22 signs with three syllables (7%), 7 signs with four syllables (2%), and 1 sign with five syllables (<1%) The mean duration of a syllable was 0.41 s with standard deviation 0.30 s.

Every (phonetic) syllable was then further divided into a nucleus and a transition. The onset of the syllable nucleus was defined as the beginning of the syllable. The end point of the syllable nucleus, i.e. the beginning of the transition, was defined as the best match with the end handshape or secondarily the end position of the hand compared to the dictionary form of the syllable, and thirdly, as the first moment that clearly belonged to the movement towards the next syllable, i.e. the transition. The syllable nucleus durations are shown in Figure 1. The mean duration was 0.24 s and the standard deviation was 0.20 s.

The segments between consecutive nuclei were transitions (with one transition occurring between the nuclei – possibly with zero duration). Sometimes no transition took place (13 cases in the dataset). This was the case in polysyllabic signs consisting of a reduplicated simple sign like *sauna*. The transition could be even negative (4 cases in the dataset) when the end of a sign was reached (e.g. a hand-body contact ending a sign) after the handshape already had transformed to the beginning of the following sign. A histogram of the transition durations is shown in Figure 2. The mean duration of a transition was 0.17 s with standard deviation 0.19 s. The transition were in average somewhat shorter than the nuclei.

2.3. Statistical analyses

A mixed effects linear regression model was used to describe the variation in the duration of the syllable nuclei in the data set. The phonetic fixed variables were the duration of the adjacent transients and syllable nuclei; phonological fixed variables were the syllabic length of the sign, the syllable position within the sign (1 for the first syllable, 2 for the second, etc.), and the sign type (function sign or content bearing). The subjects were treated as random variables in the model.

3. Results

The minimal mixed effects model used to explain the syllable nucleus durations, which did not significantly differ from the full model with all the main effects (ANOVA), consisted of the adjacent syllable nuclei durations, the duration of the post-nuclear transition, and the type of the sign (function vs. content sign). The minimal model is described in Table 1. Syllable nuclei within a function sign were produced in average 56 ms faster in comparison to the syllable nuclei within a content sign. The overall signing rate was reflected by the strong impact of the previous and following syllable nucleus durations. Somewhat surprisingly then, only the post-nuclear transition duration had an impact on the nucleus duration (and not the pre-nuclear transition).

Although the syllable structure was taken into account by including the number of the syllables and position within a sign as fixed factors, this did not have any significant effect in explaining the nucleus durations. The phonological factors, syllable position and the syllabic length of the sign, did not explain the variation in the data, and were dropped from the minimal model.

Table 1: *The minimal mixed effects model fitted to the data to explain the variation in syllable nucleus durations.*

Fixed effect	Estimate	t value
Intercept (s)	0.12	7.1
Type (function sign)	-0.056	-2.9
Duration of the post-nuclear transition	0.21	4.6
Duration of the following nucleus	0.19	4.3
Duration of the previous nucleus	0.20	4.7

4. Discussion

Lexical factors affected the duration of the syllable nuclei of the signs even when the duration of the transitions were controlled for. The function signs were shorter possibly because of

faster retrieval from the mental lexicon or more fluent production. This could be either because of the special syntactic role function words have in signing or it could be a consequence of function signs being more frequent in average than the content signs. As sign frequency is also a property of the sign, the results suggest that lexical properties influence the sign durations. In the current data, no attempt was made to control the sign frequency. Most likely the function signs in the current data set were more frequency than the content signs, which could have led to a confound. It is fully possible that the sign frequency *alone* would be sufficient to explain the sign type effect were it so that more frequent signs are produced faster *and* the function signs in the data set were more frequent. Unfortunately, the sign frequencies are not readily available for FinSL, yet.

The impact of adjacent constituents to the syllable nucleus durations is highly expected and it reflects to the local signing rate. In the results, there was an asymmetry in the influence of the transitions: only the post-nuclear transition had an significant effect on the nucleus duration while the effect of prenuclear transition was only half in size and did not reach significance (ANOVA for dropping the term, $p > 0.1$). The statistical model fitted to the current data set suggests the following asymmetry: for transitions that last longer, the preceding nucleus would be lengthened but not the nucleus following the transition. This could be a consequence of a trade-off between available time and necessary articulatory effort: for a longer distance between two consecutive nuclei more time could be allocated which could be compensated for by reduced articulation. Hence, the salience of the sign would be intact. Moreover, if a long distance within a transition is performed faster this would result in hyperarticulation. This trade-off then would move the boundary between the sign nucleus and the post-nuclear transition earlier during hyperarticulation. Importantly, the boundary is defined through the handshape which can be controlled rather independently compared to the position of the hand [22], [23].

Compared to an earlier analysis of the *syllable durations* by the current authors [10], the syllable nucleus durations show somewhat different behaviour. The syllable durations alone were shorter in polysyllabic signs than in monosyllables but here the syllable nuclei did not significantly differ as a function of the number of syllables. Also, function sign syllables were not significantly shorter than content signs although here the nuclei durations varied according to the sign type.

These opposing results can be reconciled. The bisyllabic signs often consist of reduplicating a monosyllabic sign leading to short (or non-existant) transitions. Indeed, in the current data, the sign internal transition are much shorter (mean 0.054 s) than the transitions between the signs (mean 0.22 s; Wilcoxon signed rank test, $p < 10^{-15}$). The transition durations themselves probably depend primarily on the spatial distance between the articulatory locations of the syllables, which is smaller sign internally. This remarkably shortens the duration of the syllables in polysyllabic signs. In addition to the evidence from the analysis of the last section, a direct comparison of the first syllable nucleus durations of mono vs. polysyllabic signs reveals no significant difference (Wilcoxon, $p > 0.1$).

In the current analysis of syllable nucleus durations, a relatively small effect of the sign type emerged although such an effect was not visible in the earlier syllable duration analyses. That the effect was not earlier visible could be simply due to larger variances in the syllable durations as opposed to the nucleus durations. In addition, it could be that only the nucleus durations are affected by the sign type and the duration of the transitions is solely determined by the spatial relations of the adjacent syllables.

The distributions of the durations for syllables, syllable nuclei, and syllable transitions were all non-normal. The logarithms of the respective durations show less non-normal shapes but are still clearly (QQ-plots, normality tests) different from normal. To diminish the possibility that the results would be an artifact of the non-normality of the data, we built a minimal mixed effect model for the logarithmically transformed durations. The resulting minimal model has exactly the same terms and the statistical significance of the individual factors is improved. This hints that the non-normality is not the main source of the results.

During spoken word production, frequent words tend to be produced faster when controlled for phonological length and the frequency of the word [24]. This is true for signs as well (at least what comes to the phonological length) as the syllables in the polysyllabic signs are faster [10]. The current work suggests that this phenomenon might be completely explained in the sign language context by the spatial relations of the sign components (syllables). An alternative explanation that the phonologically longer signs are produced faster because of repetition induced optimization of the syllable sequences within a sign as opposed to across sign boundaries, is not supported by the current sign language data.

5. Conclusion

In the current work we demonstrated using Finnish Sign Language that even in a sign language lexical factors affect the duration of signed segments. In addition, the syllable nucleus durations are affected on the phonetic level by the durations of adjacent nuclei and the postnuclear transition but not by the prenuclear transition. Hence, the current data analysis suggests that the transitions are more strongly attached to the signs (syllables) preceding the transitions. In addition, function signs tended to have faster syllable nuclei in the data set similar to the spoken language results. This points to a sign production model where the spatial relation of the signs (and sign syllables) determines the transition durations which in turn affect the nucleus durations alongside with the lexical properties of the sign.

Pause insertion prediction using evaluation model of perceptual pause insertion naturalness

Hiroko Muto, Yusuke Ijima, Noboru Miyazaki, Hideyuki Mizuno

NTT Media Intelligence Laboratories, NTT Corporation, Japan

Abstract

This paper describes a pause insertion prediction approach for generating more natural synthesized speech for Text-to-Speech (TTS) synthesis systems. A novel point of the proposed approach is the use of an evaluation model of perceptual pause insertion naturalness in addition to a prediction model based on machine learning. The evaluation model represents the relationship between several features related to pause insertion and the perceptual pause insertion naturalness obtained in a subjective evaluation. First, using a prediction model based on machine learning, we obtain the N-best sequences that indicate whether or not a pause is present at each phrase boundary. We then estimate pause insertion naturalness scores for each N-best sequence using the evaluation model and select the sequence with the highest naturalness score. Objective and subjective evaluation results show that the proposed approach gives better results than a conventional approach.

Index Terms: pause insertion prediction, text-to-speech synthesis, perceptual naturalness, machine learning

1. Introduction

A key to synthesizing speech with improved naturalness is (silent) pause insertion prediction at essential steps in the text-to-speech synthesis process. This is because pause insertions are important for understanding speech. Pause insertions are also important for expressing the characteristics of specific speaking styles. Wang [1] reported that the pause locations of read, expressively read, and spontaneous expressively read speech are different from each other and that irregular pause insertions can improve the expressiveness of synthesized speech. Parlikar [2] reported that natural synthetic speech for the target speaking style can be generated by using a speaking style-dependent pause insertion model. These reports indicate that one needs to be able to predict pause insertions which are suitable for the target speaking style in order to generate expressive synthetic speech.

Machine learning is a suitable way to generate expressive synthetic speech, because it can automatically train the characteristics of pause insertions from training data in the target speaking style. Various machine learning-based approaches have been proposed for predicting pause insertions, such as decision trees [3, 4], Hidden Markov Models (HMMs) [5], Maximum entropy models [6], and Conditional Random Fields (CRFs) [7, 8]. In these studies, various linguistic features, which are extracted from training data, are used for prediction and contribute the prediction performance to improve. On the other hand, it is known that the characteristics of pause insertions have wide variances [9]. Even if the linguistic features are similar, the pause locations have many variations. This indicates it may be difficult to predict more accurate pause insertions by the prediction models trained using only linguistic features.

One useful approach to alleviating this problem would be utilizing not only machine learning-based decisions but also general measures that are independent of specified training data. For example, Kim [10] utilized grammatical rules for statistical pause prediction and showed their effectiveness in reading speaking style. However, this approach would be difficult to apply to a specific speaking style that does not strictly adhere to grammatical rules. To generate expressive synthetic speech, a new measure is needed that can express the characteristics of the target speaking style.

In this paper, we focus on naturalness scores obtained from subjective evaluation. Humans can intuitively judge the naturalness of speech regardless of speaking style. By revealing the features that influence to perceptual pause insertion naturalness and usages of pause insertion prediction, it would be improving the pause insertion performance for specific speaking style. A related study [11] indicates that a perceptual accent naturalness measure obtained from a subjective evaluation is effective at speech segment selection for concatenative speech synthesis. The task of pause insertion prediction would be able to predict more accurate pauses by using perceptual pause insertion naturalness as well as the speech segment selection.

To investigate the characteristics of pause insertions that influence the naturalness of speech, we performed multiple regression analysis to analyze the relationship between several features that related to pause insertions and the naturalness scores obtained by a subjective evaluation using synthesized speech with different pauses. Then, based on the analysis, we propose a pause insertion prediction approach that utilizes the obtained characteristics for machine learning-based pause insertion prediction. We constructed a multiple regression model on the basis of the analysis and used it to evaluate the naturalness of the pause insertions predicted by machine learning. In the proposed approach, we first predict N-best hypotheses of the pause insertion prediction result by using a CRF-based pause insertion prediction. Then, we calculate the naturalness score using the multiple regression model for each N-best hypothesis and rerank them. Finally, the hypothesis with the highest naturalness score is selected from the N-best hypotheses. We conducted a preliminary evaluation of our approach on a reading speaking style corpus and obtained encouraging results.

2. Evaluation of perceptual pause insertion naturalness

In this section, we describe the details of the subjective evaluation using synthesized speech with different pauses and multiple regression analysis to analyze the relationship between several features that related to pause insertions and the naturalness scores obtained by subjective evaluation.

2.1. Subjective evaluation

2.1.1. Speech stimuli

For the subjective evaluation, we used 400 pattern synthesized speech stimuli with different sentences and pause insertion patterns. As a sentence set, 50 sentences were selected from 503 phonetically balanced sentences in the ATR Japanese speech database (Set B). Eight pause insertion patterns were used for each sentence. We did not evaluate all possible pause insertion patterns for each sentence, because it is useless to evaluate patterns humans rarely use. To evaluate patterns that humans use, we utilized patterns from the utterances of several speakers. To evaluate various kinds of pause insertion patterns, we selected speakers whose pause locations are widely distributed. In addition to them, we used the patterns predicted by a rule-based pause insertion predictor [12] to compare with the other patterns. For these purposes, we selected seven speakers and one pause insertion predictor as follows.

- One professional speaker : the pause insertion pattern was used as a general pattern.
- Six non-professional speakers : the average number of their pauses differed significantly. We used them to keep the variation of the pause insertion pattern.
- One Japanese pause insertion predictor : pause insertion pattern was predicted by a manually designed rule.

To evaluate the effects of pause insertion on naturalness, it is desirable to use speech stimuli with the same voice quality and prosody (F0 contour, phoneme duration, accent phrase boundary, and accent type). For this reason, all speech stimuli were generated by a speech synthesizer [13].

2.1.2. Experimental conditions

We had 16 subjects (seven males, nine females) listen to the 400 speech stimuli in random order and rate their naturalness of pause insertion using a 5 point scale (from 1: very unnatural, to 5: very natural). The subjects evaluated each stimulus twice. For each stimulus, the average value of the 16 subjects' scores was used as the naturalness score.

2.1.3. Experimental results

Figure 1 shows the histogram of the naturalness score for each stimulus. 96.5% of the sample scores are over 3 point (fair) because most of speech stimuli employed pause insertion patterns extracted from real utterances, while, the naturalness scores of all sample are not always more than 4 point (natural) and broadly distributed from 2.5 to 4.5. In comparison of the average score for each speaker, the patterns of the professional narrator was the highest and that of the pause insertion predictor was the lowest.

2.2. Multiple Regression analysis

2.2.1. pause distribution features used in analysis

In the multiple regression analysis, we used the following 10 features related to pause insertion, which are called "pause distribution features".

(a) The average and variance values of the number of mora in pause phrases

(b) The average and variance values of the number of content words in pause phrases

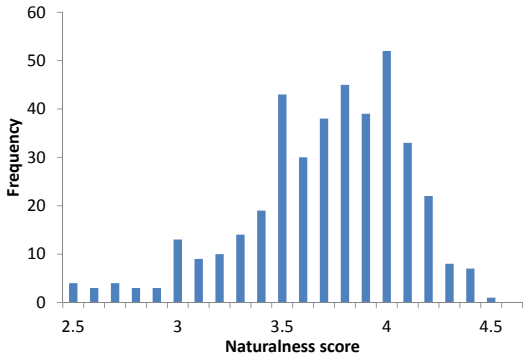

Figure 1: *Naturalness score histogram.*

(c) The existence of four outliers in the number of mora in pause phrases $(\mu - \sigma,\ \mu - 2\sigma,\ \mu + \sigma,\ \mu + 2\sigma)$

(d) The number of pauses inserted between phrases having a dependency relation

(e) The number of non-pauses inserted between phrases not having a dependency relation

These features are calculated for each sentence. A mora is a syllablesized unit in Japanese. "Pause phrase" is one or more consecutive phrases delimited by pauses. (a) and (b) are basic features related to the length and amount of information of each pause phrase. (c) is four features related to outliers. They indicate whether pause phrases that are too long or too short exist. Generally, if such pause phrases exist, the naturalness would become worse. These features can be set to a value of 1 or 0. It is set to 1 if a pause phrase exists in which the number of mora is outside the standard value. In other cases, it is set to 0. The average value μ and the standard deviation value σ, used to determine the standard value, were calculated for all 400 sentences. (d) and (e) are the features related to the relationship of modification between phrases. A previous study [14] showed that these two features affect the naturalness of pause insertions.

2.2.2. Multiple regression analysis results

We performed multiple regression analysis to model the relationship between the pause distribution features given above and the naturalness scores obtained in the subjective evaluation. To investigate the relationship of these features and the naturalness scores, we first calculated a multiple correlation coefficient. We confirmed that the naturalness scores and the estimated ones were correlated; the multiple correlation coefficient was 0.61. We also investigate the effect of each pause distribution feature on the naturalness scores. Partial correlation coefficient for each feature is shown in Table 1. From this table we can see that the features (a) (especially average value), (c) (especially $\mu - 2\sigma$), (d), and (e) were highly correlated for the naturalness score.

3. Proposed approach

By the analysis, we obtain the features that influence to the perceptual pause insertion naturalness. To evaluate the effectiveness of the features for pause insertion prediction, we developed a pause insertion prediction approach that combines the information obtained by the analysis and machine learning-based

Table 1: *Partial correlation coefficients (PCC) for each pause distribution feature.*

pause distribution feature	PCC
Average value of #mora	-0.21
Variance value of #mora	-0.10
Average value of #contents word	-0.03
Variance value of #contents word	-0.01
Outlier ($\mu - \sigma$)	-0.08
Outlier ($\mu - 2\sigma$)	-0.23
Outlier ($\mu + \sigma$)	-0.02
Outlier ($\mu + 2\sigma$)	-0.06
#pauses inserted between dependency relation phrases	-0.42
#non-pauses inserted between non dependency relation phrases	-0.24

pause insertion prediction. We constructed a multiple regression model on the basis of the analysis and used it to evaluate the naturalness of the pause insertions predicted by machine learning. We call it the "evaluation model". A block diagram of the proposed approach is shown in Fig. 2. It consists of two stages: a prediction stage and an evaluation stage.

In the prediction stage, we predict a Boolean sequence that indicates whether a pause has to be inserted after each phrase within the input phrase sequence. (We call this Boolean sequence a " pause assignment sequence"). A CRF-based pause insertion prediction model is used for prediction and N-best pause assignment sequences are output.

In the evaluation stage, for each N-best sequence, we extract pause distribution features. We then estimate the naturalness score using the extracted pause distribution features and an evaluation model of perceptual pause insertion naturalness. Finally, we select the pause assignment sequence with the highest naturalness score among the N-best sequences.

Although pause insertions were mainly predicted by word units in previous studies, however, in this study, we predict them by phrase units (also called " bunsetu" [15]) because pauses are usually inserted into phrase boundaries.

4. Pause insertion prediction model

4.1. Pause insertion modeling with CRF

In this subsection we describe the pause insertion prediction model. Whether a pause should be inserted after a phrase greatly depends not only on the various linguistic features of the phrase but also on what comes before and after the pause. Machine learning approaches may be effective for modeling such comprehensive and complex features. In this study we used the CRF, which is an effective machine learning approach for sequential labeling. Given a sequence of vectors of the linguistic features $\boldsymbol{x} = (\boldsymbol{x}_1, \cdots, \boldsymbol{x}_M)$ with M phrases, the goal is to find a highest probability sequence of pause assignment labels $\boldsymbol{y} = (y_1, \cdots, y_M)$ for M junctures after every phrase. The linguistic features of sequence $\boldsymbol{x}$ are described in Sect. 4.2. Each y_i, the i-th pause assignment label in sequence $\boldsymbol{y}$, can be 1 or 0. If a pause is inserted immediately after the i-th phrase, y_i is 1. In other case, y_i is 0.

In this study we used the linear chain CRF, a special form of CRF. The conditional probability $P(\boldsymbol{y}|\boldsymbol{x})$ is calculated as

$$P(\boldsymbol{y}|\boldsymbol{x}) = \frac{\exp(\boldsymbol{w}, \boldsymbol{\Psi}(\boldsymbol{x}, \boldsymbol{y}))}{\sum_{\boldsymbol{y}} \exp(\boldsymbol{w}, \boldsymbol{\Psi}(\boldsymbol{x}, \boldsymbol{y}))}$$

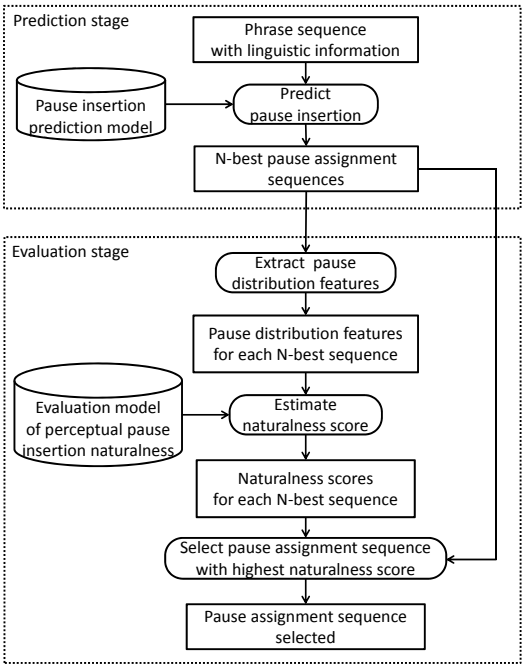

Figure 2: *Overview of proposed approach.*

where $\boldsymbol{\Psi}(\boldsymbol{x}, \boldsymbol{y})$ is a feature function and $\boldsymbol{w}$ is a parameter to be estimated from training data. CRF are usually trained by maximizing the log-likelihood over a given training set. In this study we obtained the N-best sequences in order of the probability of $P(\boldsymbol{y}|\boldsymbol{x})$.

4.2. Linguistic features for pause insertion modeling

These linguistic features were used for pause insertion modeling .

(1) Text of current phrase
(2) Syntactic category of current phrase
(3) Flag of whether current phrase modifies next phrase
(4) Text of last word of current phrase
(5) Part of speech (POS) of last word of current phrase
(6) Pronunciation of last word of current phrase
(7) Text of first word of next phrase
(8) POS of first word of next phrase
(9) Pronunciation of first word of next phrase
(10) Above features' quin-context and combinations of them

In this study, we modified the word-based features used in conventional approaches [7, 8] to suitable ones for the prediction by phrase units. We also used the features that indicate the dependency relationships between phrases.

5. Evaluation

5.1. Experimental conditions

In the following experiment, a Japanese news corpus was used. It contained 1000 Japanese news sentences uttered by one professional male narrator, with an average of 70.0 words per sentence, 23.4 phrases and 11.7 pauses. The POS, pronunciation,

Table 2: *The results of pause insertion prediction.*

	Recall	Precision	F-measure
Proposed	93.3	72.4	81.5
Conventional	93.6	68.4	79.0

and dependency relation were labeled automatically using a Japanese morphological analyzer [16] and a Japanese dependency parser [17]. Pause locations were labeled manually according to the speech data.

As a conventional approach, the 1-best result predicted by CRF-based pause insertion prediction model was used. CRF++ toolkit [18] was used for pause insertion prediction model training. We set the parameter N (the number of N-best sequences) as 10 from the preliminary experiment results.

5.2. Objective evaluation

We first compared the prediction performance of the proposed approach with that of the conventional approach. From the corpus, 100 sentences were used as the evaluation data and the rest were used as training data for the pause insertion prediction model. We performed a 10-fold cross validation test. The prediction performance was evaluated by precision, recall, and F-measure. Where, precision means the ratio of correctly inserted pauses to the total number of inserted pauses, and recall means the ratio of correctly inserted pauses to the total number of pauses in the evaluation data.

The results are shown in Table 2; the proposed approach had slightly lower recall but higher precision and F-measure than the conventional approach.

5.3. Subjective evaluation

We also compared the naturalness of synthesized speech generated from the results predicted by each approach by a pair comparison test. Since the sentences in the corpus were too long to evaluate subjectively, we truncated them to short sentences that can be listened to easily. From the corpus we selected 30 sentences for evaluation and truncated them to 148 short sentences, averaging eight seconds in length. The rest were used for training the pause insertion prediction model. We randomly selected 30 short sentences from the short sentences in which pause location differences were found between results predicted by the proposed and the conventional approaches. The synthesized speech was generated by the same speech synthesizer used for the subjective evaluation described in Sect. 2.1. The pause durations in the synthesized speech were consistently 0.5 seconds. Subjects were 24 persons (12 males, 12 females), and presented a pair of synthesized speech samples in random order and then asked which samples had better naturalness.

The preference scores obtained for the experiment (Fig. 3) show the proposed approach outperformed the conventional approach. This shows that using an evaluation model of perceptual pause insertion naturalness is an effective way to improve pause insertion naturalness in synthesized speech.

We conducted the objective evaluation using the short sentences used for the subjective evaluation. The prediction performance was shown in Table 3. From this table we can see that the prediction performance was almost the same as those using the original sentences.

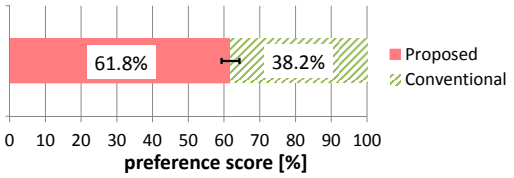

Figure 3: *Preference score from the subjective evaluation. (Error bars show the 95% confidence intervals.)*

Table 3: *The results of pause insertion prediction. (Using short sentences used for subjective evaluation)*

	Recall	Precision	F-measure
Proposed	94.1	74.4	83.1
Conventional	95.2	72.5	82.3

6. Conclusion

In this paper, we proposed a pause insertion prediction approach involving the use of an evaluation model of perceptual pause insertion naturalness for generating natural synthesized speech. Objective and subjective evaluations demonstrated the proposed approach provides better results than the conventional approach. This shows that consideration of perceptual pause insertion naturalness to pause insertion prediction is an effective way to improve naturalness in synthesized speech.

Currently the proposed approach's effectiveness has been demonstrated only for the reading speaking style. A future task is to explore its effectiveness for other speaking styles. We also intend to analyze pause duration naturalness and attempt to develop a pause duration estimation approach for generating more natural synthesized speech.

Abstract

The aim of the paper is to present the results of a perception experiment in which native and non-native listeners were asked to rate the appropriateness of resynthesized questions varying in respect to two aspects: their morphosyntactic structure (presence/absence of an interrogative marker) and the form of their final intonational contour (falling, rising and extra-rising). The goal of the experiment was to examine how non-native listeners of French did perceive the extra-rising final contour that was observed in learners' productions. Do they consider it as appropriate even if it did not occur often in the native speakers' productions? By and large, the results of the experiment show that native listeners preferred rising contours over falling ones in all question types, whereas non-native listeners rated the extra rising contours higher than French natives in stimuli having a morphosyntactic structure that differs from the one used in their L1. These results may suggest that rising contours represent a default tonal form associated with the interrogative modality not only at the beginning of the L2 acquisition process, but also in speakers' mental representation, irrespective of their L1.

Index Terms: L2 intonation, L2 acquisition,

1. Introduction

It is often assumed that the prosodic patterns observed in the productions of second/foreign language learners are mainly influenced by their L1 prosodic structure. L1 transfer is thus considered as playing a crucial role (see [1] and [2] for an overview). However, several studies have shown that, in some cases, the L1 transfer cannot be invoked to account for some observed patterns. Other factors have thus to be taken into consideration to explain singular prosodic forms of the L2 learners' grammar [3]. In previous work, for instance, we have shown that Mexican Spanish learners of L2 French produce systematically an extra-rising contour at the end of information-seeking questions (see [4] and [5]). Even if the occurrence of this form can be considered as resulting from a L1 transfer in yes-no questions, it is not possible in the case of wh-questions (see section 2.3 for more information). The overuse of this contour could thus be seen as resulting from the L2 acquisition process itself. Such explanation may have consequences on the perception, this form being not necessarily considered as accurate in French. Do the learners consider it as appropriate at various early stages of the L2 acquisition process, even if the form is not often heard?

This article is organized as follows. In section 2, we provide background information on the prosody of French and Spanish interrogatives. Section 3 focuses on the experimental protocol of the perception experiment. In section 4, we present the results obtained. Finally, the implications of the results for the theories focusing on the acquisition of intonation in an L2 are summarized in the last section.

2. Intonation in questions in French and Spanish: L1 vs. L2

In descriptions of French and Spanish intonation, yes-no questions are usually characterized by ending with a rising contours (H%), while wh-questions are associated with falling contours (L%). Nevertheless, different tonal configurations can be observed in both interrogative sentence types: falling tones could appear in French yes-no questions when the lexical content and/or the morphosyntactic structure already indicates the modality of the utterance, whereas rising patterns can appear in both Spanish and French wh-questions. In the following sub-sections, we summarize the distribution of these contours with respect to the morphosyntactic structure and to the canonical patterns usually reported in the literature.

2.1. The intonation of yes-no questions

Information-seeking yes-no questions do differ in Spanish and French with respect to their morphosyntactic forms. In Spanish yes-no questions, two morphosyntactic structures are observed with nominal subjects: either the subject precedes the verb as in an assertive sentence (1), or the subject and the verb are inverted as in (2). In contrast, French yes-no questions can be produced with a larger range of linguistic forms: in addition to the declarative structure (3), a subject-verb inversion can occur, be the subject nominal or pronominal (4), and the interrogative marker 'est-ce que' can be inserted at the beginning of the utterance (5).

(1) *¿Juan estudia?* 'Juan studies?'
(2) *¿Estudia Juan?* 'Studies Juan ?'
(3) *Vous étudiez ?* 'You study?'
(4) a. *Étudiez-vous ?* 'Study you?'
b. *Pierre étudie-t-il ?* 'Does Pierre study?'
(5) *Est-ce que vous étudiez ?* 'You study?'

As for intonational patterns, Mexican Spanish yes-no questions are produced with a rising contour regardless of the syntactic structure: a final rise, which covers approximately an octave (12 semitones), is realized from the penultimate syllable to the end of the utterance, and the final pitch target generally reaches the top of the speakers' range. This tonal pattern is perceived as an extra high rising pitch movement, and is more frequently observed in Mexico City Spanish (see [6], [7], and [8]).

In contrast, French speakers may use a larger inventory of melodic movements at the end of questions without changing the meaning of the utterance. In yes-no declarative questions (as in (3)), a rising pitch movement realized on the last syllable of utterance (or on the last accentual phrase) and covering in average 8 semitones is usually observed (see [9] and [10] among others). By contrast, in yes-no questions in which the interrogative modality (as in (4) or (5)) is expressed by a marker or the morphosyntactic form, the final contour can

be either falling L% or rising H%, the H% vs. L% contrast being in a certain extent neutralized.

In the remaining of the paper, the differences between the various tonal configurations will be noted as follows: the label H% is used for rising contours, the label HH% for extra rising one, and the label L% for falling one (see the representation in Fig. 1 in section 2.3).

2.2. The intonation of Wh-questions

The morphosyntax of wh-questions differs in Spanish and French with respect to the possible positions of the interrogative expression. Information-seeking wh-questions are always constructed with the interrogative word in utterance-initial position in Spanish (6a). By contrast, it is possible in French to utter a wh-question with the wh-expression in sentence-initial position (wh-'fronted') as in (6b), or with the expression in the position where the answered complement should occur (wh-'in-situ') as in (7):

(6) a. *¿Qué estudias?* 'What study (you)?'

b. *Qu'est-ce que tu études ?*

(7) c. *Tu études quoi ?* 'You study what?'

A cross-linguistic comparison of the tonal configurations occurring at the end of wh-questions in both French and Spanish shows that there are more similarities between both languages than in the case of yes-no questions: the final contour is often falling L% (see [6], [7], [8], [10], [11], [12] and [13]), but rising one could also be used. Note also that the extra rising contour HH% is almost inexistent in natives' oral productions in both Spanish and French in this question type (see [5], [8] and [10] among others).

2.3. Intonation of interrogatives in L2 French

In previous studies dedicated to the intonation of questions in L2 French by Mexican Spanish speakers, it has been shown that learners often use the extra rising contours HH% in yes-no and wh-questions (se [4], [5]). The fig. 1 gives a schematic representation of the contours observed at the end of the two question types –'Do you study?' for the yes-no question, and 'Where are you going?' for the wh-question– in the productions of Native French speakers (FL1), Spanish learners of French (FL2) and natives Spanish (SL1). The horizontal dotted line in the figure represents the top of the speaker's range.

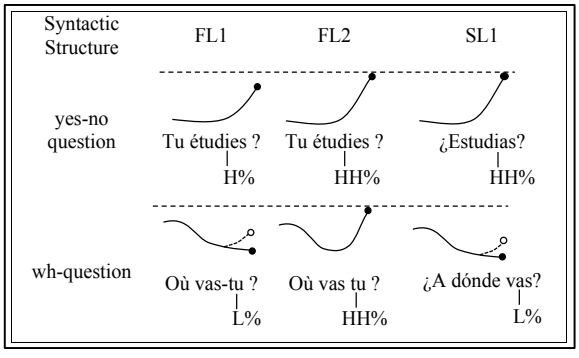

Figure 1: *Stylization of the three final boundary tones*.

From the data analyzed, [4] and [5] argued that the extra-rising tonal form HH% could be attributed to an L1 transfer in the cases of yes-no questions, since this form is quite common in the Mexican Spanish variety. Yet, for wh-questions, an analysis in terms of transfer cannot be argued for, since this question type is generally produced with a falling contour L% in Spanish. Hence, different explanations have to be found to account for the occurrence of this pattern. The first proposal we could argue for is that at an early stage of the L2 acquisition process speakers have at their disposal a reduced inventory of tonal forms, in which rising tunes (be they H% or HH%) are employed by default for expressing any kind of interrogative modality (see also [3]). The second one relies on a certain difficulty for learners to distinguish the difference between rising and extra-rising contours, since this difference is more phonetic in nature. The third one, which will not really be investigated here, assumes that learners, by being less confident, express linguistic insecurity about their performances by using such a form. The extra rising contour HH% would thus encode a lack of confidence in the L2 (see also [14]).

3. Perception experiment

In order to get some information on what could motivate the occurrence of the extra-rising contours, and to evaluate which of the first two hypotheses mentioned in section 2.3 is the most relevant, we set up a perception test. The learners had to evaluate which of the various contours (between HH%, H% and L%) is the more appropriate at the end of the different question types. If the use of extra rising contours at the end of questions is related to the speakers' L1 or to the acquisition process itself, this contour should be significantly perceived as appropriate, at least by learners at an early stage, in all settings. However, the more advanced learners should not rate extra-rising contours as accurate as beginners. If the difference between the two forms is phonetic in nature, the choice of one contour over the other should not necessarily be significant, at least for the learners. Results obtained in this experiment should thus help us to evaluate whether the preference for HH% observed in learners' oral productions is related to the L2 acquisition process, or not.

In addition, the other assumptions can be partly verified by referring to the use of the forms. Indeed, native and non-native listeners should display differences according to their L1 in the way of evaluating the different final boundary tones in relation to the morphosyntactic structure of the question. As final rises are usually HH% for Mexican native speakers (be they learners of French or not), they should rate HH% better than H% in yes-no declarative questions, whereas French native participants should rate H% better than HH%. In the case of yes-no questions, in which the interrogative modality is signaled by the morphosyntactic forms (as in (4) and (5)) as well as in wh-questions (as (6) and (7)), native listeners show a preference for H% and L% over HH%, which has rarely been observed in the data (see [4] and [5]). In the case of the L2 learners, we could expect to obtain the same results as for SL1 listeners, despite the fact that they use mostly the HH% contour. This expectation is based on the hypothesis that perception in an L2 is influenced by the participants' L1.

3.1. Experimental procedures and materials

Three classes of listeners were asked to participate to the perception test: native French speakers, native Mexican speakers, and Mexican learners of L2 French. The stimuli consisted of 96 resynthesized information-seeking questions (66 in French and 30 in Spanish). They were classified in four sets: (i) yes-no questions without any interrogative marker in

declarative form (as in (1) and (3)); (ii) yes-no questions with a syntactic marker indicating the modality of the utterance (French only, as in (5)); (iii) wh-'fronted' questions (as in (6)); and (iv) wh-'in-situ' questions (French only, as in (7)). The questions contained in set (i) displayed two different final rising contours: HH% and H%. Interrogatives in sets (ii), (iii) and (iv) had three different final tones: HH%, H% and L%.

Two native phoneticians (one for either language) recorded stimuli at the Laboratory of Linguistics from the University of Paris Diderot. At a first step, we obtained a stylization of the entire F0 trace associated with the various questions. At a second one, the final contours were manipulated in *Praat* in order to obtain perfectly coherent realizations. The manipulation was achieved along the following guidelines:

1. The HH% contour was obtained from the H% final rise in the natural stimuli, which were manipulated so that the rise would span >11 semitones.
2. The H% contour was also manipulated with *Praat* in order to enhance comparability between stimuli (we wanted to avoid mixing natural and manipulated stimuli): rises of 8 semitones were decreased to 6, while rises of 6 semitones were increased to 8 st.
3. The L% contours were extracted from phoneticians' realizations and manipulated into low flat plateaus.

In figure 2, we illustrate the manipulations that were carried out in the experiment:

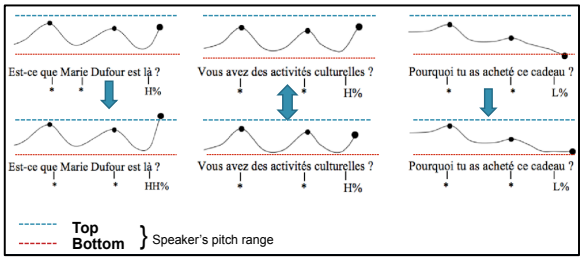

Figure 2: *Stimuli manipulation*.

The final syllable of each question (on which the tonal contour is realized) was composed exclusively of sonorants and mid oral vowels. Spanish questions were stressed either on the penultimate or on the final syllable. As for French wh-'in-situ' questions, a noun followed the interrogative word in order for the rise related to the pitch accent to be anchored on the wh-word.

3.2. Participants and task methodology

As mentioned three categories of participants were set up, the native speakers being control groups and the non-native speakers the experimental group. This latter group (hence FL2) was composed of 23 native Mexican Spanish speakers aged 24.7 years on average (*SD* 5.59) who attended a French course at the university of Mexico. These participants were classified into two sub-groups according to their level of proficiency in L2 French: 14 and 9 students were positioned at A2 and B1 level respectively (according to the CEFR). One of the two control groups was composed of 17 native speakers of French aged of 29.5 years (*SD* 11.14), and the other control group (SL1) consisted of 16 native speakers of Mexican Spanish aged 32.5 years on average (*SD* 8.14). The FL1 and FL2 groups were tested on French stimuli, while SL1 participants were tested on Spanish stimuli.

Since the tree contours tested here are actually acceptable in both French and Spanish, without implying a specific meaning in the investigated questions, we choose a methodological procedure that allows evaluating how these differences are perceived as gradient by native and non native listeners. Therefore, we opted for a rating task methodology.

Participants were asked to read on a computer screen different discursive contexts presenting a scenario for each question. They were instructed to listen to the resynthesized questions inserted in each scenario, and to evaluate their melody within a 1 to 5 scale (1= melody is inappropriate, 5= melody is appropriate). 66 fillers were included in the test, stimuli were randomized, and the test was presented in 4 batches to each group of participants (batches were also randomized). The test was carried out in a quiet room with an ordinary computer and high-quality headphones.

4. Results

Listeners' ratings were separated in four sets for the analysis, each set being associated with a question type: yes-no declarative questions, yes-no questions with an interrogative marker, wh-'fronted' questions, and wh-'in-situ' questions. In order to analyze the ratings attributed to the stimuli by the various groups of participants, and to test which differences were statistically significant, we constructed linear mixed effect models that took into account the predictor variables Contour (HH%, H%, L%), Group (FL1, FL2, SL1) and random intercepts and slopes for Subjects, for each of the structures which were tested separately. The contribution of each predictor variable was assessed using model reduction and likelihood ratio tests (χ^2).

With regard to yes-no declaratives questions, results showed significant main effect of Contour for ratings: listeners rated HH% higher than H% ($p<.01$). There was, however, no main interaction between Group and Contour for the ratings, i.e., all participants prefer extra rising tunes independently of their L1 in this question type (FL1 included). It was expected that, on the basis of the canonical rising patterns pointed in section 2, Spanish listeners would evaluate better HH% than H%, whereas French native listeners would prefer H%. So, the results obtained for this question set cannot help validating the hypothesis of a difference between L2 and natives speakers: FL1 participants prefer extra-rising contours to rising ones, even if this tonal contour is not frequent in their oral productions, as well as in the canonical description of French intonation.

As for yes-no questions with a lexical or morphosyntactic marker, we found a main effect of Group interacting with the Contour for the ratings: FL2 rated rising tunes (H% and HH% grouped) higher than the falling ones, while FL1 did not show a clear preference ($p<.0001$). In other words, the distribution of ratings for this question set depends on the native language of listeners. In this case, the two Groups did not show a preference for either H% or HH% ($p>.05$). As illustrated in Fig 3, ratings for L% in yes-no questions with a marker were extremely different across the two groups. These results could be interpreted as showing that non-native listeners prefer rising tunes, even when the modality of the sentence is marked by others means.

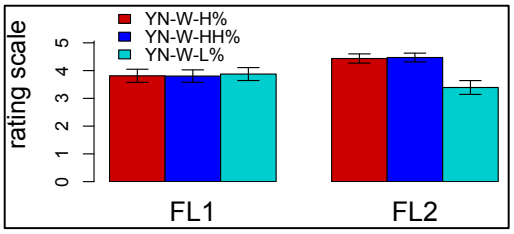

Figure 3: *Ratings given to yes-no marked questions*

In the set containing wh-questions with fronted wh-words, the analysis revealed that all listeners preferred rising contours (HH% and H% grouped) to falling ones ($p<.0001$). When comparing ratings of Groups concerning only the H% and HH%, it appears that there are significant differences as well: all participants rated higher H% than HH% ($p<.01$). Contrary to our expectations, there is no a main effect of interaction between Group and Contour in ratings. These results revealed that all groups, independently of their linguistic background, show a preference for H% in this structure. The results obtained cannot allow supporting any hypothesis. Both native and non-native speakers do show preference for tunes that they do not use so much.

An analysis carried out for wh-'in-situ' questions showed that there is a main effect of Contour for scores: all participants prefered rising tunes (H% and HH% grouped) to falling ones ($p<.001$). However, an analysis modeling the interaction between Group and Contour for ratings (rising vs. falling) did not reach significance: all participants, be they French or Spanish natives, prefer rising contours than the falling ones for this question set. When we excluded the falling contours, we found a significant interaction between the Group and Rising Contours (H% vs HH%) for ratings: FL2 evaluated the extra-rising contour better than H%; whereas FL1 did not show any preference ($p<.05$). These differences are illustrated in figure 4:

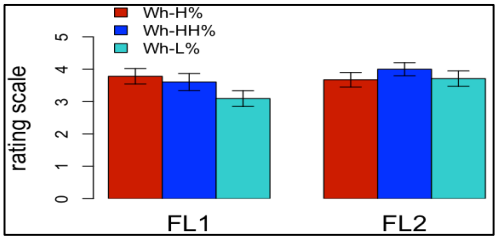

Figure 4: *Ratings given to wh-'in-situ' questions.*

Finally, in order to test whether the proficiency level had an effect on the choice of contour, we carried out an analysis including all question types. Main effects were found for ratings of Contour: rising tunes (H% and HH% grouped) received higher scores than falling ones. When comparing only ratings attributed to rising contours (excluding L%), results showed that all learners evaluated HH% higher than H% ($p<.05$). Nevertheless, no significant interaction between proficiency level and Contour on the rating choices was found. In other words, all FL2 listeners attributed ratings in the same way, despite their proficiency in L2 French.

5. Discussion and conclusion

In a global perspective, this study shows that all listeners, independently of their L1, rated rising contours better than falling contours when listening to yes-no and wh-questions, showing that there is a discrepancy between the patterns observed in oral productions and the perception. Regarding the scores of native listeners, the study revealed unexpected results. On the one hand, native listeners prefered rising tunes over falling tunes in questions they usually produced with falling contours (wh-questions). On the other hand, expected differences in rating concerning the form of the rising tunes (H% vs. HH%) were not observed in yes-no questions: FL1 listeners showed the same tendency as the other groups in rating the HH% contour higher, even though they do not employ it in their oral productions. These results suggest that rising tunes are considered as a universal prototypical form for declarative questions, regardless of their phonetic form (H% or HH%). In addition, rising forms are associated with all types of questions in the mind of both French and Spanish listeners, even if the contours that surface in the productions may be falling for some question types. In other words, listeners preferred rising contours because it is the form they associate with questions in their mind, independently of the fact that it does not correspond to what they produce. This explanation goes along the lines of Ohala's Frequency Code and Gussenhoven's Effort Code (see [15]).

In wh-questions, native listeners did not prefer the extra rising contour HH%. This could possibly result from the fact that this tune is unfamiliar to them for these question types. In addition, learners provide higher ratings for rising tunes (H% and HH%) associated with yes-no questions with a marker and with 'in-situ' questions than native listeners do. Interestingly, in the case of wh-'in-situ' questions, learners display a preference for the HH% contour in comparison to native speakers. By and large results show that native listeners prefer rising tunes displaying a familiar or natural increase in pitch for wh-questions (H% covering approx. 8 semitones like in their L1), and non-native listeners actually prefer uncommon extra-rising contours (HH% increasing more than 11 semitones) when listening to L2 stimuli. This is even more so in the case of questions with a morphosyntactic form that does not exist in the learners' L1. This interesting result suggests that the use of the HH% contour may be is related to the occurrence of a linguistic form that does not exist in their L1. This form could thus be seen as a default form in the case of linguistic insecurity. Further research on this issue is necessary to confirm that hypothesis and guaranty that results may not result from the task itself that asks for a kind of metalinguistic analysis.

Where do questions begin? – phrase-initial boundary tones in Hungarian polar questions

Katalin Mády[1], *Ádám Szalontai*[1,2]

[1]Research Institute for Linguistics, Hungarian Academy of Sciences, Budapest, Hungary
[2]Eötvös Loránd University, Budapest, Hungary
{mady|szalontai}@nytud.hu

Abstract

Hungarian prosody is left-headed, as suggested by the placement of the accent on the initial syllable on the level of prosodic words and the placement of the strongest pitch accent on the first accented word of the prosodic phrase. Earlier studies have pointed out that the left edge of the intonational phrase can bear a phrase-initial boundary tone that distinguishes between string-identical *wh*-interrogatives and *wh*-exclamatives. In this paper, two other string-identical sentence types, polar questions and declaratives, are investigated with respect to their prosodic features. Polar questions were characterised by a higher f0 maximum and a lower sentence-initial f0 than declaratives. The only pitch accent within the sentence was low, whereas declaratives had falling pitch accents. Sentence-final f0 and the pitch level of the accented syllable did not show a consistent pattern across speakers. It is concluded that low sentence-initial f0 together with the high t! one on the penultimate syllable is a relevant marker of polar questions in Hungarian.
Index Terms: intonation, phrase-initial boundary tone, polar question, declarative, sentence type.

1. Introduction

1.1. Left-headedness in Hungarian prosody and syntax

Hungarian prosody is left-headed, as suggested by the placement of the accent on the initial syllable on the level of the prosodic words and the placement of the pitch accent on the first accented syllable of the prosodic phrase [1, 2]. [3] who builds on earlier observations by [4] and [5] suggest a mapping rule between prosody and syntax that aligns the left edge of the syntactic phrase with the left edge of the phonological phrase. [6] makes a similar claim, namely that the nuclear stress rule of [7] operates in a direction opposite to that in English in that the primary phrasal stress falls on the left edge. This correlates well with the structure of the Hungarian clause, which can be divided into two basic units, first the topic (optional) which is linearly followed by the predicate (obligatory) at the left edge of which is the focus position, bearing the primary a! ccent. If a focussed constituent is present, it leads to the deaccentuation of the verb and the post-verbal elements within the same prosodic unit.

(1) [$_{Top}$ Tegnap] [$_{Pred}$ [$_{Foc}$ János] ette meg a levest]
yesterday John ate PV the soup
'Yesterday it was John who ate the soup.'

Due to the obligatory nature of the predicate, it is this syntactic structure that best correlates with higher level prosodic units, namely the intonational phrase. The word order of the Hungarian clause is determined by information structure: the constituent which is focussed is placed in the immediate pre-verbal position, thus receiving the main pitch accent in the clause [6]. In neutral sentences (those with broad focus) this position is usually occupied by the verbal prefix (PV in (1) above), which bears the main pitch accent in these cases. However if there is a focussed constituent and a verbal prefix, the prefix occurs immediately after the verb.

1.2. Sentence types and prosody in Hungarian

In theoretical classifications of clause or sentence types, the set of basic sentence types includes declaratives, interrogatives and imperatives, whereas exclamatives are considered to be outside of this set [8, 9]. The basis for this distinction is that while basic sentence types are definable with the help of a small number of necessary and sufficient formal criteria in the languages where they occur, there do not seem to be equally available unambiguous formal criteria for setting apart structures that express the meaning attributed to exclamatives. Instead, exclamatives can be only characterised by their intonational pattern.

Exclamatives were described as having a "high tone followed by a slow descent" by [10] previously. In a recent production study, string-identical *wh*-interrogatives and a particular type of *wh*-exclamatives were compared with respect to their tonal differences [11]. The analysis was based on tonal categories such as phrase-initial and phrase-final boundary tones and pitch accent patterns along with a parametric analysis of f0. Although it was expected that *wh*-exclamatives contained a higher f0 maximum than *wh*-interrogatives and a higher phrase-final boundary tone, they had actually lower f0 maxima than *wh*-interrogatives, and there was no difference between the sentence-final f0 values. The main distinction was the shape of the (only) pitch accent on the *wh*-word: exclamatives had rising accents, interrogatives falling ones. It was not clear whether the accent patterns were the primary cues for the into! national distinction, or whether they were a consequence of different phrase-initial boundary tones as had been proposed by [12] for *wh*-interrogatives. A follow-up perception experiment [13] with deaccented particles before the pitch-accented *wh*-word showed that sentence-initial f0 enhanced sentence-type identification, whereas the pitch accent pattern and sentence-final f0 did not.

Another example of sentence types that are only distinguished by their intonational patterns are yes/no interrogatives and declaratives. [14] and [15] suggest that there is an L* accent on the verb and an H L% boundary tone spread over the penultimate and final syllables. According to [16], the perception as a question is enhanced both by a higher f0 and a relatively late

timing of the peak within the penultimate syllable. It is not clear whether the L* pitch accent and a phrase-initial boundary tone contribute to the intonational distinction between these sentence types.

For the prosodic description of the two sentence types, the following questions are of interest: (1) Is there a sentence-initial tonal distinction? (2) Does the rising-falling sentence-final tone in interrogatives result in higher f0 due to truncation? (3) Are the L* accent and the H tone in questions indeed lower and higher in terms of absolute values than the corresponding values in declaratives?

2. Material and methods

2.1. Material

The study used five pairs of string-identical sentences with the structure in (2):

(2) De most végül lámpa is van náluk ./?
But now in the end lamp also be.3SG with them
'But in the end they have a lamp with them.'
'But in the end do they have a lamp with them?'

The first three items of the string *De*, *most*, and *végül* are unaccented discourse particles. These were included to provide enough phonological space for the sentence-initial boundary tones to manifest independently of the main pitch accent which in this sentence falls on *lámpa* 'lamp', the constituent in the focus position of the predicate. The combined length of these discourse markers was 4 syllables in all target sentences. The target sentences were preceded by disambiguating contexts.

The expected prosodic pattern for both questions and declaratives was to contain one single intonational phrase, 2–3 deaccented particles (4 syllables altogether) and one pitch accent on the focussed word with post-focal deaccentuation. The last pitch accent preceded the sentence-final boundary by 4–8 syllables, which typically resulted in an overall rising f0 between the accented and the penultimate syllable for questions, and a flat or falling contour for declaratives. Sentences that contained more than one prosodic phrases or several pitch accents were excluded from further analysis. 296 utterances in total were analysed.

There were 7 subjects (all female) with a mean age of 21 years. Their task was to read aloud sentences that were presented to them on a screen using the experimental software SpeechRecorder [17]. Each pair of sentences was presented five times in individually randomized order.

2.2. Methods

The following parameters were investigated:

- sentence-initial f0 (on the first vowel),
- sentence-final f0 (on the last vowel),
- lowest f0 on the accented syllable,
- f0 maximum within the sentence.

F0 was measured using Praat's standard autocorrelation method with a window length of 30 ms and a window shift by 5 ms. Tones with an f0 minimum below 130 Hz were regarded as creaky-voiced.

Additionally, pitch accents were labelled with respect to their pattern. Categorisation relied on the actual f0 movements rather than on phonological labels.

Mixed models with the random effects subject and sentence were carried out for each parameter. Significance was tested by the `Anova()` function of the `car` package in R, and the significance level was set to $p < 0.05$. Hertz values were transformed into semitones.

3. Results

Figure 1 shows typical examples of a declarative and an interrogative sentence. The declarative contains one pitch accent that falls on the first syllable of the word *LÁMpa* 'lamp'. The falling accent is typically found in pre-verbal elements within the predicate [18]. The polar question contains one pitch accent on the same syllable which has a low tone. The f0 maximum is associated with the penultimate syllable.

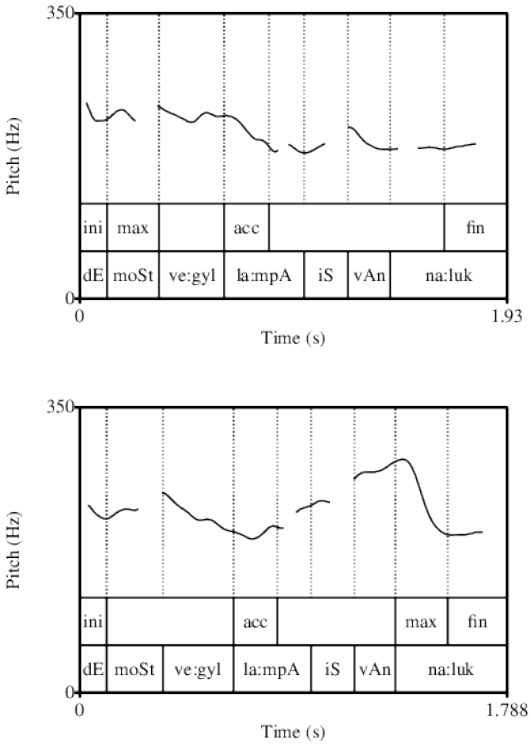

Figure 1: *Pitch contour of the declarative sentence 'But in the end they have a lamp with them' (top) and the polar question 'But in the end do they have a lamp with them?' (bottom). Measurements described in Section 2 were based on the syllables marked as* ini, acc, max, fin.

3.1. Sentence-initial f0

There was an overall tendency for sentence-initial f0 to be lower in interrogatives (mean = 206 Hz) than in declaratives (mean = 224 Hz, difference: 1.48 semitones, $p < 0.005$). The tendency was present in 6 out of 7 speakers (see Fig. 2). Intra-speaker differences ranged from -0.03 to 5.88 semitones. Occurrences of creaky voice were rather low in this position (3% of all cases), and they were evenly distributed between declaratives and polar questions.

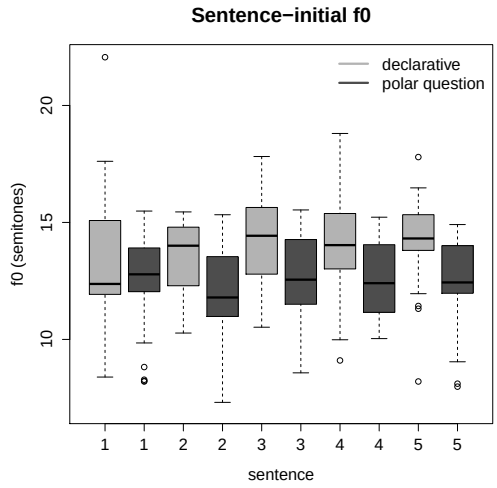

Figure 2: *Sentence-initial f0 in semitones. Pairwise comparison of sentences (top) and speakers (bottom).*

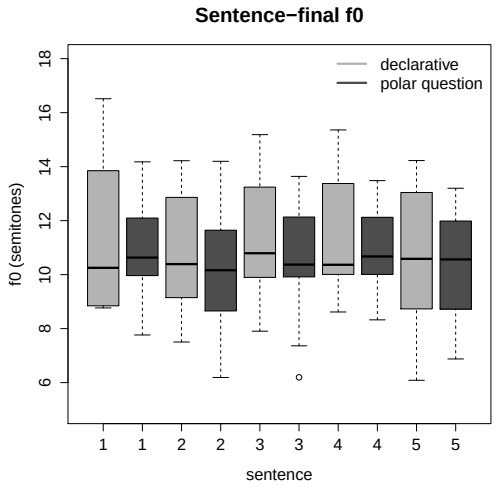

Figure 3: *Sentence-final f0 in semitones. Pairwise comparison of sentences (top) and speakers (bottom).*

3.2. Sentence-final f0

As is shown in Fig. 3, sentence-final f0 in interrogatives was realised somewhat lower (mean = 185 Hz) than in declaratives (190 Hz, difference: 0.48 semitones, $p < 0.005$). This tendency was present in 4 out of 7 speakers. Intra-speaker differences ranged from -1.82 to 4.42 semitones. 34% of all sentence-final syllables were produced with creaky voice, and their occurrences in the two sentence types were equal.

3.3. F0 maximum

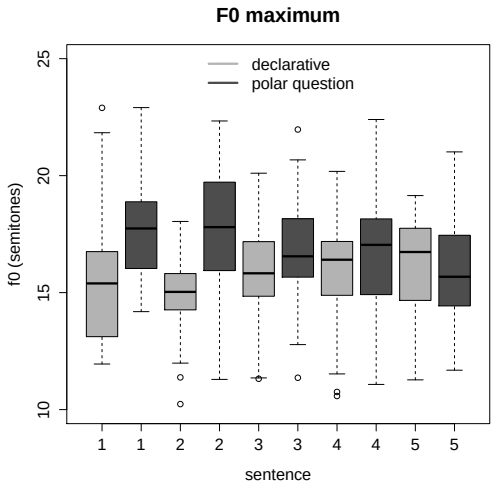
The maximal f0 was significantly higher in questions than in declaratives (269 Hz vs. 248 Hz, 1.39 semitones, $p < 0.005$, see Fig. 4). One out of 7 speakers showed an opposite pattern. Intra-speaker differences ranged from -3.13 to 1.88 semitones, and the voicing was always modal.

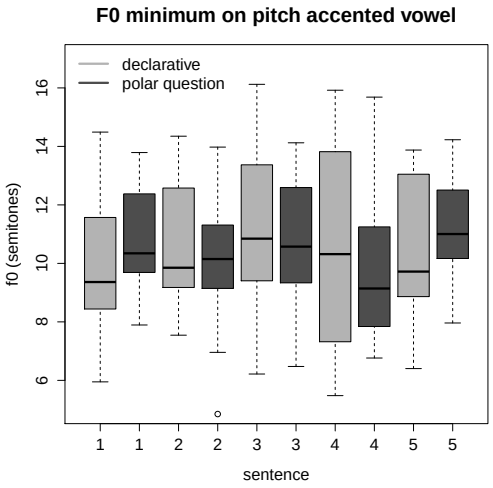
The maximal pitch in polar questions is presumably perceived even higher than the actual f0 suggests, since the maximum appears later in the sentence than in declaratives, and it is relatively higher compared to the declination line.

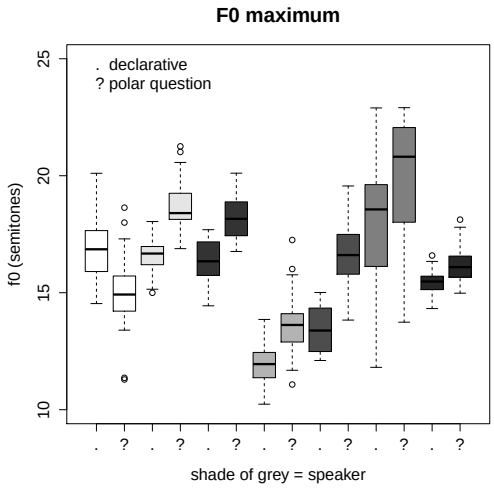
3.4. Pitch accent

Declaratives and polar questions are characterised by different pitch accents. The default pitch accent for focussed words in declaratives is a falling one, typically H*+L, see [18, 19]. Polar questions are realised with low or rising accents [16, 14]. In order to test whether the lowness of the f0 of the pitch accent is relevant for the distiction, the lowest f0 on the accented syllable was measured.

As demonstrated in Fig. 5, there was no clear tendency across speakers with respect to local f0 minima. The mean f0 was slightly higher for declaratives (187 Hz) than for questions (184 Hz, $p = 0.02$), but this is reflected only in 4 out of 7 speakers, and the mean difference was only 0.2 semitones which is only slightly above the just noticeable difference. The intra-speaker difference ranged from -0.42 to 1.72. Creaky voicing occurred in 7% of all questions, whereas it was half as frequent in declaratives.







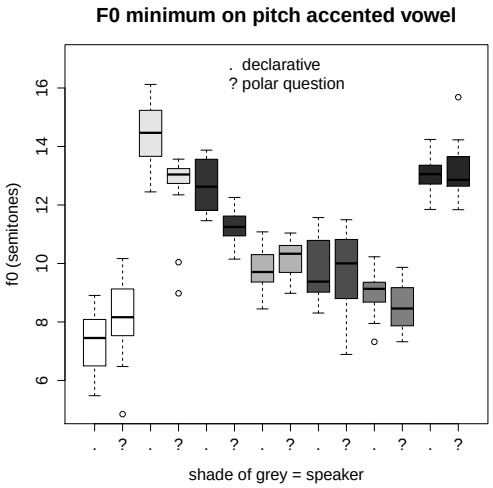


Figure 4: *F0 maximum in semitones. Pairwise comparison of sentences (top) and speakers (bottom).*

Figure 5: *Local f0 minimum in pitch-accented vowels. Pairwise comparison of sentences (top) and speakers (bottom).*

4. Discussion and conclusions

The above results show that string-identical polar questions and declaratives differ both in terms of their tonal pattern and their f0 parameters. A consistent intra-speaker pattern was only observed for sentence-initial f0 that was lower and the overall f0 maximum that was higher in questions. Speakers did not show a homogeneous pattern with respect to the utilisation of sentence-final f0 and the local f0 minimum on the pitch-accented vowel.

As was said in the Introduction, string-identical *wh*-interrogatives and exclamatives are distinguished by higher sentence-initial f0 and higher f0 maxima for interrogatives, whereas sentence-final f0 does not play a role. The present data also show a higher f0 maximum for interrogatives, but a *lower* sentence-initial f0. Thus, it cannot be generalised that interrogatives were marked by higher sentence-initial f0 altogether, but it seems that sentence-initial f0 is indeed relevant for the sentence type distinction. Sentence-final f0, however, is rather inhomogeneous and is thus not expected to be a crucial marker for polar questions and declaratives. These results further corroborate the importance of the the left edge of prosodic units in Hungarian.

Two questions need further investigation in the close future: (1) Can the perceptual relevance of phrase-initial boundary tones for polar questions and declaratives be stated? (2) Is a high f0 maximum generally characteristic for interrogatives, and if yes, is it a linguistic or a pragmatic feature?

Encoding and decoding Confidence information in speech

Xiaoming Jiang [1], *Marc D. Pell* [1]

Abstract

This study aims to investigate the perceptual-acoustic correlates of vocal confidence. Statements with different communicative functions (e.g., stating facts, making judgments) were spoken in confident, close-to-confident, unconfident and neutral voices. Statements with preceding linguistic cues (e.g. I'm positive, Most likely, Maybe, etc.) or no linguistic cues were presented to sixty listeners in a perceptual study. The listeners were asked to judge whether statements conveyed some level of confidence, and if so, they were asked to evaluate the level of confidence of the speaker. The results demonstrated that the intended levels of confidence varied in a graded manner in the perceptual rating score; the more confident the statement intended to be, the higher the rating. In general, the neutral voice was judged to be more confident than the close-to-confident voice, but less than the confident voice. The presence of a linguistic cue tended to increase ratings of confident voices but decrease ratings of voices in the less confident voice conditions. To evaluate how specific prosodic cues are used to encode and decode confidence information, acoustic analyses were performed on the stimuli without the linguistic cue based on the mean perceptual rating of speaker confidence for each item. Results showed that statements rated as confident versus unconfident differed in the mean and the variance of fundamental frequency (f0) as well as speech rate, with confident statements exhibiting lower mean f0, smaller f0 variance, and faster speaking rate than unconfident statements. The perceived level of confidence was differentiated in the mean fundamental frequency in a parametric way, the lower the level of confidence, the higher the mean f0. Confident voices were also distinct from the other three conditions in terms of mean and range of amplitude (i.e., loudness). These findings shed light on how linguistic and paralinguistic cues reveal confidence-related information to listeners during speech.

1. Introduction

Humans have the ability to encode different types of emotive and social meanings in speech communication, which are often understood by listeners through an inferential process that weighs evidence from available linguistic and paralinguistic cues. Among the different emotive states that can be expressed are emotive devices that serve to foreground speaker-content (*evidentiality* devices). Within this category, *confidence* refers to cues that provide evidence of the reliability, correctness, or truth value of a speaker's statement; in social interactions, listeners make inferences about the confidence of other speakers to make appropriate decisions based on the perceived reliability of what is said, and they may also use this information to associate specific social or personality traits to the speaker (e.g. perceived confidence is usually associated with persuasiveness, [1]). It is suggested that evidentiality/confidence is communicated through the choice of specific linguistic structures (e.g. modal adverbs) and/or the speaker's prosody (e.g. changes in pitch / intonation contour and other acoustic parameters to make speech sound doubtful, certain, authoritative, submissive, etc.). However, little empirical work has been conducted on how different levels of confidence are realized by a speaker in terms of prosodic variation, nor is it well known how speakers use prosodic and linguistic cues in the decoding of speaker confidence. The goal of the present study was to supply preliminary data on perceptual and acoustic features of utterances that convey varying levels of confidence in English, as a first step for advancing knowledge of how evidentiality devices operate in speech communication.

2. Methods and results

2.1 Emotion elicitation study

2.1.1 Participants

Six native Canadian English speakers (Mean age in years = 22.8, three females) were recruited to produce statements expressing different levels of confidence in their native language. Speakers were selected for having lay experience in acting (e.g. in community theatre) or in public speaking (e.g. radio) and were compensated $35 after the recording session.

2.1.2 Materials

One hundred and fifty-one sentences were constructed by a native speaker of Canadian English (one of the authors, MDP). Sentences were of three types: 67 were statements describing a fact, 40 were descriptions of one's intention to initiate an action, and 44 were descriptions of one's judgment toward other people or things. Each sentence was intended to be produced in a neutral manner and to convey three levels of confidence about the subject matter: confident, close-to-confident, and unconfident. In order to facilitate production of sentences that were inflected to convey different levels of confidence in a way that was as natural as possible, lexical phrases consistent with each level of confidence were used as the beginning of the sentence during recording. For the confident level, speakers began with either "Definitely", "For sure", "I'm certain" or "I'm positive"; for the close-to-confident level, they produced "I think" "Most likely", "I'm pretty sure", "I'm almost certain"; and for the unconfident level, they began with "Maybe", "Perhaps", "It's possible", "There's a chance". Finally, 151 wh-questions were also created to facilitate naturalistic expressions of each sentence during the recording session by having speakers produce target sentences as part of a mini-dialogue (e.g. What will happen? – We will run out of gas). Care was taken that none of the questions led speakers to emphasize specific constituents in

the sentence, but rather, they could freely respond to the question with the appropriate level of confidence.

2.1.3 Elicitation and recording procedure

Each speaker was recorded separately in a sound-attenuated chamber. Sentences conveying neutral affect and each of the three levels of confidence were recorded in a separate block during the elicitation study. The neutral level always preceded the other levels. The order for recording specific confidence levels was randomized across speakers. Within each confidence condition, the three types of sentences (facts, intentions, judgments) were also recorded in a separate block. The order for recording specific type of sentences was randomized across confidence levels.

To facilitate expressions of confidence that were as naturalistic as possible, we created a dialogue setting in which the actor responded to questions posed by a female examiner, who was a native Canadian English speaker. For each confidence level, the examiner asked the question constructed for each target sentence and then the speaker produced the sentence with the appropriate level of confidence as if answering the speaker's question. The examiner provided clues to the speaker at the onset of each level that included descriptions of a scenario that would be likely to elicit the target level of confidence [2]. However, at no time did the examiner never model the vocal features that may be associated with specific impressions of confidence to participants. In the confident/close-to-confident/unconfident recording blocks, the speaker was instructed to produce the lexical phrase followed by the main sentence stem and to try to portray the level of confidence in their voice (prosody) throughout the sentence. They repeated each sentence twice. Recording blocks were separated by a short break to help the transition between modes of social expression. After producing each confidence level, speakers were asked to rate on a 7-point confidence scale (1=not at all confident, 7= very confident) how confident they were subjectively feeling when they produced sentences in each condition; the mean ratings for the six speakers were 6.5 in the confident voice condition, 4.7 in the close-to-confident condition, 1.8 in the unconfident condition, and 5.0 in the neutral condition.

All utterances were recorded onto digital media (Tascam Recorder) using a high-quality head-mounted microphone. The recordings were transferred to a computer and were saved as individual sound files in Praat. To reduce the number of exemplars included in the perceptual rating study, the two repetitions of each item produced by a given speaker were initially evaluated by two native English speakers to select the best (single) exemplar per item/speaker, based on a judgment of which item conveyed the intended target level of confidence, while excluding items that sounded unnatural (i.e., posed) and/or that had recording artifacts. This process yielded 3624 stimuli in total (6 speakers x 4 confidence levels x 151 items).

2.2 Perceptual study

2.2.1 Participants

A total of 60 listeners took part in the study (31 females and 29 males, with the mean age 25.2 years, mean education 16.6 years). All listeners were born and grew up in Canada and had English as their first language. None had lived outside of Canada for more than 1 year. All participants had normal hearing and no history of psychiatric or neurological disorders.

2.2.2 Materials and procedure

To test the perceptual recognition of confidence from utterances that contained lexical phrases or just prosodic cues, all recordings were further edited by removing the lexical phrase; this produced two versions of each statement with and without the lexical phrase ("with-cue" and "no-cue statement"). The resulting 6342 statements (6 speakers x 4 confidence levels x 151 items 2 cue types) were divided into six experimental lists (each with 1057 statements). The "with-cue statement" and the "no-cue statement" with the same sentence stem produced by the same speaker in the same prosody were never repeated in one list. Statements in each list were randomized for each listener and were separated in 20 short blocks. Each list was judged by 10 participants.

Listeners were tested separately or in pairs in a quiet experimental lab and were asked to perform two tasks sequentially. After presented with a statement, they first judged whether the statement conveyed some level of confidence by clicking YES or NO printed in two squares on the screen; they were informed that the level of confidence could be signaled by a lack of confidence or much confidence. If they answered YES, a 5-point scale was presented on the screen and they were asked to rate the speaker's level of confidence by choosing a number that best fit their impression of the last statement. A same number scale was also shown if they answered NO, however, they were asked to select any number to continue to the next trial.

2.2.3 Data analysis

A univariate analysis of variances were performed on the mean rating score of speaker's confidence for all statements of the two speakers, taking intended level of confidence (confident vs. close-to-confident vs. not confident), cue type (with lexical cue vs. no lexical cue), and type of utterance function (fact vs. intention vs. judgment) as three independent factors. Further analysis was planned when interaction between the factors were significant.

2.2.4 Results

Table 1 and Figure 1 demonstrate the mean perceptual ratings of with-cue and no-cue statements of each utterance type and in each level of confidence. The univariate ANOVA on all perceptual data revealed a significant main effect of level of confidence, $F(2, 1794)=2948.76$, $p<0.001$. Post-hoc Tukey's comparison confirmed that the speaker's confidence was rated the highest in the confident condition, followed by close-to-confident stimuli, followed by the unconfident stimuli. There was significant effect of cue type, $F(1, 1794)=215.78$, $p<0.001$, suggesting that with-cue statements were in general rated lower than the no-cue statements. The effect of type of utterance function was also significant, $F(2, 1794)=13.63$, $p<0.001$, suggesting that statements of intention were rated lower overall than statements of fact and judgment, with the

latter two not different from each other. Moreover, there was a significant interaction between level of confidence and cue type, $F(2, 1794)=136.20$, $p<0.001$ and a significant interaction between level of confidence and type of utterance function, $F(4, 1794)=2.40$, $p<0.05$. Separate analysis on each level of confidence revealed a significant effect of cue type for all levels of confidence: for confident, $F(1, 598)=51.80$, $p<0.001$, for close-to-confident, $F(1, 598)=257.28$, $p<0.001$, and for unconfident, $F(1, 598)=129.94$, $p<0.001$. Post-hoc comparison revealed a higher rating for the with-cue than the no-cue statement in the confident condition, whereas *lower* ratings were observed for the with-cue than no-cue statement in the close-to-confident and unconfident conditions.

Separate analysis also revealed an effect of type of utterance function for confident, $F(2, 598)=4.74$, $p<0.01$, for close-to-confident level, $F(2, 598)=12.98$, $p<0.001$, but not for unconfident level, $F(2, 598)=1.70$, $p>0.1$. These findings suggested that the lower ratings for intentions than for the other two functional types were most prominent in the confident and the close-to-confident conditions.

In order to examine the difference between the intended-neutral and the other levels of confidence, an additional ANOVA on the no-cue statements only revealed a significant effect of level of confidence, $F(3, 1195)=670.58$, $p<0.001$. Post-hoc comparison revealed that the intended-neutral utterances were rated as comparable to the close-to-confident utterances, lower than confident and higher than the unconfident utterances.

Table 1. Mean and standard deviation of the rating score of speaker's level of confidence for with-cue and no-cue statements in each intended confidence level.

	Confident				Close-to-confident			
	With Cue		No Cue		With Cue		No Cue	
Utterance Type	Mean	SD	Mean	SD	Mean	SD	Mean	SD
Fact	4.54	0.29	4.36	0.30	3.31	0.38	4.08	0.36
Intention	4.50	0.29	4.28	0.31	3.28	0.47	3.75	0.61
Judgment	4.56	0.27	4.42	0.29	3.48	0.37	4.00	0.48

	Unconfident				Neutral	
	With Cue		No Cue		No Cue	
Utterance Type	Mean	SD	Mean	SD	Mean	SD
Fact	2.29	0.36	2.84	0.66	4.14	0.33
Intention	2.24	0.33	2.70	0.59	3.91	0.32
Judgment	2.29	0.37	2.76	0.65	4.05	0.31

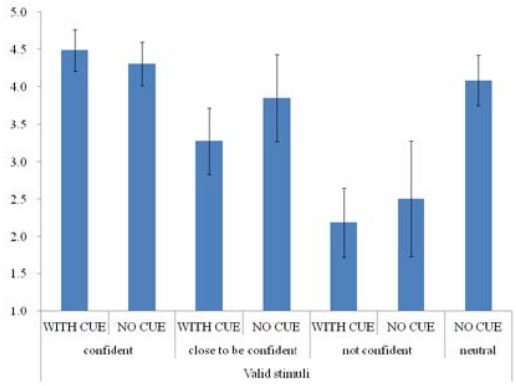

Figure 1. Perceptual rating scores of speaker's confidence for both with-cue and no-cue statements in each intended level of confidence

2.3 Acoustic study

2.3.1 Data analysis

In order to evaluate how different levels of confidence were acoustically differentiated in statements perceived as conveying confidence without lexical cues, acoustic measures were derived and analyzed only for "no-cue" statements. Due to the large number of intended neutral exemplars perceived as conveying some level of confidence, the statements with the frequency of "yes" response below 6 out 10 in the binary task were assigned as neutral, the statements with the frequency of "yes" response above 8 out of 10 were assigned as with-confidence. Among the with-confidence statements, the target level of confidence was re-assigned based on the perceptual results (see below). Those with the mean perceptual score above 4.2 in the 5-point rating task were designated as "confident", those with a mean score between 3.2 and 3.8 were designated as sounding "close-to-confident", and statements with a mean score below 2.8 were assigned to the "unconfident" condition.

Five acoustic measures that frequently differentiate among vocal emotion categories [2] [3] [4] were analyzed, including the mean fundamental frequency (mean f0, in Hertz), the range of fundamental frequency range (f0 variance, in Hertz), the mean amplitude (mean amplitude), the range of amplitude (amplitude variance), and speaking rate (in syllables per second). A normalization procedure was applied to the first four measures before comparing between speakers [2] [4]. Acoustic analyses were performed using Praat speech analysis software; the results for statements of fact for one male and one female speaker are reported here.

A multivariate analysis of variance (MANOVA) was performed on all valid no-cue statements that fell in the perceptual range defined for each target level of confidence. The mean and range of f0, mean and range of amplitude and speech rate were taken as dependent factors and the target level of confidence was considered as independent factors. A series of univariate ANOVA were further performed on each acoustic measure. We report the perceptual data for no-cue

statements from two speakers (1 male and 1 female) in the following section.

2.3.2 Results

Based on preliminary analysis of the two speakers, a total of 192 recordings were subjected to analysis. Table 2 demonstrated the mean perceived level of confidence and the values for each of the five acoustic parameters computed for the no-cue statements that were reassigned based on the ranking of the confidence perception. The one-way MANOVA was performed on acoustic data with the four perceived levels of confidence as independent variables and seven acoustic features (normalized mean f0, normalized f0 range, normalized mean amplitude, normalized amplitude range and speech rate) as dependent variables. The MANOVA indicated that the effect of level of confidence on the linear combination of the five acoustic parameters was significant, Wilk's λ = 0.575, $F(21, 523)=5.30$, $p<0.001$. Subsequent univariate analysis on each acoustic parameter revealed that the effect of level of confidence was significant for mean f0, $F(3, 188)=36.93$, $p<0.001$, f0 range, $F(3, 188)=4.16$, $p<0.01$, mean amplitude, $F(3, 188)=3.34$, $p<0.05$, amplitude range, $F(3, 188)=2.96$, $p<0.05$, and speech rate, $F(3, 188)=2.49$, $0.05<p<0.1$. Post hoc (Tukey's) comparisons revealed that the normalized mean f0 increased in value over neutral, confident, close-to-confident and unconfident meanings; the neutral level revealed a higher normalized f0 range and a higher speech rate than the three with-confidence levels, which did not exhibit any differences. Statements perceived as confident displayed both a higher mean amplitude and a higher amplitude range than statements in the other three conditions, which did not show any differences in amplitude measures. Statements perceived as not conveying any confidence were spoken more quickly overall than statements conveying the three levels of confidence.

Table 2. Mean normalized acoustic values for the no-cue statements produced by two speakers to express three levels of confidence and to the neutral level based on the perceived level of confidence.

Perceived level of confidence	Confidence rating	Mean f0	f0 variation	Mean amplitude	Amplitude range	Speech rate
Confident	4.50	0.40	1.37	1.23	1.96	4.61
Close-to-confident	3.60	0.65	1.86	0.96	1.58	4.50
Unconfident	2.30	0.76	1.85	1.02	1.64	4.27
Neutral	3.90	0.28	1.09	1.14	1.80	5.05

3. Discussion

This study demonstrates that listeners make use of prosodic information in speech to perceive different levels of confidence of a speaker when expressing facts, intentions, and making judgments which occur frequently in discourse. In particular, statements rated as conveying different levels of confidence were acoustically distinct in their f0 characteristics, with the more confident the statement intended to be the higher the confidence rating, among other acoustic distinctions. The additional presence of a lexical phrase that signaled speaker confidence had varying effects on perceptual ratings depending on the level of speaker confidence communicated: the presence of the lexical cue in confident statements tended to amplify confidence ratings, whereas lexical phrases in statements that lacked full confidence (close-to-confident, unconfident) tended to attenuate impressions of confidence, yielding lower ratings for "with-cue" utterances in these conditions. Interestingly, different utterance types (facts, intentions, judgments) differed in subtle but significant ways in how listeners perceived speaker confidence from prosodic cues. These findings are broadly consistent with Pell [5] who found that the attitudinal and interpersonal significance of prosody can be perceptually differentiated by both healthy and right-hemisphere-damaged adults, extending these findings to a group of healthy young adults.

The acoustic analysis on the no-cue statements further demonstrated several important mechanisms underlying the acoustic realization of confidence-related information in speech: 1) the f0 variance and the speech rate differentiated the with-confidence and neutral statements; 2) the mean f0 predicted the levels of confidence in a parametric way; and 3) the mean amplitude and the amplitude change highlighted the confident-level specifically. Taken together, our findings indicate that prosodic information guides how listeners infer the confidence state of a speaker, and that these pragmatic inferences may be affected by both linguistic and paralinguistic cues in speech communication, and may vary for different speech acts.

Aspects of Prosodic Phrasing in Turkish

Jane Kühn

Department of Linguistics (SFB 632), University of Potsdam, Germany
jkuehn@uni-potsdam.de

Abstract

This pilot study investigates the prosodic marking of contrastive in-situ focus in monolingual Turkish. The results of the production study are based on a phonological and phonetic analysis of information structure modified target sentences. The prosodic analyses reveal (i) feature that derive properties of prosodic phrasing which are inherent to phrase languages [5]. It is shown that Turkish is a radical splitting language since each prosodic word (ω) [14] forms its own phonological phrase (φ) [14] indicated by a high phrase tone (H-) aligned to ω- final syllables. The language´s preference for radical splitting of simple SOV sentences is maintained in information structure modified targets by one speakers group, but modified by another group in favor of wrapping adjacent given constituents into one φ. The analyses reveal (ii) that prosodic cues are not crucial to mark in-situ focus in Turkish, but they may be used to contextualize information structure. If focused constituents are marked at all by prosodic means they do not show an increased pitch like most Germanic languages, but focused constituents are aligned to prosodic boundaries. The data motivate the claim that prosodic alignment is an adequate way to describe the prosodic realization of focus in Turkish.

Index Terms: Turkish, focus, alignment

1. Introduction

Turkish is claimed to have two distinct focus marking strategies: syntactic movement and prosodic focus marking in-situ [2, 6, 9], i.e. when the focused constituent remains in the default word order. Previous studies on prosodic focus marking in Turkish describe focus in the original meaning of prominence as an increase of acoustic parameters and the modulation of pitch accents [10]. Correspondingly, different tunes are described for different information structural parts: e.g. H*L- for focused and L*H- for given constituents [15]. H-boundary tones are assumed for pre-nuclear phrases, and an H* nuclear pitch accent is designated to align to the immediately pre-verbal position in syntactically un-marked sentences [11], as demonstrated in Figure 1.

Figure 1. *Broad focus intonation contour in SOV*

H-	H*	L- L%
(subject)xp	(object	verb)vp

All tones are usually aligned to the last syllable of a ω, since Turkish word stress is final [12]. However, a recent acoustic analysis [8] reveals that Turkish shows no straightforward pitch accent modification of the focused constituent for in-situ focus. Despite the lack of pitch range expansion a change in the f0 contour is observed for final and initial focus: A focused verb in SOV declaratives shows an *immediately pre-focal rise* on the preceding constituent and post-focal compression (PFC) is observed after initial focus.

Concerning the cross-linguistic realization of focus prominence, typological studies [1, 3] show that focus is not necessarily marked by an increase of acoustic parameters such as f0, duration and intensity, as in most Germanic languages. Focus can also be captured by means of prosodic alignment understood as the correspondence between the edge of a syntactic and/or phonological constituent and the focused part of a sentence [13, 15]. On the basis of mapping theory [16], [17] proposes WRAP which offers at least three strategies for mapping: (a) radical splitting where each syntactical phrase (xp) forms its own (φ), (b) moderate wrapping where each xp forms its own φ and non-phrasal elements are wrapped with the closest phrase, and (c) radical wrapping where every element of the biggest xp gets wrapped into one φ. In the prominence theory of focus [17] focus needs to be maximally prominent which can be achieved by a modification of the phrasing structure, either by swapping of pitch accents or by the introduction and/or deletion of prosodic phrase boundaries. In focus as alignment theory [3] focus alignment may be obtained even in the absence of prominence.

This paper presents data that support the classification of Turkish as a phrase language [7] showing that high tones aligned to ω- final syllables represent phrase boundaries. Furthermore, the optionality of prosodic marking of in-situ focus is demonstrated. A change in phrasing according to information structure states prosodic alignment as optional tool to mark focus in Turkish.

2. Hypotheses

With regard to previous acoustic measurements [8] which did not succeed in identifying pitch increase as a focus marker, but revealed a modification of f0 by means of PFC and *pre-focal pitch increase* two assumptions are examined in the pilot production study:

- High tones on word final syllables do not represent typical pitch accents aligned to word stressed syllables but are phrase delimiting boundary tones.
- In-situ focus is prosodically marked by a modification of the phrasing structure, i.e. focus is aligned to prosodic boundaries by means of boundary insertion/deletion.

In practice, the high tone (H*) on nuclear constituents described by [11] was expected to be a further boundary tone in accordance to the pre-focal high tones (H-) observed by [11]. Since [8] describes a rise on (H*) in the immediately pre-focal position it was expected to be the result of the introduction of a boundary tone and not an increased pitch accent aligned to a ω stressed syllable. The previously

observed *immediately pre-focal rise* and PFC [8] were expected to be the results of boundary insertion and/or deletion to satisfy focus alignment.

3. Method

This production experiment is a modified replication of [8]. Both studies adopt the methodology of [18] to elicit in-situ focus on different constituents.

3.1. Stimuli

Five target sentences with a simple SOV structure including an accusative object were designed. Each target contained the same number of comparable segments: a three syllabic subject, a four syllabic object, and a three syllabic verb. To elicit the introduction of boundary tones and the status of (H*) vs (H-), only subjects and objects with non-final lexical word stress were considered to avoid that pitch accents and boundary tones would fall on the same segment. Each sentence was elicited as a contrastive focus condition, i.e. when the interpretation of a linguistic expression is limited to a set of contrasting alternatives. Targets were preceded by a question eliciting contrastive focus on either the subject, the object, or the verb. As a baseline, a broad focus condition was elicited for all targets. The contrastive constituent of the targets was always presented as the first alternative in the preceding questions. The elicitation of contrastive in-situ focus was furthermore supported by the focus sensitive question particle -mı attaching to the contrastively focused alternatives in the preceding questions. The morphological marker should help to avoid the triggering of a default reading prosody in the following answer and reduce errors concerning the focused constituent. Additionally, the focused items were presented with underlining to avoid prosodic pattern repetitions since the question-answer pairs were presented without fillers. In (1) a list of the target sentences is provided. In (2) the question-answer pairs are exemplarily provided for target sentence (a).

(1) *Target sentences.*

(a) Fahıre Naca'sını seviyor.
Fahıre Nacı-POSS-ACC love-PRS(3SG)
Fahıre loves her Nacı.

(b) Nasrettin babasını üzüyor.
Nasrettin father-POSS-ACC sadden-PRS(3SG)
Nasrettin saddens his father.

(c) Macide kardeşini çiziyor.
Macide sibling-POSS-ACC draw-PRS(3SG)
Macide draws her sibling.

(d) Nadide ablasını özlüyor.
Nadide sister-POSS-ACC miss-PRS(3SG)
Nadide misses her sister.

(e) Yasemin aynacıyı dinliyor.
Yasemin mirror dealer-ACC listen-PRS(3SG)
Yasemin listens to the mirror dealer.

(2) *Contrastive focus questions preceding target (a).*

(broad) Ne oluyor ?
What be-PRS(3SG)
What happens?

(subject) Fahire mi Naci'sini seviyor, Meral mı?
Fahire Q Naci-POSS-ACC love-PRS(3SG) Meral Q
Does Fahire love Naci or Meral?

(object) Fahire Naci'sini mı seviyor, polisi mi?
Fahire Naci-POSS-ACC Q love-PRS(3SG) police man Q
Does Fahire love Naci or the police man?

(verb) Fahire Naci'sini seviyor mu, üzüyor mu?
Fahire Naci-POSS-ACC love-PRS(3SG) Q sadden-PRS(3SG) Q
Does Naci love or sadden Naci?

Each pair of target sentence and preceding question was presented subsequently in its four focus conditions. No repetitions were made. 140 utterances were recorded: 7 speakers x 5 sentences x 4 foci.

3.2. Subjects

Seven native Turkish speakers, four females and three males, from Ege Universitesi in Izmir participated in the experiment. At recording time they were aged between 20 and 27, had no previous specific linguistic knowledge and no speaking or hearing disabilities. All of them were monolingual speakers; most of them had some basic foreign language skills in a second language.

3.3. Recording process

The data were recorded in a translation laboratory. The target sentences and preceding questions were presented on a power point slide. The subjects were asked to read out aloud first the question and subsequently the answer. The interviewer was a native Turkish speaker who was schooled to ask the participant to repeat the question-answer pairs in cases of discrepancies concerning the understanding of the task.

4. Analyses and results

4.1. Phonologic analysis

A phonological annotation of 135 target sentences was done by the author and double checked by a native Turkish speaker. Five utterances had to be excluded from the analyses due to creeky voice, slip of the tongue or hesitation. The phonological annotation of the *f0* contour among the different focus conditions of the whole ιp was done for each target sentence and speaker. All target sentences were manually segmented in Praat on the syllable level. Supra-segmental labeling basically follows [11], but is adapted and modified with respect to the features observed in the data using general ToBi labeling advices, since Turkish lacks a conventionalized annotation system. Special attention was paid to boundary tone insertion/ deletion under the changing foci.

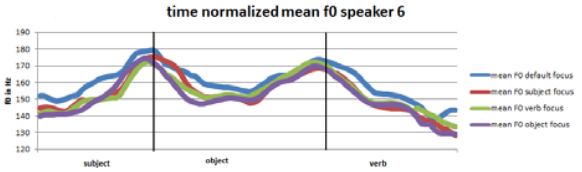
The descriptive phonological analysis revealed that all speakers of the production experiment implemented a high tone (H-) on the ultimate syllable of the subject and a further high tone (H-) on the following object in all broad focus and object focus sentences. In addition to the high tones on the last syllable of each non-final ω, some speakers arbitrarily implemented pitch accents on the word stressed syllables of the lexically accented words. A low final boundary tone (L%) was aligned with the ι-phrase final verb. Figure 2 demonstrates the broad focus intonation contour and phrasing of Turkish SOV declaratives for all speakers as observed in the data.

Figure 2. *Broad focus intonation contour in SOV*

(H*) H- (subject)φ (H*) H- (object)φ L% (verb)φ

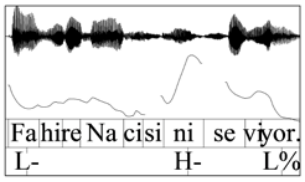
Concerning the tonal modification corresponding to different focus conditions, two groups were identified. For group A (speakers 1, 2, 3, 5, 6) the observed tonal implementation as shown in Figure 2 was not modified by information structure. Neither a categorical modification of the described high tones, nor the insertion or deletion of tonal boundaries was observed in the different focus conditions. Figure 3 displays the time normalized f0 of the realization of the four focus conditions of one male speaker averaged across all target sentences.

Figure 3. *Mean f0 contour in four focus conditions.*

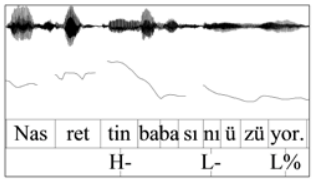


For group B (speakers 4 and 7) f0 modification was observed in different focus conditions. Like the remaining speakers they implemented a high tone (H-) on the rightmost syllable of each non-final ω. For subject focus both speakers continued implementing H- on the subject, but deleted the following H- of the object. De-accentuation continued until the ι-phrase final low boundary tone (L%). Speaker 7 used de-accentuation only in four of the five subject focus conditions. For verb focus they deleted or compressed the high tone on the subject, but implemented (H-) on the object. The verb was always aligned with (L%). Examples 1 and 2 show the modified f0 contour in verb and subject focus of group B.

Example 1. *F0 of verb focus in target sentence (1).*



Example 2. *F0 of subject focus in target sentence (2).*



4.2. Phonetic analysis

Due to the group dependent results of the phonological description, the analysis was amplified by a phonetic analysis. Maximum f0 of (H-) and break introduction were measured for each speaker and focus condition. Since group A showed no phonological modification of the f0 contour, it was tested, if the modification was phonetic in terms of a gradient modification. The test concerned the question whether break introduction and/ or a gradient modification of (H-) indicate a change in phrasing by establishing prosodic boundaries to align focused constituents, as stated in the hypothesis. The phonetic analysis was done time-normalized by the introduction of 10 measure points per syllable using a general purpose PRAAT script Prosody Pro [19]. The script enables comparison across all target sentences, focus conditions, and speakers. Each sentence was corrected manually with respect to spurious pitch values.

In a first step, the maximum f0 values were averaged across the five target sentences and four focus conditions for each speaker. The mean maximum f0 values on the high tones of the subject and the object of each focus condition and sentence were compared with each speaker to test if the downstep relation refers to focus alignment in the sense of a change in phrasing indicated by a reset. A reset by means of tonal upstep was considered in the case that the high tone of the second constituent was higher than the high tone of the preceding constituent. The maximum f0 analysis showed speaker-dependent variation. Downstep on the second high tone was not implemented in 34 sentences. A correlation between focus and upstep was only found for the speakers of group A. For verb focus, the maximum f0 on the objects excelled the maximum f0 of the preceding subject in all target sentences for both speakers corresponding to the tonal deletion/ compression observed in the phonological analyses. Nonetheless, upstep was also observed in other focus conditions for both speakers. For the remaining speakers, no clear relation between upstepped high tones and focus conditions was found and the tonal values of subsequent constituents were rather arbitrarily implemented and not obligatorily following downstep. Table (1) summarizes the upsteps implemented by all speakers.

Table 1. *Upsteps per speaker and focus condition.*

Upsteps according to focus condition								
speaker	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**total**
amount	7(18)	7(19)	0(20)	6(20)	3(19)	2(19)	9(20)	34 (135)
default	1	2	0	1	0	1	2	**5**
subject focus	2	2	0	0	0	0	1	**4**
object focus	0	1	0	0	1	1	1	**3**
verb focus	**4**	2	0	**5**	2	0	**5**	**18**

In a second step, all target sentences were tested concerning break implementation. The test concerned the question whether prosodic breaks may serve as an indicator for focus prominence and focus induced change in phrasing in the sense of pre-focal break introduction like in French [4]. Break introduction showed speaker dependent variation. Only speaker 4 used considerable breaks of around 0,05s. The other speakers rather showed a tendency to final lengthening. Speaker 3, 5, and 6 used none to one break. The breaks implemented by speakers 1, 2 and 7 were mainly used after the subject, mapping syntactical phrasing. Sometimes speaker 1 and 2 used additional breaks after the object. There was no straightforward implementation of the breaks after the subject and/ or object and no correlation to focus for speaker 1, 2 and 7. Speaker 4 implemented a break after the subject in all target sentences, unless in verb focus. In verb focus she used a pre-

focal break after the object and deleted the preceding break after the subject. Figure 4 shows how prosodic breaks assisted syntactic or prosodic phrasing in the data of this study.

Figure 4. *Prosodic break implementation*

Syntactic phrasing:	(S)[break] (OV)

5. Discussion and conclusion

The phonological description and the phonetic analysis of information structurally modified target sentences only partly fulfill the initial hypotheses.

The analyses of broad focus sentences offer a new contribution for the general description of the tonal structure in Turkish. The data revealed that each non-final ω in simple SOV sentences bears a high tone on the ultimate syllable. This high tone cannot be interpreted by means of general pitch accent implementation as in previous tonal descriptions, since it is not aligned to metrically strong syllables. The word stressed syllables were only additionally and arbitrarily aligned to less prominent pitch accents indicating that the prosodic structure in Turkish is primarily based on prosodic phrasing and less on the notion of pitch accents. From the present data the high tone on the last syllables of non-final constituents is interpreted as a high phrase tone (H-) aligned to the right boundary of each non-final ω. Consequently, Turkish is interpreted as a phrase language. It's prosodic structure is characterized by radical splitting, where each constituent forms its own φ and the function of H- is interpreted as delimiting φ on a supposed φ level. The concept of phrase language established by [5] is extended here to the inclusion of pitch accents aligned to word stressed syllables (Figure 2).

The analyses of information structure modified sentences revealed two groups in the prosodic realization of focus in Turkish. The phonological annotation and the acoustic measurements of maximum f0 and break implementation showed that group A did not change the tonal implementation and prosodic phrasing structure as observed for broad focus. For group B the study revealed that speakers change the prosodic structure according to focus. Whereas in the broad focus condition the same f0 contour was observed as for group A, group B implemented (H-) on the subject for subject focus and deleted the following high phrase tone to its right, approving the observation of PFC by [8]. For verb focus, the pre-focal (H-) on the subject was deleted or compressed and only the high tone on the object was implemented. The observed tonal deletion/ compression shows a change in phrasing according which is interpreted as an indicator for the prosodic alignment of focus. In subject and verb focus the broad focus phrasing structure as observed in the study and characterized by radical splitting changes. The focused constituent is separately wrapped into its own φ whereas the remaining given constituents are radically wrapped into a one further φ as long as they are adjacent. For object focus radical splitting was also maintained for subject and verb by group B, since the given elements were not adjacent and the focused constituent is claimed to be separately wrapped into an independent φ.

The variation of break implementation in the data show that prosodic breaks can be used for the individual organization of utterances on a supra-segmental level reflecting segmental and supra-segmental properties of the language. Hence, break implementation can assist phrasing, but has to be accompanied by tonal features to assist focus alignment and does not indicate focus on its own.

The acoustic analysis of maximum f0 on focused and un-focused subjects and objects revealed that a register change by means of upstep indicating a reset to establish a new φ is not related to information structure. Furthermore, the speaker-dependent variation in the data motivate the assumption that downstep is not systematic in Turkish.

Based on the group specific observations in the prosodic realization of contrastive in-situ focus in the present study it is assumed that prosodic focus marking in Turkish is optional. Turkish does not require a prosodic focus marking per se, but focused constituents are optionally aligned with prosodic boundaries. It is assumed that a preceding context which already sufficiently identifies the focused constituent overrides the need for a prosodic focus marking. Nonetheless, a prosodic representation of information structure was observed in the pilot, which can successfully be described by prosodic alignment. I thus interpret the results suggesting that Turkish can be classified as a boundary language in the framework of focus typology, and as a phrase language such as Hindi or French [4, 5] in the notions of general language classification. Figure 5 summarizes the general phrasing structure in Turkish as observed in the data and its modification according to the contrastive focus condition.

Figure 5. *Prosodic alignment in Turkish*.

Broad/object focus phrasing:	(S)φ ($O_{(F)}$)φ (V)φ.
Subject focus phrasing:	(**S_F**)φ(OV)φ.
Verb focus phrasing:	(SO)φ(**V_F**)φ.

Concluding, certain limitations concerning the data interpretation have to be made: (i) the alignment approach is based on the observations of a small data set and needs to be confirmed on the bases of more data. (ii) The observed phrasing structure is based on an analysis of simple SOV declaratives. Further research on more complex syntactic representations has to be done to confirm the implementation of the supposed phrase delimiting high tones. (iii) In order to access the reliability of the production data and the resulting claim of focus alignment, a perception test is necessary.

Abstract

Sesotho is a tonal Southern Bantu language which has so far received extremely little attention by the speech research community. We consider tone modelling for Sesotho using the Fujisaki model-based analysis with a view to the development of a text-to-speech (TTS) system. Fujisaki analysis can be used to indicate the tone associated with a syllable, but it often differs from the surface tone that would be available for TTS synthesis. We investigate instances in which the surface tone differs from the tone indicated by Fujisaki analysis, and determine the effect of these discrepancies on speech quality. The amplitude of Fujisaki tone commands is manipulated to match the surface tones, and the resulting resynthesized speech subsequently analysed by perceptual tests. We find that the effect of inserting tone commands at high surface tone syllables is more severe than matching the Fujisaki tone commands with low surface tone syllables, in terms of naturalness. Furthermore, some discrepancies can be attributed to errors in the surface tonal transcription. However, on average, all manipulations lead only to a mild degradation in speech quality. We conclude that the Fujisaki model is a feasible way to model tone in Sesotho even in the presence of limited and under-developed linguistic resources.

Index Terms: Fujisaki model, Sesotho, surface tonal transcription, text-to-speech synthesis

1. Introduction

Accurate prosodic modelling is crucial for natural-sounding text-to-speech (TTS) systems and can be achieved by correct modelling of pitch in tonal languages. For example, Ekpenyong et al. [1] found that the use of tone marking contributes significantly to the quality of synthetic Ibibio speech. In Sesotho, tone is not marked in the orthography, but must be deduced by the process of surface tonal transcription. This relies on morphological analysis, a tone-marked pronunciation dictionary, and a set of tonal rules. Each one of these three components can introduce errors, for instance, Schadeberg [2] and Roux [3] have pointed out the inconsistency of Sesotho tone-marked dictionaries.

The Fujisaki model is a tractable and powerful tool for prosody manipulation that has proven to be effective for modelling fundamental frequency (F0) contours. Its validity has been tested for several languages [4, 5, 6, 7] some of which are tonal languages such as Thai [8] and Mandarin [9]. It has been shown that the tone of a syllable can be represented in the Fujisaki model as a tone command, which is a pulse indicating where the rising and falling of F0 occurs.

Sesotho uses a register tone system with two tones, high and low. The Fujisaki model and surface tonal transcription have shown a strong agreement on the interpretation of tone in Sesotho sentences [10]. The purpose of this paper is to identify, investigate and perceptually evaluate those cases where the Fujisaki tone commands and surface tone labels do not agree. We want to determine if the mismatch between the actual F0 realisations and the surface tones seriously degrade the prosodic quality.

In modelling Sesotho prosody, certain phenomena must be taken into consideration. Tone sandhi is a phonological change occurring in tonal languages, in which tones occur in combination with other tones. It is present in Sesotho as pointed out by Demuth [11], and is modelled by the surface tonal rules HTD (spreading of a lexical high tone to the immediate right syllable) and IHTS (iterative spreading of a high tone to the end of a verb). Other tonal rules, however, do not model tone sandhi. Ekpenyong and Udoh [12] emphasise the importance of tone sandhi and its effect on the overall F0 contour in tone languages.

The Obligatory Contour Principle (OCP) is a phenomenon where adjacent identical tone elements are prohibited. According to Yip [13], OCP violations can be avoided in a variety of ways, such as tone deletion, blocking of spreading if it leads to adjacency, or fusion between tones. However, OCP in some cases is violable [13]. In Sesotho surface tonal transcription, OCP is observed via the RBD (dissociating the immediate right branch of a multiply-linked high tone syllable if, and only if, there is a high tone syllable immediately after the target of the HTS rule), LBD (delinking the immediate preceding left branch of a multiply-linked high tone syllable if it is preceded by a high tone syllable) and FR (exempting syllables at the end of a phonological phrase from the application of tonal rules) rules [14]. In contrast, OCP is not fully observed by the Fujisaki analysis and this is evident in the production of prolonged tone commands instead of exclusively single-syllable tone commands. Peak delay is observed when the F0 peak corresponding to a high-toned syllable occurs in the following syllable [15, 13], while anticipation is observed when a high tone is realised on the preceding syllable [16]. The former aspect is modelled in the surface tonal transcription via the HTS1, IHTS and GTI rules. The latter feature is not modelled in surface tone transcription. Both are observed in the Fujisaki analysis.

2. Data preparation

The following sections describe the compilation, preparation, annotation, and selection of the data on which our experiments are based.

2.1. Experimental data

Our data is drawn from a corpus that is based on a set of weather forecast bulletins obtained from the weather bureau in Lesotho. The corpus comprises a total of 256 sentences with an average of 23 words per sentence, and a total of 51 minutes of speech. The original audio data had a poor signal-to-noise ratio, making it unsuitable for use in TTS development. For this reason, the sentences were re-recorded by the first author, who is a female native speaker of Sesotho. Recording was performed in a quiet studio environment using a large membrane SHURE KSM32SL microphone. All recordings were made at a sampling rate of 48kHz.

For tone modelling in African tonal languages, in which tone is not indicated by the orthography, an algorithm that predicts the tonal labels of syllables in a word is a prerequisite [17]. As a starting point, we compiled a suitable domain dictionary for weather forecasts using two published tone-marked dictionaries – a Sesotho dictionary by Du Plessis et al. [18], and a Northern Sotho dictionary by Kriel and van Wyk [19]. The dictionaries contain lexical tones for each word.

Next, the sentences in our corpus were annotated with underlying tones from the dictionary. From this underlying tone transcription, a surface tone transcription was deduced by means of a morphological analysis as well as the tonal rules described in [14].

On completion of the surface tonal transcription, the sentences were annotated at word and syllable levels using Praat [20]. F0 values were extracted at a step of 10ms and inspected for errors. The F0 tracks were subsequently decomposed into their Fujisaki model components applying an automatic method originally developed for German [21]. Initial experiments in [22] had shown that the low tones in the critical words of the minimal pairs could be modelled with good accuracy without employing negative tone commands. Consequently, high tones were associated with Fujisaki tone commands with positive amplitude, while low tones had no associated tone command (i.e. zero amplitude).

2.2. Selection of mismatched syllables

First we selected from our data cases in which a Fujisaki tone command corresponds to one or more low surface tones. In general, the Fujisaki tone command spanned more than one syllable. Table 1 classifies the pattern of surface tones associated with each such tone command. Each low surface tone indicates a discrepancy. With this in mind, we selected cases in which a Fujisaki tone command coincided with one or more low surface tones. In total, 63 such cases were isolated from our data.

We also considered cases in which a high surface tone was not accompanied by a Fujisaki tone command. Examples of 1, 2, 3 and 4-syllable sequences with high surface tones but no corresponding Fujisaki tone command were identified in the data, and are listed in Table 2. In total, 64 such cases were isolated from our data.

Table 1: *Instances in which Fujisaki tone commands correspond to low surface tones (FHSL).*

Surface tone pattern	Number of syllables	Number of cases
Alternating, e.g. LHLHL	≥ 2	40
Low surface tone labels only, e.g. LLL	≥ 1	7
Any other combination, e.g. LHHL	≥ 2	16
TOTAL		63

Table 2: *Instances in which high surface tones do not correspond to Fujisaki tone commands (FLSH).*

Number of syllables	Number of cases
1	26
2	22
3	13
4	3
TOTAL	64

3. Pitch contour modifications

In the previous section, two types of mismatches between the Fujisaki model and the surface tone labels were identified. In this section, these mismatches are "resolved" by either inserting or removing the Fujisaki tone command in order to match the predicted surface tones.

3.1. Case FHSL: High Fujisaki tone associated with low surface tone

For cases in which the Fujisaki tone command coincided with a syllable with a low surface tone, the amplitude of the tone command was set to zero. Figure 1 illustrates this modification.

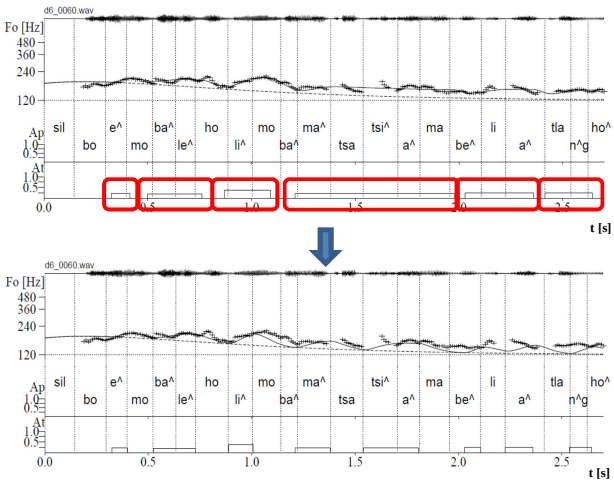

Figure 1: *Modifying Fujisaki tone commands to coincide with low surface tone syllables. The top panel shows an original utterance with surface tone patterns in the following order: HL, LHHL, LHL, HHLHHLH, HLH, and LHH. The bottom panel illustrates a change in pattern after modification. The phrase reads "Boemo ba leholimo ba matsatsi a mabeli a tlang ho …" – "The weather in the next two days …"*

When the Fujisaki tone command corresponded to a sequence of syllables with both high and low surface tones, the amplitude of the tone command was set to zero only for low surface tone syllables. The onset t_1 and/or offset t_2 times were unchanged for high surface tone syllables. In all other cases, t_1 and t_2 coincided with syllable boundaries. The optimal alignment of tone command onsets and offsets appears to be language-dependent [8, 23], and its determination for Sesotho remains the subject of ongoing work.

3.2. Case FLSH: High surface tone associated with low Fujisaki tone

In the case of high surface tone syllables with no Fujisaki tone command, tone commands with average amplitude were inserted and t_1 and t_2 were set to syllable boundaries. Sixty-four modified phrases were generated, in line with Table 2. Figure 2 illustrates an example of the modification, where the top panel shows the original utterance, and the bottom one displays the prosodic group generated (indicated by a rounded rectangle) to coincide with high surface tone markings.

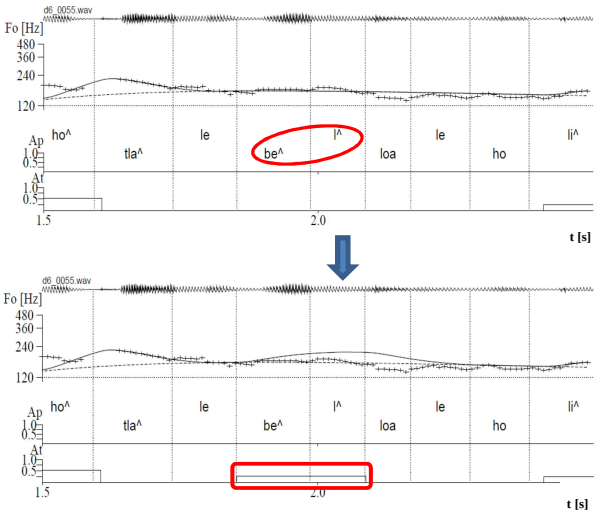

Figure 2: *Inserting a tone command. The top panel indicates a sequence of two high surface tone syllables, be^ and l^, with no Fujisaki tone command. In the bottom panel, a tone command is created for these syllables. The partial phrase reads "ho tla lebelloa leholi…" – "the sky will be expected …"*

4. Perceptual Evaluation

Perceptual evaluation of the modified phrases was carried out by twenty-one Sesotho speakers (7 females, 14 males). All subjects are native Sesotho speakers from Lesotho, and are students at the University of Stellenbosch. The classification of the data and the evaluation process are detailed below.

4.1. Data

For each group in Section 3.1, modifications were applied to the Fujisaki tone commands, after which the utterance was resynthesized using the PSOLA-based Praat ManipulationEditor (20) [19]. Tone commands which were inserted in Section 3.2 were also resynthesized in a similar manner. The resulting phrases were collected for perceptual testing.

Table 3: *Data used for perceptual evaluation.*

Modification	Modified phrases	Unmodified phrases	Total
FHSL: Fujisaki tone command removed	63	6	69
FLSH: Fujisaki tone command inserted	64	6	70

The data for evaluation included a number of unmodified phrases to serve as a baseline. Table 3 gives a summary of the data for the two modifications and groups.

4.2. The evaluation process

DMDX [24] was used to perform all perceptual evaluations. Subjects listened to the utterances in a quiet room using a headset. Evaluation of the data was based on a rating scale intended to reflect naturalness, as shown in Figure 3. Subjects were asked to rate each individual audio file according to this scale.

An informal SUS intelligibility test [25] of the modified phrases was also performed. Words from the modified and unmodified phrases were randomly selected to form semantically unpredictable sentences (Table 4). The sentences generated were each five words long. These were then resynthesised and the listener requested to indicate what they heard. Due to time constraints, this was performed by only one native Sesotho speaker.

1	Sounds like a mother–tongue speaker
2	
3	Sounds almost like a mother–tongue speaker
4	
5	Definitely not a mother–tongue speaker
6	
7	Disturbingly unnatural speech, hard to understand
8	Don't know

Figure 3: *The rating scale used for perceptual evaluation.*

Table 4: *Data used for the SUS intelligibility test.*

	FHSL	FLSH	Unmodified
Number of words	106	115	108
Number of sentences	21	23	22

5. Results

Phrases rated with an 8 ("Don't know") were excluded from the following analysis. In other cases, average scores according to the scale in Figure 3 have been considered.

Figure 4 illustrates the overall average perceptual scores resulting from the two types of modification described in Section 3. Unmodified phrases are perceived to be most natural, although interestingly they were usually not awarded a score of "1". The figure also shows that, on average, removal of a Fujisaki tone command is slightly less detrimental to perceived quality than the insertion of a tone command. However, even in the latter case, the perceived score is just above 2, neighbouring "almost mother tongue".

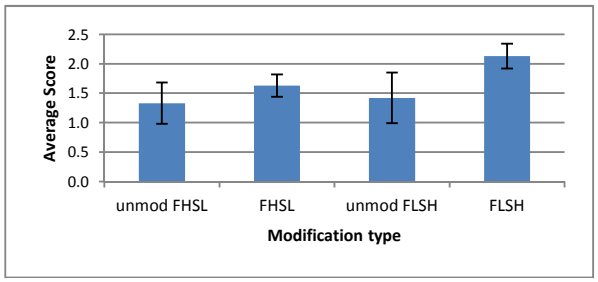

Figure 4: *Overall average perceptual scores for FHSL and FLSH modifications. Vertical bars denote 95% confidence intervals.*

From the FHSL data described in Table 1, we isolated a subset consisting of cases where a Fujisaki tone command was associated with a sequence of between 1 and 3 low surface tone syllables. This data is summarised in Table 5, while Figure 5 shows the corresponding results of the perceptual evaluation. For each case, the Fujisaki tone command amplitude was set to zero for one, two, or three consecutive syllables. The results show that 1 and 2 syllable modifications are rated similarly. Although 3-syllable modifications show larger degradation, the reliability of this average is low due to the small number of samples (4).

Table 5: *Instances in which Fujisaki tone commands correspond to consecutive low surface tone syllables.*

Consecutive low tone syllables	Number of cases
1	20
2	8
3	4
TOTAL	32

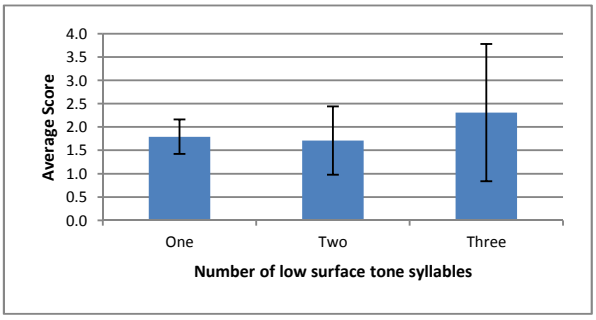

Figure 5: *Average perceptual scores when removing the Fujisaki tone command associated with 1, 2, and 3 consecutive low surface tones. Vertical bars denote 95% confidence intervals.*

Figure 6 shows a similar analysis for the FLSH data described in Table 2. The results are similar across number of syllables.

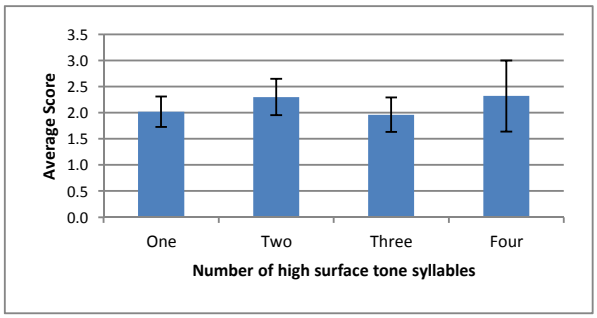

Figure 6: *Average perceptual scores when inserting Fujisaki tone commands for 1, 2, 3, and 4 consecutive high surface tone syllables. Vertical bars denote 95% confidence intervals.*

Table 6 shows the results from the informal intelligibility test described in Section 4.2. The intelligibility score is based on the number of words identified correctly in each sentence. Sentences composed of unmodified words have the highest intelligibility score, with the lowest score obtained for FHSL modifications. Removal of the Fujisaki tone command therefore appears to have a much higher detrimental effect on intelligibility than its insertion.

Table 6: *Intelligibility scores for FHSL, FLSH, and unmodified utterances.*

Modification	Intelligibility Score [%]
FHSL	38.1
FLSH	60.9
Unmodified	77.3

Finally, each of the 127 mismatches described in Tables 1 and 2 was considered individually in order to determine the source of the discrepancy. Tables 7 and 8 describe the results of this investigation. The totals exceed the values in Tables 1 and 2 because each mismatch can be due to more than one factor.

The tables show that tone sandhi, OCP and peak delay are major contributors of mismatches, while incorrect dictionary entries are less so. One phenomenon not yet taken into consideration in the deployment of both methods is downstep, which will be explored in future work.

Figure 7 illustrates the perceptual score due to the mismatch effect by each phenomenon on naturalness. Overall, the discrepancies where the Fujisaki tone command was inserted significantly affect naturalness than when the tone command was removed.

Table 7: *Mismatches in the FHSL case.*

Description	Number of instances
Tone sandhi is observed by the Fujisaki analysis but not by the relevant surface tonal rules.	33
Surface tone transcription observes OCP but Fujisaki analysis does not.	38
Peak delay is observed by the Fujisaki analysis but not by the relevant surface tone transcription rules. (The FR rule observes peak delay only for relative verbs and for ultimate syllables whose lexical tone is high.)	18
Anticipation is observed by the Fujisaki analysis but it is not modelled by the surface tone transcription rules.	19
Incorrect dictionary tone	10
Unresolved	5
TOTAL	123

Table 8: *Mismatches in the FLSH case.*

Description	Number of instances
Tone sandhi is observed by the surface tonal transcription but not by the Fujisaki analysis.	40
OCP is violated in the surface tonal transcription by adjacent high-tone syllables, but not violated by the Fujisaki analysis.	38
The Fujisaki analysis does not observe peak delay while the surface tonal transcription does.	23
Incorrect dictionary tone	18
Unresolved	5
TOTAL	124

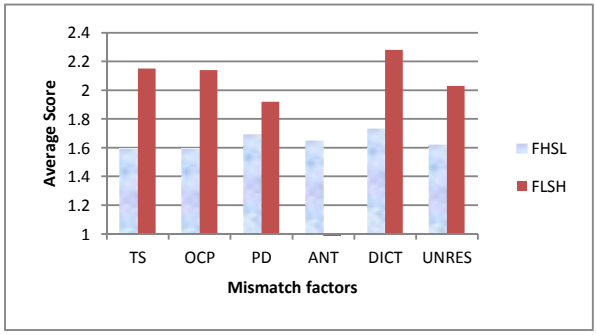

Figure 7: *Sources of mismatch between surface tone and Fujisaki tone commands, and their effect on naturalness. TS = tone sandhi, PD = peak delay, ANT = anticipation, DICT = incorrect tone in dictionary, and UNRES = unresolved cases.*

6. Conclusions

When considering TTS for a very poorly resourced language, such as Sesotho, the reliance of imperfect resources, including dictionaries, morphological analyses and tonal rules, is inescapable. In this paper we have performed experiments to determine the effect of these mismatches on the perceived quality or resynthesized speech. We find that, overall, the modifications applied to "rectify" the mismatch lead only to mild degradation in the perceived quality of the speech. From this we conclude that Sesotho TTS based on the Fujisaki model for tonal and prosodic modelling is feasible, even when based on imprecise resources. An analysis of the sources of the discrepancies indicates scores of error and that much can be gained by the improvement of the surface tone transcription process.

MUSICAL INTERVALS OF TONES IN CANTONESE ENGLISH

Suki S.Y. Yiu

Linguistics Department, University of Hong Kong

syutji@hku.hk

Abstract

It has been shown that the relative pitch levels of Cantonese tones closely correspond to musical intervals (MIs) [1]. Given that an emerging tone language, Cantonese English, has developed tone under the substrate influence of Cantonese, this paper examines the correspondence between the newly emerged tones and MIs, and how the musical analogy relates to those established for Cantonese.

The fundamental frequencies of the tones produced by six speakers of Cantonese English were extracted with Praat, then time-normalized across rhymes. The mean values of the interval points of two tones were expressed in terms of ratio, then matched with the closest MI on the musical scale.

This paper demonstrates that the pitch levels of tones in Cantonese English correspond to MIs, given the converging ranges of MIs for different speakers and similar MIs of different tone pairs for different speakers. It also shows that the MIs of tones in Cantonese English are related to the corresponding tone pairs for Cantonese. The viability of MI as a means to understand the tonal system of non-tonal languages whose speakers' native language is tonal extends the link between the use of pitch in speech tones and music.

Index Terms: tone and music, musical interval, frequency ratio, Cantonese English, Hong Kong English

1. Introduction

To record the principal phonetic characteristic of lexical tone, i.e. fundamental frequency (F0), Chao developed the 5-level transcription of tonal pitch variation（五度標記法）with the use of sliding-pitchpipes [2]. When the pitch of the pitchpipe matches the pitch of the linguistic tone, the pitch values of a linguistic tone (the starting and ending points, also a turning point between the two if any) can be notated on a staff. The major advantage of this method is that the relativity of pitch, and therefore spatial relationship among lexical tones, could be recorded musically. The tones are represented phonologically on a tone scale with five numeric values from 1 to 5, a method usually adopted for Chinese languages [3]. Echoing Chao's method of notating the lexical tones via a musical means, this paper explores how linguistic tones can be understood in terms of musical intervals (MIs) based on the phonetic data obtained in Cantonese English.

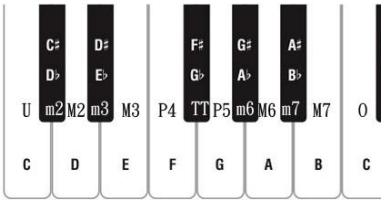

Figure 1: *MIs from C on piano keyboard [1]*

A MI is a perceptual distance of pitch, expressed in form of a ratio to show the distance between two adjacent notes on a scale. Figure 1 shows a chromatic scale on a piano keyboard. Different MIs are expressed in abbreviated forms: unison (U), minor (m), major (M), perfect (P), tritone (TT) and octave (O).

Let the leftmost C be an anchor key, one step up counts as one semitone. Moving from C to C♯ involves one semitone, and its MI is a minor second. Two semitones or one whole tone is involved when moving from C to D, and the corresponding MI is a major second. The longer the distance, the more the semitones involved, and the bigger the MI. Notably, the difference between two keys is relative in terms of MI. For example, the distance from C to E and from E to G♯ is the same: the MIs are both major thirds, with four semitones. As relativity of pitch is a core characteristic of phonemic tone, MI serves as a link to understand linguistic tones musically.

The MIs of linguistic tones can be obtained by calculating the frequency ratios of the tone pairs in a tone inventory, a method particularly useful for describing intervals in both Western and non-Western music. The absolute pitch of one tone is expressed in the form of a ratio to another tone. The ratios can then be matched with the closest MI on the musical scale. It has been shown that the pitch intervals of Cantonese tones closely correspond to the number of semitones derived from the MIs [1]. Given that Cantonese English has developed tone under the substrate influence of Cantonese, is there a musical basis or analogue to the tone inventory of this emerging tone language? If so, how does the musical basis or analogue relate to that for Cantonese?

Cantonese English is an emerging language which owns its distinctiveness in many linguistic aspects that are worth paying attention to for the sake of providing a neutral and unbiased description [4]. Many phonological aspects of Cantonese English have been studied so far [5-9]. Specifically, the use of pitch in Cantonese English, unlike tones in Cantonese, is perceptually distinct but carries a low functional load, with few if any minimal pairs in normal speech. This paper refers to this systematic use of pitch as tone, and examines the relationship among these tones, as described in recent works like [6, 10-13].

The goals of this paper are to find out the correspondence between the new tones and MIs, and examine how the musical analogy relates to those established for Cantonese. The first working hypothesis is that the pitch levels of tones in Cantonese English correspond to the MIs. This predicts that the ranges of MIs for different speakers should display a convergent pattern, and the MIs of different tone pairs for different speakers should be similar. The second working hypothesis is that the MIs of tones in Cantonese English are related to those for Cantonese. This predicts that there are corresponding tone pairs in Cantonese English and Cantonese.

2. Linguistic tone and musical tune

2.1. Relativity in tone and tune

The relationship between language and music has been shown to be multifold. In recent works on tone-melody mapping, the

conformity between lexical tone and melody in vocal songs has been the focus [14-22]. Both speaking and singing involve vocalization and manipulation of pitch, but composition of songs sometimes requires fixed pitch notation while pitch in speech tones is a relative concept in principle. Depending on the pitch of the adjacent, or even neighboring, tones in speech, the interpretation of tones may vary. If the pitch of the adjacent or neighboring tones is lower, the target tone will be perceived as a higher tone. Likewise, higher pitch of the adjacent or neighboring tones makes the target tone a lower tone [23]. Relativity is an important characteristic not only of speech tone, but also of musical tone because not everyone, even musicians, has absolute pitch, and many people sing songs with the right intervals but not at the fixed pitch transcribed in the musical notation. They need to attune their instruments and the pitch of their voice with the help of tuning devices.

2.2. Cantonese tones and musical intervals

Since relativity of pitch is crucial to the link between tone and tune, one would expect correspondence between the frequency ratios of tones in speech and tones in sung melody. [19] used a ratio called High-Low Quotient for each of the twenty Chinese languages by dividing the F0 of the highest pitch level with the F0 of the lowest pitch level articulated by a given speaker of each language. Instead of only using the highest and lowest F0, [22] identified six pitch intervals (1-2, 1-3, 1-5, 2-3, 2-5 and 3-5) in Cantonese and calculated the frequency ratios involved when transiting from one pitch level to another with single utterance data by five speakers from [24]. Though both studies claimed that the frequency ratios did not align with the musical intervals neatly, the values were close and seemed to show patterns.

[1] proposed an MI analysis for speech tones in Cantonese similar to the one adopted by this paper. It collected F0 data of Cantonese tones and calculated the frequency ratios for all of the seven tone pairs in Cantonese (T1:T3, T1:T6, T1:T4, T2:T5, T3:T6, T3:T4 and T6:T4) from multiple utterances produced by six speakers. Since the frequency ratio and the MI share the same way of calculation using the equation $\frac{F0x}{F0y}$, the frequency ratio for the speech tones is named as MI.

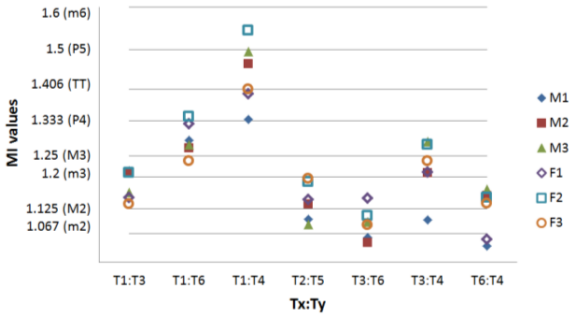

Figure 2: *Cantonese MIs of all subjects [1].*

Figure 2 shows the MIs identified for the six subjects. F/M1 to M/F3 represent fe/male speakers numbered 1 to 3 respectively. It was found that the minimal distance between two tones in Cantonese is a minor second for the tone pair of T3:T6, with pitch levels 3-2. The maximal distance between two tones in Cantonese is a perfect fifth, which is found for the tone pair of T1:T4, with pitch levels 5-1. This coincided with the findings in tone-melody mapping, where a tonal transition from 5-1 is found to be mapped onto a musical interval of a perfect fifth [20, 22]. Figure 2 demonstrates that MI is a possible scale to portray tones in a tone inventory produced by multiple speakers, and to display the spatial relationship between different tone pairs in each speaker's tonal space.

2.3. Musical intervals and semitones

MIs allow tonal analysis be done without committing to specific tuning systems which divide an octave slightly differently, thus avoiding small yet possibly significant effects of such differences on the interpretation of the spatial relationship of the tones in a tone inventory. Comparison of linguistic tones can be obtained through MI ratios ranging from 1 to 2 in an octave. Switching from one tuning system to another can be done by changing the ratios which the MIs are based on.

One can also divide the MI ratios into smaller logarithmic units like semitones by $\log_2 MI * 12$, and so as cents by $\log_2 MI * 12 * 100$. Adopting a logarithmic unit of measurement will fit the reported logarithmic characteristic in perception [25] and production [26] of pitch in speech.

This paper adopts the just intonation tuning system as provided by 5-limit tuning, where the main intervals and just intervals are found to sound pleasant and well-tuned to most people.

3. Methodology

Six Cantonese English speakers balanced for gender were chosen as subjects. They were born after 1980 and raised in Hong Kong. Their age ranged from 21 to 32 years old, representing young adult speakers of Cantonese English.

The data was elicited using a wordlist providing a comprehensive coverage of the syllable structure, vowel and consonant inventories, and surface tones of Cantonese English. The criteria for stimulus construction are listed in Table 1 below. 24 target items were randomized with 8 fillers during elicitation.

Table 1. *Criteria for stimulus construction.*

	Description
Syllable structure	(C)V(V/N/C)
Vowel	Syllables mainly contain but not limited to 3 cardinal vowels [i], [a], [u]
Consonant	[t], [b], [ʃ], [m], [k], [l], [s], [g], [n], [p], [ɹ]/[w], [f], [d]
Tone category	M(id), H(igh), Mf(alling), L(ow), Hf

The subjects were asked to produce each word three times in a row so that the basic position (initial, medial or final) of each target item in an utterance was controlled, for instance, *arm-arm-arm*. A total of 2376 target syllables (= 66 target syllables x 3 repetitions x 2 sets x 6 subjects) were recorded. Recordings were made with Praat (ver. 5.3.39) [27] with a sampling frequency of 22050Hz in a sound-proofed recording booth.

F0 tracks of the items in the utterance final position were extracted with Praat, then time-normalized at 10% interval points across the rhyme of each syllable with Praat script ProsodyPro (ver. 4.3) [28]. Based on the above categorization of tones, tone profiles of individual speakers were generated in the form of line graphs. The mean values of the ten interval points of each of the two tones were expressed as a ratio in

order to match with the equivalent ratio for the closest MI. The MI of each tone pair was then used to map the closest MI on the musical scale. For the sake of accuracy, the MIs were expressed in numbers, as in Table 2. Since the tones seemed to be restricted to certain syllable positions in a word, the selection of tones relevant for the calculation of MIs will be discussed in the following section after presenting the Cantonese English tone profiles.

4. Results and discussion

4.1. F0 profiles of subjects

The Cantonese English F0 profile of each subject was generated in form of line graphs like Figure 3. Recall that the words were repeated three times when recorded so as to control the position of the words in an utterance. Only the words in the utterance-final position are used because they display richer materials for tonal analysis. Also, since the placement of tones in Cantonese English seems to be restricted in certain syllable positions of a word, three graphs, from left to right, are used to present the tones occurring in the word-initial, word-medial and word-final positions respectively. H, M and L are each shown by solid, dashed and dotted lines.

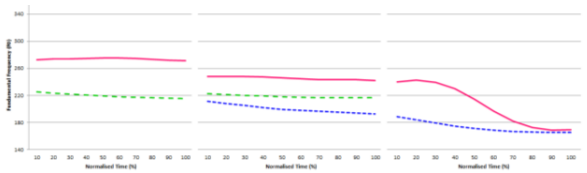

Figure 3: *Cantonese English tone profile of speaker F2.*

As observed above, not all of the five tones surface in all three positions in a word. H and M surface in both word-initial and word-medial positions. In the word-final position, the lower curve is regarded as a boundary L, and the upper curve with a distinguishable falling contour is a H transiting to a boundary L. Additional data shows that the more syllables between the rightmost H and the boundary L, the flatter the slope of each curve. The intervening tones from the rightmost H in a word to the boundary L are excluded from the calculation of MIs. To minimise declination effects, H and M in word-medial position and L in the final position are selected, given that the L only surfaces at the right boundary of a word. Also noticeable from the data is that M only occurs before H, and H only occurs before L. There are some variations concerning the details of the pitch contours, but the patterns described above generally hold across subjects.

4.2. Tones in Cantonese English on MI scale

The pitches of each pair of tones were expressed as a ratio and compared with the pitch ratios for the closest corresponding MIs. The data of speaker F2 is used as an example.

Table 2. *MIs of speaker F2.*

$\bar{T}x$:$\bar{T}y$	$\bar{T}x$ (Hz)	$\bar{T}y$ (Hz)	$\bar{T}x/\bar{T}y$	Closest MI	Closest MI ref. value	No. of semitones
H:M	245.2154	218.3493	1.123042	M2	1.125	2.008939
H:L	245.2154	172.9993	1.417436	TT	1.40625	6.039400
M:L	218.3493	172.9993	1.262140	M3	1.25	4.030460

Table 2 shows all possible combinations of ratios for the Cantonese English tones, H, M and L, of speaker F2. The first column ($\bar{T}x$:$\bar{T}y$) is filled with the ratio to which each row of data corresponds. The second and third columns ($\bar{T}x$ and $\bar{T}y$) are the mean F0 of the ten interval points on the tonal contour for each tone in Hz. The column $\bar{T}x/\bar{T}y$ shows the ratios in numbers. The ratios are then matched with the closest MI in the next column, followed by the actual ratio values for each MI. The last column shows the number of semitones calculated by the equation provided in Section 2.3. Let us take H:M as an example. The mean F0 of H and M are 245.2154 Hz and 218.3493Hz respectively. Their ratio is 1.123042 (= $\frac{245.2154\ \text{Hz}}{218.3493\ \text{Hz}}$),closest to a major second,having a ratio of 9:8, i.e. 1.125, and around two semitones. Figure4 shows the results using a similar method for each subject as in Section 2.2.

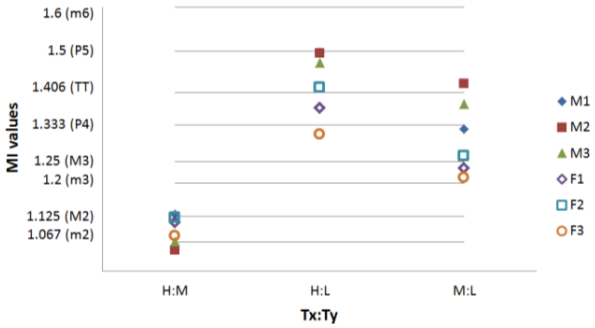

Figure 4: *Cantonese English MIs of all subjects.*

4.2.1. *Distance between linguistic tones and tone space*

The distance between two tones in a tone pair is reflected by the values of the MIs. The MIs of all subjects fall within the range of minor second to perfect fifth. A minor second is the shortest distance that two musical tones could have on a keyboard, with the distance of one semitone. A perfect fifth is the distance from C to G (cf. keyboard in Figure 1), with seven semitones in between. H:M is the tonal pair with the smallest MI (from minor to major second) whereas H:L is the pair with the biggest MI (from perfect fourth to fifth). M:L came within a minor third to a tritone.

Speaker F3 has a relatively narrow MI range – all tones are spaced within a perfect fourth, with five semitones between the highest and lowest tones. On the contrary, the male speakers have the widest range – their tones are spaced within a perfect fifth, with seven semitones between H and L. In other words, the tonal space of male speakers is wider than for the female speakers, especially for speaker F3. The tonal space of speakers F1 and F2 is wider than speaker F3 but still narrower than for the male speakers.

A wider tonal space allows a wider range of MIs. This can be checked by the number of semitones between the highest and lowest MIs of the subjects. Speaker F3 uses MIs ranging from a minor second to a perfect fourth, within four semitones, while speakers M2 and M3 use MIs from a minor second to a perfect fifth, within six semitones. Close to speakers M2 and M3 is speaker M1, who uses MIs from a major second to a perfect fifth, in five semitones. The MIs of female speakers all range within four semitones with different starting and ending MIs: speakers F1 and F2 range from major second to tritone, while speaker F3 ranges from minor second to perfect fourth.

4.2.2. *Spatial relationship among linguistic tones*

The spatial relationship among different tones in a tone inventory is reflected through comparison between the MIs of

different tone pairs in a tone inventory. By comparing the MIs of different tone pairs, whether M is closer to H or L in Cantonese English can be figured out. In Figure 4, H:L has the highest MI. Since there are only three tones, H and L ought to be at opposite ends with M somewhere in between. Interestingly, instead of being in the middle of H and L, M is closer to H than L. This relationship among the tones in Cantonese English is so neat that it holds across the MI profiles of all six speakers. This unanimity displayed by the subjects suggests that the M is not randomly assigned to anywhere between H and L in Cantonese English, and hence has a stable position in the tonal space of Cantonese English.

4.2.3. Flexibility of linguistic tones

The flexibility of linguistic tones is reflected by the range of MIs, i.e. the extent to which the MIs of different speakers cluster for different tone pairs. The more unanimous MIs (minor or major second) for H:M confirm that the interval between these tones corresponds to minimally one semitone while the more flexible MIs (perfect fourth, tritone or perfect fifth) for H:L indicates that a wider range of MIs are allowed.

4.3. Comparing the new tones with canonical tones

Given the above tonal analysis of Cantonese English in terms of MIs, the next question is how the tone system of Cantonese English is similar to or different from that of its substrate language Cantonese. If the MIs of tones in Cantonese English can be related to Cantonese, not only does it show that MIs link speech tones and musical tones together, but it also serves as a link between the phonological tones in canonical tonal languages like Cantonese, and languages like Cantonese English where the tonal elements are probably substrate influence from one's tonal native language. With a similar methodology and the same subjects, this section compares the MIs of the new tones in Cantonese English and the canonical tones Cantonese.

The six phonemic tones in Cantonese are T1 [55], T2 [25], T3 [33], T4 [21], T5 [23] and T6 [22], according to [29]. Among the seven possible combinations of tone pairs in Cantonese and the three possible tone pairs in Cantonese English, the following tone pairs are selected for comparison: T1:T6, T1:T4 and T6:T4 in Cantonese, and H:M, H:L and M:L in Cantonese English respectively.

4.3.1. Distance between linguistic tones and tone space

The MIs for the tone pair whose tones are most distant from each other in Cantonese English (H:L) and Cantonese (T1:T4) are very close. They are the same for speakers M2, M3 and F1in both languages. The MI of speaker M1 is greater in Cantonese English by two semitones, while for speakers F2 and F3, their MI is smaller in Cantonese English by one semitone. H:L in Cantonese English and T1:T4 in Cantonese have the largest MI across speakers, ranging from perfect fourth to fifth. This suggests that the total pitch range used is much the same for Cantonese English and Cantonese.

For the other two tone pairs in both languages under comparison, while the smallest MI in Cantonese English and Cantonese are H:M and T6:T4 respectively, H:M is also the one with the smallest MI in the tone system of Cantonese English but T6:T4 is not in that of Cantonese. This could be due to the fact that the tonal space of Cantonese is more crowded than that of Cantonese English so that there can be even more fine-grained categorisation of tones.

4.3.2. Spatial relationship among linguistic tones

M is closer to H than L in Cantonese English, but T6 is closer to T4 rather than T1 in Cantonese across subjects. This may be due to having no perfect equivalent for Cantonese English M in Cantonese. The M in Cantonese English is slightly higher than T6 but not as high as T3 in Cantonese. Also, the unanimity displayed for the assignment of M suggests that the M in Cantonese English, like T6 in Cantonese, has a stable position in the tonal space, and hence in the tone inventory of Cantonese English.

4.3.3. Flexibility of linguistic tones

Unlike Cantonese, where the tone pair whose tones are most distant from each other, i.e. T1:T4, is also the most flexible tone pair in terms of MIs (perfect fourth, tritone and perfect fifth), the tone pair whose tones are second distant from each other, i.e. M:L is the most flexible tone pair (minor and major third, perfect fourth and tritone) in Cantonese English. The MIs of H:L are also quite flexible (perfect fourth, tritone and perfect fifth) but not as M:L, suggesting that a choice between transiting from H to L or from M to L should be available in tone-melody mapping.

The tone pair whose pitches are closest to each other in Cantonese English, i.e. H:M, is also the least flexible tone pair in terms of MIs (minor and major second), similar to T6:T4 (major third and perfect fourth) among the three tone pairs under comparison in Cantonese. That said, if all seven tone pairs are taken into account, the least flexible tone pair is T3:T6 (minor and major second), which is also the tone pair whose pitches are closest to each other.

5. Conclusions and implications

This paper has examined the correspondence between the new tones and MIs, and how the musical analogues relate to those for Cantonese. It has been demonstrated that the pitch levels of tones in Cantonese English correspond to the MIs in terms of the distance between/among tones and the flexibility of tonal intervals, given the converging ranges of MIs for different speakers, and similar MIs of different tone pairs for different speakers. It has also been shown that the MIs of tones in Cantonese English are related to those for Cantonese to some extent, with corresponding tone pairs in Cantonese English and Cantonese.

By demonstrating that such a musical treatment of linguistic tone is viable, it has been shown that MIs serve as a means to understand the tonal system of non-tonal languages whose speakers' native language is tonal, with characteristics of tones invisible in other existing approaches but visible through the MI glass. It has also extended the link between the use of pitch in speech and music. It seems promising to apply the proposed method to more new varieties of languages with a larger sample. Considering the convergence of tonal characteristics in Cantonese English, also in comparison with Cantonese, this paper supports the view that Cantonese English is an emerging tone language.

6. Acknowledgments

I thank Stephen Matthews and Diana Archangeli for their thought-provoking discussions. I also thank Lianhee Wee, Cathryn Donohue, 'lab rats' Winnie Cheung and Queenie Chan, the three anonymous reviewers and the six subjects.

Rhythmic Patterns in Native and Nonnative Mandarin Speech

Abstract

Rhythm plays an important role in the naturalness of speech. This study compared rhythmic patterns of Mandarin speech between native speakers and two groups of L2 speakers whose first languages were Cantonese and English, respectively. The study started from isolated words, but focused on continuous speech, for which eleven durational metrics were used as objective rhythm indicators. The results on continuous speech showed that nonnative Mandarin gave a quite similar rhythmic mode as native one in terms of rate-normalized/independent metrics, but shifted towards the stress-timed class in terms of raw metrics, regardless of the rhythmic class of the L1. This seems to conflict with the L1 transfer effect and the results for isolated words, but it coincides with auditory impression and can be explained by speech rate difference and the lengthening effects associated with the change in prosodic structure.

Index Terms: rhythm, durational metrics, nonnative speech, Mandarin, Cantonese, English

1. Introduction

As an important prosodic property, rhythm plays a key role in the naturalness of speech. There used to be a tradition of classifying spoken languages in the world into three rhythmic classes, i.e., 'stress-timed', 'syllable-timed', and 'mora-timed' [1-3]. This classification was based on the notion of isochrony, which assumes the existence of units of nearly equal duration in speech: syllables for syllable-timed languages such as French and Italian, inter-stress intervals for stress-timed languages such as English and German, and morae for mora-timed languages such as Japanese.

However, experimental studies have failed to find any acoustic evidence to support the existence of isochronous units [4-6]. Thus, the so-called isochrony is only an impressionistic property which correlates with a number of phonological aspects such as syllable structure, vowel reduction, and stress [4]. Instead of searching for isochronous units, many recent studies came to find out acoustic metrics that could correspond roughly to the auditory impression of rhythmic distinctions, by inspecting the durational variability of consonantal and vocalic intervals, such as ΔC (standard deviation of consonantal duration), %V (percentage of vocalic duration) [5], and PVI (Pairwise Variability Index) of vocalic and consonantal durations [6, 7]. Similar metrics were also applied to syllable duration [8, 9]. These studies showed that such durational metrics could categorize spoken languages into different rhythmic classes. Also, they suggested that the difference in rhythm was not categorical; instead, various languages could be on a continuum between extreme rhythmic patterns [4, 6].

It has been widely recognized that English is a typical stress-timed language [2], in which there is perceptually a roughly constant amount of time between successive stressed syllables, and relatively low %V, high ΔC, and high PVIs tend to be measured acoustically [5, 6]. To accommodate the stress-timed rhythm, there is a tendency for unstressed syllables to be shortened. In contrast, Cantonese is deemed a typical syllable-timed language [8], in which successive syllables perceptually have roughly constant duration, and relatively high %V, low ΔC, and low PVIs tend to be measured acoustically. Mandarin (in mainland China) also shows a syllable-timed pattern, at least in read speech, but it is less typical than Cantonese as evidenced by various acoustic measures [8].

Besides rhythmic studies for native speech, there are also a few studies on rhythmic patterns for nonnative speech, e.g., English L2 by Mandarin and Cantonese L1 speakers [9], and the effects of L1 on L2 for Dutch, English, and Spain speakers [10]. This is important as objective rhythmic metrics may be applied in computer-assisted language learning systems.

The findings of these studies, however, are not consistent. In some cases nonnative speech is rhythmically between L1 and L2, coinciding with the general hypothesis of L1 transfer effect, while in other cases nonnative speech is rhythmically almost identical to L1 or L2, or even shows a pattern overshooting L2 – hence opposite to the L1 transfer effect. It is not easy to interpret such inconsistencies, though speech rate variation and selective lengthening have been used for explanation [9, 10]. This may lead us to question the validity of these rhythmic metrics for nonnative speech.

Since there have been few rhythmic studies on nonnative Mandarin speech, we attempt to fill the gap. We selected two groups of L2 Mandarin speakers who were native in American English and Hong Kong Cantonese, respectively. The reason for selecting these two groups is that English and Cantonese represent two opposite rhythmic classes as we described above.

2. Speech Data

2.1. Comparison in Phonology

The three languages concerned here, i.e., Standard Mandarin, Hong Kong Cantonese, and American English, contrast sharply in the phonological structure. Mandarin and Cantonese are tone languages of monosyllabic nature in the morpheme sense, while English is a stress language of polysyllabic nature.

Both Mandarin and Cantonese have a very simple syllable structure (C)V(C), and each syllable has a tone. In addition to monosyllabic nature in the morpheme sense, Cantonese has a higher frequency of monosyllabic words than Mandarin, thus further enhancing its monosyllabic nature. Cantonese does not have a contrast in lexical stress while Mandarin does – there is no lexical stress in the phonological sense but there is a neutral tone functioning as an unstressed syllable which usually has a shortened duration.

English, on the contrary, is a polysyllabic language with a more complex syllable structure: with the use of consonant clusters, English syllables can be (C)(C)(C)V(C)(C)(C)(C). Also, English is a stress language, for which the syllables in a polysyllabic word differ in the degree of lexical stress.

2.2. Materials

Read speech was used in the present study for the purpose of a controlled comparison among three groups. Two sets of Mandarin speech materials were designed. Speech Material I consisted of disyllabic and trisyllabic words which were used for analysis of timing in isolated words, while Speech Material II consisted of short stories which were used for investigating rhythmic patterns in continuous Mandarin speech.

Speech Material I included disyllabic and trisyllabic words with neutral tone (T0). The corpus of disyllabic words included four tonal combinations, with four lexical tones in the former syllable and T0 in the latter. With 10 words designed for each disyllabic tonal combination, there were altogether 40 disyllabic words. For trisyllabic words, T0 could occur in the mid and/or the latter syllable, and thus the corpus of trisyllabic words included 16 + 16 + 4 = 36 tonal combinations with T0. With two words designed for each trisyllabic tonal combination, there were altogether 72 trisyllabic words.

Speech Material II included three short stories, each with a length of about 200 syllables. One story was 'North Wind and Sun' as widely used in phonetic study. All three stories were easily understood by L2 Mandarin learners at the intermediate or advanced level, as confirmed by the nonnative subjects.

2.3. Subjects and data collection

Three groups of subjects were recruited: MM, CM, and EM. The MM group, including 3 males and 3 females with an average age of 20, consisted of native speakers of Mandarin, who were undergraduate students majoring in broadcasting and hosting arts, all professional in Mandarin pronunciation. The CM group, including 1 male and 5 females with an average age of 22, consisted of L2 Mandarin learners who were born in Hong Kong and were native in HK Cantonese. The EM group, including 3 males and 3 females with an average age of 22.5, consisted of L2 Mandarin learners who were born in USA and were native in American English. The subjects in both CM and EM groups were L2 Mandarin learners at the intermediate or advanced level. They had studied Mandarin for at least two years, and had already passed Level 5 of HSK, the Chinese proficiency test.

Speech recording was conducted in a sound-proof room after the subjects had got familiar with the reading materials and made sure that they had known the exact pronunciations. The recording was done at each subject's normal speech rate and was monitored by the experimenter. Once there was a mispronunciation or disfluency, the subject would be asked to repeat recording the word or the utterance until success.

2.4. Data analysis

By visual inspection of the waveform and the spectrogram, speech materials were segmented and labelled manually. Each word in Speech Material I was segmented into syllables, while Speech Material II was segmented into consonants, vowels, and pauses. Any pauses in the speech, either silent or not, were excluded from our analysis. On the basis of acoustic instead of phonological criteria, glides were classified as vowels, because the formant transition between a glide and a vowel nucleus in Mandarin is usually smooth, without an abrupt change.

Unlike for Speech Material I, labelling of Speech Material II was conducted not only for segments and tones but also for break indices, following a ToBI-like approach [11]. Three layers of break indices were adopted: prosodic word boundary (B1), minor prosodic phrase boundary (B2), and major prosodic phrase boundary (B3). A prosodic word is a basic unit that is tightly integrated in prosody. B2 differs from B1 in that B2 is accompanied by one of the following perceivable features: a short pause, a pitch resetting, or a final lengthening. B3 tends to be accompanied by a much longer pause than B2.

The labelling of break indices was more subjective than that of segments and tones. To ensure the reliability, we asked four labelers to do the labelling independently after an iterative training and discussion (the cross-labeler consistency reached 96% at the end of this stage). After their labelling, the consistency across the four labelers turned out to be 86%. We then finalized the labelling by double checking those apparently inconsistent labels.

For Speech Material II, the durations of vocalic and consonantal (i.e., intervocalic) intervals were measured. A vocalic interval is the section between the onset and the offset of a series of connected vowels/glides, while a consonantal interval is the section between the onset and the offset of a series of connected consonants. For Speech Material I, we simply measured the durations of individual syllables.

The following seven rhythmic metrics based on vocalic and consonantal interval durations [5, 7, 12] were calculated for each subject, and then were averaged across all subjects.

ΔC: the standard deviation of consonantal durations
ΔV: the standard deviation of vocalic durations
%V: the proportion of vocalic durations in the speech
VarcoC: (ΔC / mean consonantal duration) × 100
VarcoV: (ΔV / mean vocalic duration) × 100

$$rPVI\_C = \left(\sum_{k=1}^{m-1} \left| d_{Con_k} - d_{Con_{k+1}} \right| / (m-1) \right)$$

$$nPVI\_V = 100 \times \left(\sum_{k=1}^{m-1} \left| \left(d_{Vow_k} - d_{Vow_{k+1}} \right) / \left(\left(d_{Vow_k} + d_{Vow_{k+1}} \right) / 2 \right) \right| \right) / (m-1),$$

Here, VarcoC and VarcoV are rate-normalized metrics, which were introduced because ΔC and ΔV were found to be negatively correlated with speech rate [10]. PVI indicates the absolute durational difference between each pair of successive units [6]. Two PVI values, i.e., raw and rate-normalized, were calculated for consonantal and vocalic intervals, respectively, as vocalic duration was more sensitive to speech rate while consonantal duration carried more language variability [7].

Following [8, 9], four syllabic metrics were also calculated on the basis of syllable duration, including ΔS, VarcoS, rPVI_S, and nPVI_S, which were defined in the same way as their counterparts for consonantal and vocalic durations.

3. Results

3.1. Timing in isolated words

We started our study from isolated words in Speech Material I. The average percentages of duration for T0 syllables in a word are shown in Table 1, where X indicates any of the four lexical tones. In the case of trisyllabic words with two T0 syllables, the percentages of all three syllables are presented. In all cases MM gives the minimal durational ratio of T0 (in the case of X+T0+T0 the mid syllable should be the shortest, and hence the ratio of the mid T0 is compared), indicating that nonnative speakers did not shorten T0 adequately and hence decreased the durational variation in a word. In other words, nonnative speakers did not differentiate unstressed syllables from others

appropriately. Thus, it is expected that the rhythmic patterns of their continuous speech might be shifted further towards the syllable-timed extreme, especially for Cantonese L1 speakers.

Table 1. *Percentages of duration of T0 syllable in a word.*

Group	X+T0	X+T0+X	X+X+T0	X+T0+T0		
				X	T0	T0
CM	46.0	26.1	33.6	32.7	33.8	33.5
EM	47.4	25.0	33.3	34.7	30.2	35.1
MM	38.6	23.3	30.0	37.6	28.0	34.4

3.2. Rhythmic measurements for continuous speech

We then investigated rhythmic patterns for continuous speech in Speech Material II, using all eleven metrics described above.

Table 2 gives the statistical results of comparing the means of various rhythmic metrics among three groups. The left shows the *p*-values for one-way ANOVA, while the right shows the results of Bonferroni post-hoc tests only for those metrics showing significant main effects. For ΔC, ΔV, rPVI_C, nPVI_V, and rPVI_S, there are main effects of group, and the differences are significant only between native and nonnative groups – there is no significant difference between CM and EM. Besides, there is a marginally significant effect of group for ΔS, but no significant effects for the other metrics.

Except for nPVI_V, all those metrics that differentiate native and nonnative speech are non-rate-normalized; most of the rate-normalized metrics, however, have not provided any distinction between native and nonnative speech. The average speech rates turned out to be 4.14, 4.16, and 5.05 syllables per second for CM, EM, and MM, respectively. There was a main effect of group ($p < 0.001$). Bonferroni post-hoc tests showed that there was no significant difference between CM and EM; there was, however, a significant difference between MM and CM at $p < 0.01$, as well as between MM and EM at $p < 0.001$. This not only verifies that native speech is generally faster than nonnative speech, but also shows that the two nonnative groups have almost equal language proficiency in Mandarin.

It has been shown that ΔC, ΔV, and rPVI_C are negatively correlated with speech rate [10]. Therefore, the observed differences in ΔC, ΔV, and rPVI_C between native and non-native speakers might be the results of speech rate differences. While using VarcoV instead of ΔV helps capture rhythmic patterns better, rate-normalization of consonantal metrics such as ΔC and rPVI_C removes phonotactic differences between languages and hence cannot discriminate rhythmic classes, as shown in [6, 10]. Hence, we adopt raw metrics for consonants and rate-normalized/independent metrics for vocalic intervals.

Table 2. *Significance levels for the differences in rhythmic scores between the three groups.*

Metric	ANOVA	Bonferroni post-hoc test		
		CM–EM	CM–MM	EM–MM
ΔC	0.010**	0.614	0.013*	0.005**
ΔV	0.041*	0.536	0.017*	0.057†
%V	0.475	–	–	–
VarcoC	0.489	–	–	–
VarcoV	0.564	–	–	–
rPVI_C	0.013*	1.000	0.062†	0.016*
nPVI_V	0.024*	0.847	0.208	0.023*
ΔS	0.058†	–	–	–
VarcoS	0.499	–	–	–
rPVI_S	0.037*	1.000	0.142	0.046*
nPVI_S	0.275	–	–	–

* indicates $0.01 < p < 0.05$, while ** indicates $p < 0.01$.
† indicates marginally significant.

To compare the results with previous findings, in Figure 1 we plot the average values of ΔC and %V for different languages, including Mandarin [13], Cantonese [8], and seven other languages [5]. It can be seen that native Mandarin and Cantonese should both be classified as syllable-timed, though the distance in %V from these two to the other four syllable-timed languages is even farther than between the four syllable-timed languages and the three stress-timed languages. For non-native Mandarin, CM and EM are quite close to each other. They share almost the same %V with MM, but both have a much larger ΔC than MM (even larger than the stress-timed languages), showing a tendency of shifting towards stressed-timed languages in the dimension of ΔC, regardless of the L1. On the whole, all the languages in Fig. 1 can be clustered into four sets in the ΔC vs. %V space; native Mandarin/Cantonese, as well as nonnative Mandarin, looks distinctly deviated from other languages, probably due to their monosyllabic nature.

In Figure 2, we plot the average values of nPVI_V and rPVI_C for different languages, including Cantonese [8] and five other languages [6]. It can be seen that native Mandarin and Cantonese should both be classified as syllable-timed (the position of Spanish in [6] is somewhat suspicious because it differs from the results in [10, 14] substantially). For non-native Mandarin, CM and EM are close to each other. They differ from MM mainly in rPVI_C, showing a tendency of shifting towards stressed-timed languages in the dimension of rPVI_C, regardless of the L1.

Among four syllabic metrics, Mok [8] found that rPVI_S gave the best separation between stress-timed and syllable-timed languages, ΔS gave the second best separation, while nPVI_S and VarcoS were not good separators. As shown in

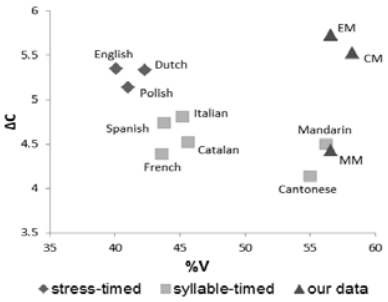

Figure 1: *ΔC and %V for different languages.*

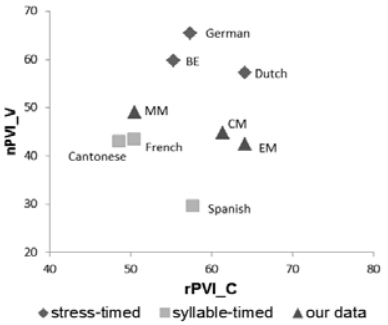

Figure 2: *nPVI_V and rPVI_C for different languages.*

Table 2, the syllabic metric that gives the best distinction among three groups is rPVI_S, followed by ΔS. This is in line with the result for separating stress-timed and syllable-timed languages in [8]. To compare with previous findings, Table 3 lists the average values of rPVI_S and ΔS, for three groups of subjects here and for six languages examined in [8] – English and German are stress-timed while others are syllable-timed.

We have noticed that MM in the present study and Mandarin in [8] give substantially different values. This is quite possibly due to speech rate difference between the materials used in the two studies – hence caution should be made in comparing absolute rhythmic scores between studies, as suggested in [10]. In spite of this, CM and EM showed a tendency of shifting from MM towards the stressed-timed class in terms of both rPVI_S and ΔS. This also coincides with the results for ΔC and ΔV (the latter is not illustrated here). It should be noted that rPVI_S, ΔS, ΔC, and ΔV showing the same tendency are all non-rate-normalized metrics.

Table 3. *Syllabic metrics for different languages.*

Language	rPVI_S	ΔS
English	115.50	88.74
German	99.62	80.78
Mandarin	86.08	75.80
Italian	82.68	67.61
French	75.89	55.30
Cantonese	63.62	57.48
EM	75.70	63.41
CM	72.44	60.32
MM	60.20	51.91

4. Discussion

Comparison of rhythmic characteristics for CM, EM, and MM on the basis of durational metrics has shown that nonnative Mandarin gives almost the same rhythmic mode (i.e., syllable-timed) as native Mandarin in terms of rate-independent (%V) or rate-normalized metrics, but it is shifted towards the stress-timed class in terms of raw durational metrics, regardless of the rhythmic class of the L1. Surprisingly, this does not accord with our expectation from the observation on isolated words, and also conflicts with the general hypothesis (i.e., L1 transfer effect) that the rhythmic pattern of nonnative speech should be intermediate between L1 and L2. However, this does coincide with our auditory impression of nonnative Mandarin speech – basically syllable-timed but meanwhile accompanied by mistaken stress assignment and relatively frequent breaks.

The first conflict can be explained by the fact that stress in continuous speech is not a simple copy of lexical stress pattern but is affected by many other factors. This has been confirmed by our auditory impression that some nonnative subjects assigned stress mistakenly in their utterances, enlarging the contrast of stressed vs. unstressed syllables. It is more difficult to interpret the second conflict, for which the differences in speech rate (viz., nonnative speech is generally slower due to the lack of fluency) can be the best explanation, especially for the larger raw metrics for nonnative speech. In addition, a complex and selective lengthening effect may also account for the observed results, as already mentioned in [9, 10].

This can be further analyzed from the view of prosodic structure. Table 4 shows the numbers of prosodic boundaries at different layers for all subjects. While there is little difference between CM and EM, it is obvious that nonnative speakers produced more prosodic boundaries than natives, especially for B1. The total numbers of higher-layer prosodic boundaries (B2 and B3) are similar, but nonnative subjects have fewer B2 and more B3 than natives.

The results in Table 4 are in line with our auditory impression that nonnative subjects were less fluent in speech and tended to divide an utterance into more chunks, sometimes with longer pauses in between, and even produced some words syllable by syllable. Table 5 lists the distribution of prosodic words with different numbers of syllables for all subjects, showing that CM and EM produced monosyllabic and disyllabic prosodic words more frequently than MM. Besides the lack of fluency, the stronger monosyllabic nature of Cantonese (than Mandarin) may also contribute to the large number of monosyllabic prosodic words for CM.

Because prosodic boundaries are usually accompanied by segmental lengthening such as word-initial and phrase-final lengthening, insertion of more prosodic boundaries leads to more lengthening, which may contribute to a higher variation of duration, causing the larger raw durational metrics.

Table 4. *Numbers of prosodic boundaries.*

Prosodic boundary	CM	EM	MM
B1	1047	1001	801
B2	144	165	247
B3	271	295	196
Total	1462	1461	1244

Table 5. *Numbers of prosodic words in various lengths.*

Group	1-syl	2-syl	3-syl	4-syl	5-syl	≥ 6-syl
CM	226	820	310	84	13	9
EM	184	849	338	74	12	4
MM	106	585	316	166	44	27

5. Conclusions

We have compared the rhythmic patterns of Mandarin speech between native speakers and two groups of L2 speakers who were native in Cantonese and English, respectively. Study on isolated words showed that nonnative speakers did not reduce unstressed syllables adequately. For continuous speech, eleven durational metrics were used to analyze rhythmic patterns. It was shown that nonnative Mandarin gave a quite similar rhythmic mode as native Mandarin in terms of rate-normalized or rate-independent metrics, but shifted towards stress-timed languages in terms of raw metrics, regardless of the rhythmic class of the L1. The result can be explained by speech rate difference and lengthening effects associated with the change in prosodic structure. It coincides with our auditory impression of L2 speech, for which the perceived rhythm may not be classified in a traditional binary/ternary way, but is usually a mixture. In this case, we may need to find better metrics, and the relationship between rhythmic metrics and other measures related to fluency and naturalness needs to be further studied.

Laughing, Breathing, Clicking - The Prosody of Nonverbal Vocalisations

Jürgen Trouvain

Phonetics, Saarland University, Saarbrücken, Germany
trouvain@coli.uni-saarland.de

Abstract

When analysing human spoken communication the focus on the linguistic side lies on speech with its verbal message, whereas the focus on the non-linguistic side usually is on the visually transported information such as gestures and facial expression. However, speech, especially in talk-in-interaction, also features numerous nonverbal vocalisations including various forms of laughter and inhalation noises as their most frequent forms. Although nonverbal vocalisations are usually short in duration they may provide rich information on linguistic, paralinguistic and extralinguistic levels including prosodic phrasing, cognitive load, affective state or speaker identity. The paper provides an overview of the phonetic and prosodic structure and the timing of laughter and audible breathing. Special attention is given on conversational speech, where we can frequently find situations in which interlocutors overlap temporally and on apical click sounds that often occur with inhalation before upcoming articulation but also during word-finding difficulties.

Index Terms: laughing, speech respiration, clicks, paralinguistics, pauses

1. Introduction

Speech communication is concerned with the analysis and processing of *verbal* communication. In contrast, *nonverbal* communication is often associated with *visual* information like gestures from hands, arms, eyes and other parts of the body, particularly the face. However, there is also *vocal* nonverbal communication. Crystal [6] divides the paralinguistic features into *voice qualifiers* (such as whispery, breathy or creaky voice) and *voice qualifications* (like laugh, giggle, sob or cry). The latter group belongs with physiological reflexes (like sneezing, coughing or snoring), to non-word vocalisations that are termed nonverbal vocalisations (NVVs) [47] or non-lexical sounds [51].

Although it is a matter of dispute what counts as verbal and what as nonverbal, for many vocalisations there is no doubt about their non-linguistic status, such as for *vegetative sounds* or physiological reflexes. Snoring, moaning (e.g. in sports), swallowing sounds, chewing noises, hiccup, coughing, sneezing, clearing the throat, yawning or panting (after physical exercise) are not primarily communicative and not all are under voluntary control. Typically, vegetative sounds are not learned. However, there are vegetative sounds that require some level of learning such as lip smacking or blowing one's nose. Some vegetative sounds can be used deliberately like clearing the throat ("ehem") to indicate e.g. "I'm here now". Thus, deliberate vegetative sounds require pragmatic knowledge and the control of the vocal apparatus.

Affect sounds include vocalisations such as laughing, weeping, cheering, crying aloud or screaming and many other types. Conventionalised forms of these affect sounds include the deliberate use of moaning and yawning as well as imitations of coughing and snoring. Often, these vocalisations are called affect bursts, e.g. [35].

Sometimes all sorts of NVVs occur under the umbrella of *interjection*s or *sound objects* [33] as words or utterances with either an emotional and/or an affective connection such as "ouch" or "wow" or as imitative expressions like "miaow" or "knock-knock". There are various grades of lexicalisation among the interjections: "Damned!" or "Shit!" are clearly verbal vocalisations whereas "woosh" or "bing" seem to be less conventionalised. Some interjections are affective words with an ungrammatical phonology such as "pst" or "shh" (no vowels) and "ts-ts-ts-ts" (clicks).

There are further potential candidate utterances for NVVs on the basis of their over-simple or ungrammatical phonotactics. *Hesitation particles*, also known as fillers or filled pauses, such as "uh" or "uhm", can be phonetically regarded as targetless vowels plus a potential neutral nasal consonant. *Feedback utterances* or response tokens include humming signals like "hm" or "yeah" and "uhu" which require hardly any vocal tract control. Usually they are used as backchannel signals but potentially also for asserting and other kinds of attitudinal expression in conversations.

A universal phonetic behaviour is the use of *melodies* with one's own vocal apparatus. Melodies without text can be hummed, sung or whistled but probably not in everyday conversation. In this context the melodies and utterances of babies and toddlers in their pre-linguistic phase should be mentioned where prosody is presumably used without any articulatory targets in the vocal tract.

In conversations, as the most common form of speech communication, NVVs seem to occur more often than in read aloud speech and other forms of controlled speaking situations. An analysis of NVVs in six annotated corpora of conversational speech [47] revealed that breathing noises and laughter were by far the most frequent NVVs in the inspected data. Interestingly, laughs were always present as an annotation category in the different corpora whereas breathing (or similar concepts such as in- or exhalation) was not. Hesitation particles and feedback utterances were usually considered as words and were therefore not counted as NVVs.

In the following sections an overview is given with respect to laughing, breathing and clicking - three phenomena that are linked to the prosodic concept of *pause*. Usually pauses are classified as filled and unfilled pauses [15] whereas the latter are often regarded as silent pauses. Admittedly this 'silence' often contains audible phonetic activity.

2. Laughing

Stereotypically, laughter is associated with a vocal expression of joy that is often spelled "haha". However, investigations of the acoustics of laughter show a huge range of variability for several parameters of "haha"-like laughter. For instance the 'vowel' as the vocal tract reflection in laughing is highly variable between laughs but also in the same laughs [1]. This is also valid for the number of reduplicated laughter 'syllables'

and the duration of laughs. In longer laughs, inspiratory breathing can occur at locations of the 'consonant' and there can be an onset and an offset before and after the staccato-like structure of the "haha"-syllables. We note that such a stereotypical laugh shows a great degree of variability and also complexity [42], see Fig. 1[1].

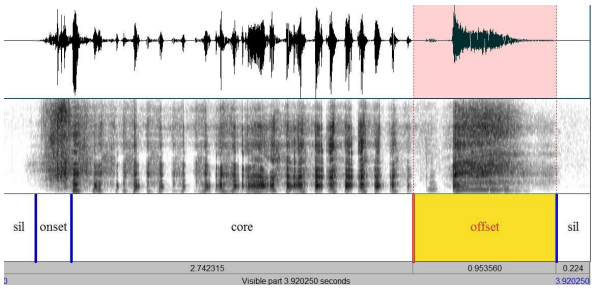

Figure 1: *A complex laugh (as a feedback utterance) with a strong inhalation as an offset (spk R06, duration: 3.9 sec).*

The stereotypical laughs belong to *song-like* laughs [1]. However, not all laughs are alike, as Bachorowksi et al. [1] show in several studies. One important distinction is whether a laugh is voiced or unvoiced [16]. Lab experiments show that females and males use voicing in laughs differently (females prefer voiced laughs) [1, 16]. Unvoiced laughs also have a tendency for conspiracy and less trust [5]. Forms of unvoiced laughter include snort-like and grunt-like variants and sometimes just a short forced exhalation. It becomes clear that laughter is *not only one* form with some variations of this main form but rather *a bundle of forms* with variations for each of these forms.

A special form is the so-called speech-laugh [29, 41] where laughter is produced simultaneously with articulated speech. Note that speech-laughs are different from smiled speech, and that speech can be affected by both, laughing and smiling. In Crystal's terminology [6] speech-laughs and smiled speech belong to voice qualifiers whereas laughs, coughs, sneezes and other NVVs belong to voice qualifications. Speech-laughs can represent a considerable number of all laughs in spontaneous data sets [29, 41, 49] and they are mainly used as self-comments.

Laughter is mainly associated as a signal of emotion displaying happiness, joy, amusement and other forms of well-being. Apart from these positive characteristics there are also negative emotions like maliciousness or simply nervousness. Further important functions of laughter are social bonding or creating affiliation [19]. Presumably, one's decision to join a laughing event, or not to join it, can serve various social functions in addition to transporting affective information.

Investigations of laughs in dialogues reveal that in a considerable number of laughs both speakers overlap with each other (Fig. 2 - as a contrast see a laugh overlapping with speech in Fig. 3). This shared laughter often happens at locations where the speaker with the turn invites the partner to join in the common laugh in order to take the turn [19, 28, 48].

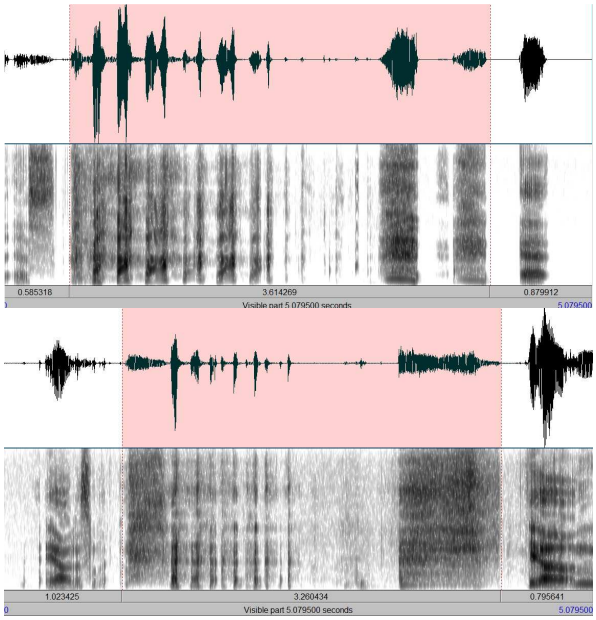

Figure 2: *Overlapping laughter (coloured) with speaker at top (L06) starting to laugh after his speech, speaker at bottom (R06) joining in and taking the turn (duration: 5.0 sec).*

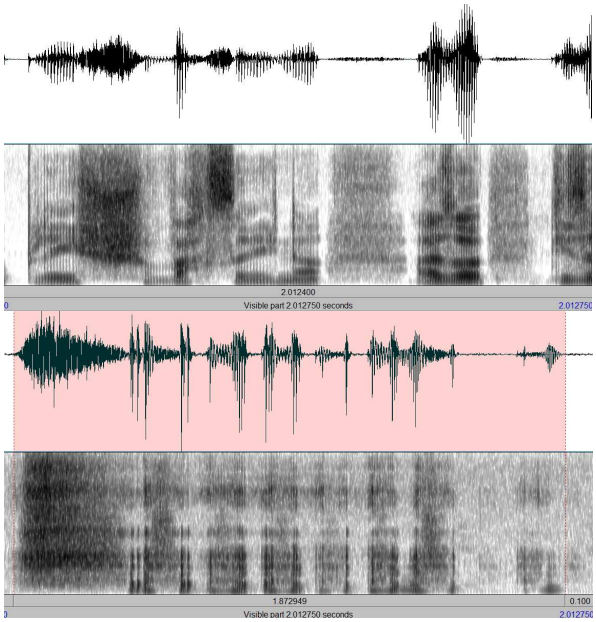

Figure 3: *A laugh at the bottom (R06), starting with an inhalation onset, overlapping with speech of the speaker at the top (L06) (duration: 2.0 sec).*

The prosodic organisation of laughter can be considered at three different levels:

- *The laugh itself.* A voiced laugh follows certain variations of rhythmical, pitch and intensity patterns. Song-

[1] All figures show waveforms and spectrograms (0-8 kHz) of excerpts from the "Lindenstrasse" corpus [18] (six German dialogues, separate channel for each speaker). Acronyms like L06 refer to the left-channel speaker from dialogue 06. L/R02 are female, L/R 06 are male.

like laughter is sometimes characterised as staccato-like. However, a strict application of staccato-like replications of "laugh-syllables" in manipulated laughter leads to the percept of unnaturalness [21].

- *Laugh integrated in the speech*. Laughs are not independent of the preceding articulation phases, e.g. the intensity of a laugh is adapted to the intensity of the preceding speech (cf. [46]). In addition, speech-laughs as vocal productions of speech and laughing by the same speaker at the same time are paralinguistic voice qualifiers and can be seen as tone of voice.
- *Laughing as a construct of interactional behaviour*. A considerable number of laughs in conversations are produced as speaker-overlapping vocalizations. These overlapping laughs (laugh of one speaker overlaps with laugh of the other) show significantly higher values in terms of fundamental frequency, intensity, duration and voicing [48].

3. Breathing

Respiration in speech usually leads to audible noises of breathing which can strongly vary between individuals in terms of duration and intensity of the frication noise [23]. Inhalation noises can be distinguished from exhalation noises and both types can occur as oral or nasal or combined oral-nasal sounds [20].

In read but also in spontaneous speech, audible inhalation noises are usually found in pauses at major prosodic breaks, while pauses that include breathing noises are generally longer than those without breathing [17]. There seems to be a correlation between breath pauses and higher-ranked constituents of the prosodic hierarchy. However, in many prosodic annotation schemes such as ToBI [2], breathing information is not used for determining the boundary strength but should be treated under 'miscellaneous'. Obviously respiration plays a role in controlling and planning linguistic units of various size. The planning of longer phrases is usually indexed by a deeper inhalation with a subsequent, more intensive and/or longer inhalation noise compared to the planning of shorter phrases [11, 34, 53].

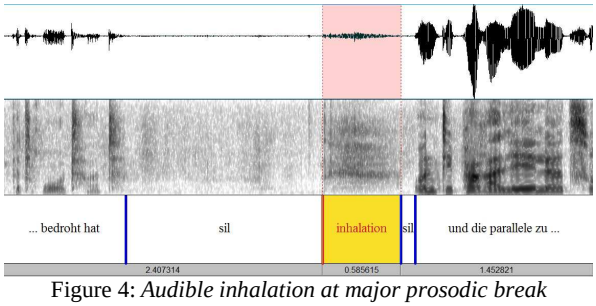

Figure 4: *Audible inhalation at major prosodic break after silence (filled by interlocutor with feedback expression) and before next phrase (speaker R02, duration: 4.5 sec).*

Despite the correlation between inhalation and prosodic planning, the respiratory kinematics of inhalation does not necessarily lead to *audible* breathing noise, as is the case in quiet breathing but also sometimes in speech [45].

Audible breathing can have an impact on how listeners perceive speech tempo. For instance, horse race commentaries are usually described as getting faster the closer the horses are coming to the finish. However, acoustic analyses of those commentaries [43] reveal that the articulation rate remains the same over the race and that the number of pauses increases towards the end instead of decreasing as expected. The main characteristic of these pauses in the final part is that they are shorter and filled with strong inhalation noise - together with an immense increase of the mean pitch.

Paralinguistically, inhalation noises are used for the display of affect such as startle and surprise [35]. Breathing noises are also components of cultural patterns, e.g. as markers of politeness in Korean [54].

Individual patterns of audible breathing and its acoustic correlates are of great interest for forensic research. Duration, intensity and spectral distribution of the frication noise indicate typical differences between individuals [23, 24]. It remains an open question to what extent audible breathing patterns can be reliably associated with the corresponding speaking voice and whether it is possible to impersonators to imitate the breathing of another person.

Attempts to integrate inhalation sounds in speech synthesis are rare. Studies either tested the recall rate and the preference of synthesised sentences with and without preceding breath sounds [52, 44], or inhalation noises were integrated in expressive synthesis as affective sounds [39]. A further example is the modelling of inhalation pauses for speech synthesis beyond single-sentence prosody [3].

As already mentioned in the previous section, audible inhalation can represent a substantial part of laughter, either as an inter-vocalic part dividing two bouts of a voiced song-like laugh or as an offset in a complex laugh (see Fig. 1). Inhalation also plays a role in producing click sounds (in non-click languages) which will be presented in the next section.

4. Clicking

Usually clicks are associated with phonemes occurring in languages in the Southern part of Africa [25, 26]. In contrast to vowels and pulmonic consonants clicks are plosives produced with an ingressive velaric airstream mechanism [22] with two closures, one in the front (i.e. with the lips or the tip of the tongue) and one in the back at the velum, forming a small pocket of air. While both closures are maintained, the tongue moves down. The result is an enlargement of the air pocket and thus a decrease of the pressure of the air therein. Then the front closure is released, followed by the release of the back closure resulting in the click sound.

In 'non-click languages' apical clicks are used as paralinguistic signals, e.g. to express disapproval but also to indicate "yes" or "no" [12]. They can also be used for imitation (e.g. horses) or for addressing animals. Another type are so-called *weak clicks* which are non-intended sounds that come as a coarticulatory by-product [10, 27, 38] when consonants with a closure at the alveolar ridge are followed by a consonant with a velar closing gesture. The release of the alveolar closure followed by the release of the velar closure can lead to a click with a low intensity. Moreover, clicks are used in musical styles with vocal percussion such as beatboxing [32].

In contrast to all the aforementioned uses and types of clicks, recent studies of conversational data in non-click languages such as English and German show that clicks are frequently used for marking new sequences [14, 31, 40, 55, 56], sometimes also to express a stance [31] but also before

feedback utterances and when searching for the right words [40], see Figs. 5 and 6.

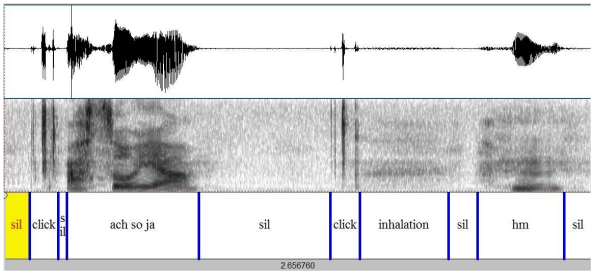

Figure 5: *Two clicks: first click between silence and the feedback utterance "ach so ja" ("I see, yes"), second click between silence and inhalation noise, followed by silence and the feedback token "hm" (speaker R02, duration: 2.6 sec).*

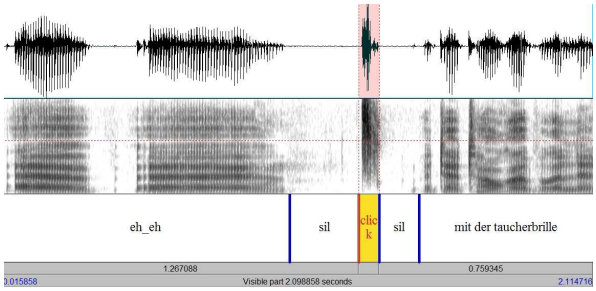

Figure 6: *A click during a word search with two hesitation particles followed by silence, the click, silence and fluent speech (speaker R06, duration: 2.1 sec).*

Interestingly, most speakers of the inspected data sets seem to use clicks, although individual speakers show different frequencies of occurrences. Despite the observed individuality there are limitations of the individual clicking behaviour to be reliably used in forensic phonetics [14].

Producing an apical click is normally unproblematic for a speaker of a "non-click language". The articulation of quasi-lexical items such as "ts-ts" to express disapproval requires a planning of the apical and a tongue body gesture together with inhalation. In contrast to such a conscious choice, the clicks in spontaneous discourse probably occur as by-products of an increased inhalation. Articulatory measurements of speech in preparation show that the tip of the tongue together with the increased inhalation may cause click sounds [37]. Although a velaric airstream cannot be excluded, it is more likely that an inhalation gesture with a sudden and strong vertical downwards movement of the larynx combined with an increased glottal opening provides the necessary negative pressure [9].

It remains an interesting topic for future research whether there is a universal tendency to use clicks as indices for new sequences and other pragmatic functions. The variability of the paralinguistic clicks across languages is still to be explored, particularly their phonetic substances. More knowledge about the phonetics of clicks in languages other than English and German is needed before we can reach a better understanding of what is a vegetative by-product and what is part of a linguistic system.

5. Discussion and conclusion

In vocal communication, particularly in interaction with interlocutors, numerous nonverbal vocalisations can be found. Despite various attempts to describe NVVs [6, 7, 30, 47, 51], a generally accepted framework including a theoretical foundation is missing. For instance, it is a matter of debate whether and which NVVs should be considered as 'conversational grunts' [7, 51].

From the perspective of vocal production, NVVs seem to entail no (or a low) active control of vocal tract configurations. NVVs are mainly characterised by their activities at the subglottal and glottal level and by their temporal control.

Looking at the prosody of NVVs we can see that some NVVs like a voiced laugh (see Fig. 1) show a complex prosodic make-up that can be regarded independently of its neighbouring context. Often NVVs like inhalation noises reveal how they are embedded in their context. Duration and intensity of an inhalation noise provide information on various levels: on the prosodic-syntactic level about the length of the upcoming phrase [11, 53] and the strength of the break [17]; on the prosodic-pragmatic level together with clicks about new sequences [55]; on the paralinguistic level about the degree of arousal [35, 43]; and on the extralinguistic level about patterns typical for certain individuals [13, 23, 24]. In talk-in-interaction, speakers change the prosodic shape of NVVs in accordance with the communication partner as it is the case for speaker-overlapping laughter [48].

Many NVVs occur in speaking situations that are listener-oriented and embedded in a communicative context. They are rarely observed (and not always welcome) in speaker- and text-oriented speech. Speech synthesis, mainly performed as text-to-speech conversion of single utterances, should not ignore NVVs when the aim is to generate more natural and more expressive speech [4]. Synthesis of laughter in isolation [50] is a promising starting point. However, conversational speech synthesis requires a deeper knowledge of the prosody of NVVs. On the recognition side in speech technology, initiatives like the paralinguistic challenges [36] show that NVVs are seen as important social signals.

Most spontaneous discourse (beyond single utterances) contains NVVs. This paper attempted to present the complexity of NVVs by touching upon laughing, breathing and clicking. For a better understanding of the prosody of vocal communication it is time to move the NVVs from the 'miscellaneous' tier to a more systematic description.

Abstract

Very little is known about how listeners incorporate "intonational" information in whispered speech during online language processing. We present data showing that listeners can incorporate information about boundary tones in whispered speech rapidly, but this process is complicated by additional structural biases as well as by the fact that speakers do not produce cues to boundary tones consistently in whisper. Listeners, however, are able to adapt to these differences in order to correctly identify different boundary tones in whisper.
Index Terms: boundary tones, online processing, whispered speech

1. Introduction

In earlier work we investigated the online processing of high (H%) versus low (L%) boundary tones in normal speech, and found that they are processed as quickly as pitch accents [1-5], and with very few interpretation errors. The main acoustic cue to boundary tones, and intonation in general, is thought to be the speaker's fundamental frequency (f0). But when a speaker whispers, f0 is not being produced. This paper begins to address how listeners process boundary tones produced in whispered speech when f0 is absent.

Offline studies have shown that listeners can identify and discriminate boundary tones in whispered speech [6,7]. Performance is worse than in normal speech, but well above chance level, indicating that there are prosodic cues to boundary tones available in whispered speech as well. However, it is unclear how listeners process whispered boundary tones online and which cues they use in doing so. Using a targeted language game, an acoustic analysis of multiple speakers' boundary tones, and a crowd-sourcing perception experiment, the online processing of and adaptation to whispered boundary tones were investigated.

2. Online processing of whispered boundary tones

In earlier research, we developed a "targeted language game" using the visual world eye-tracking paradigm [8] that is sensitive to the time-course of processing boundary tones: [9]. Here we used that paradigm to study the online processing of whispered speech. The participant played a card game against the computer by means of a verbal interaction, and the game was designed in such a way so that on critical trials only the boundary tone indicated whether the computer's move was a statement (signaled by L-L%) or a yes-no question (H-H%). Syntactic cues were removed by having the computer use elliptical sentences of the form '*Got a <card category>*', which could be elliptical versions of either '*I have got a <card category>*.' or '*Have you got a <card category>?*'. The game elicited different actions (thus different fixation patterns) from the participant in response to questions vs. statements, allowing us to assess listeners' online categorization of boundary tones.

The goal of the game was for the opponents to discard cards from their (virtual) hands by matching them to a match card, a face-up card in the middle of the screen (Fig. 1a). Each player also had a stack of block cards, the top one of which could be used to block the other's matches (Fig. 1b). Upon perceiving a question from the computer, the player would look at the playing cards, and upon perceiving a statement, the player would look at the block card. There were four card categories, each represented by a black and white line drawing shown on the match, playing or block card (shoe [ʃuː], wheel [wiːl], candy [kændi], window [wɪndoʊ]). The center of the match card was placed equidistant to the center of the mean size of the playing card set, and the center of the block card.

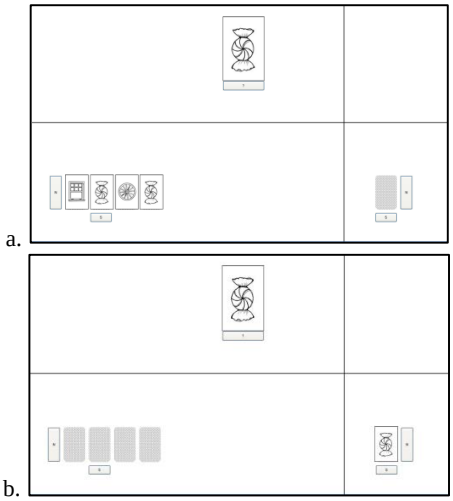

Figure 1: *Screenshots of the game with the match card (top center), the player's playing cards (bottom left) and block card (bottom right); the player (a) looks for possible matches when asked; and (b) looks to block the computer's stated move.*

2.1. Materials

The computer's whispered moves were pre-recorded: eight were target sentences (4 statements/ 4 questions) and nine were fillers (3 statements/ 6 questions). Fillers were used to introduce syntactic variation into the computer's speech (e.g., '*Do you have a candy?*'). Also recorded as computer 'utterances' were moves to keep track of turns during the game (e.g., '*It's your/my turn.*'), to respond to the player's

questions for a match (e.g., '*Yes.*' or '*No.*') and to block the player's match (e.g., '*I am blocking you.*'). The utterances representing the computer's moves were recorded in a sound-treated booth using an Audio-technica ATM75 head-worn microphone and a Marantz PMD 670 solid state recorder (mono, 32 kHz, 16 bits). The speaker was a 23-year-old female native speaker of American English.

Table 1 presents acoustic measurements taken over the target words' final syllables, that is the boundary tone landing sites. It shows mean intensity, duration, and the first through third formants, measured over the mid 50 ms of a vowel using the Burg method implemented in PRAAT [10]. The measurements show a comparable duration for statements and questions, a higher intensity in questions than statements, and in many cases higher formant values for questions.

Table 1. *Acoustic content of the final vowels, per target word, spoken as statement (S) or question (Q).*

	Speech act	Int. (dB)	Dur. (ms)	F1 (Hz)	F2 (Hz)	F3 (Hz)
candy	S	54.0	171	452	2720	3089
	Q	60.8	169	537	2925	3352
shoe	S	60.5	323	570	1679	2748
	Q	62.8	318	611	1832	2900
wheel	S	66.2	390	642	2551	2901
	Q	67.8	399	771	2653	3014
window	S	65.1	254	790	1766	2744
	Q	70.7	236	858	1683	2844

2.2. Participants and procedure

Fifteen American English participants were recruited at the University of Rochester, NY, USA (informed consent obtained). They were given both written and oral instructions. During testing the verbal interaction was recorded using a Realistic 33-984A Highball dynamic unidirectional table microphone placed between the computer speakers and the player, so that it would register both interlocutors. Eye movements were recorded using a head-worn ASL eye-tracker at 30 Hz, and a Sony DSR-30 digital video recorder, with Sony 184 DVCAM digital videotapes. Before the test started, the participant played a practice game that contained all possible game situations. Calibration was checked throughout the test game and always occurred before a new turn for the participant. The entire session lasted 30 to 45 minutes.

The order of events (question vs. statement) during the game was fully determined, but the order for the card items (candy, shoe, etc.) was rotated and balanced across four lists. For target utterances, the wave file started 1400 ms after the match card had changed. For filler items, the preceding silence was variable, but at least 1200 ms, thus introducing variation to increase the naturalness of the computer's utterances, as a real player also would not respond at regular intervals. The computer utterances were played to the participants at a comfortable listening level over computer speakers.

2.3. Results and discussion

The 33 ms video frames were coded manually from the onset of a target utterance until the participant's verbal response, i.e. a variant of '*I can('t) match/block*'. Five locations were coded: (1) the playing cards, (2) the match card, (3) the block card, (4) other on-screen locations, and (5) track loss. Saccade-initial frames were counted as fixations to the landing site.

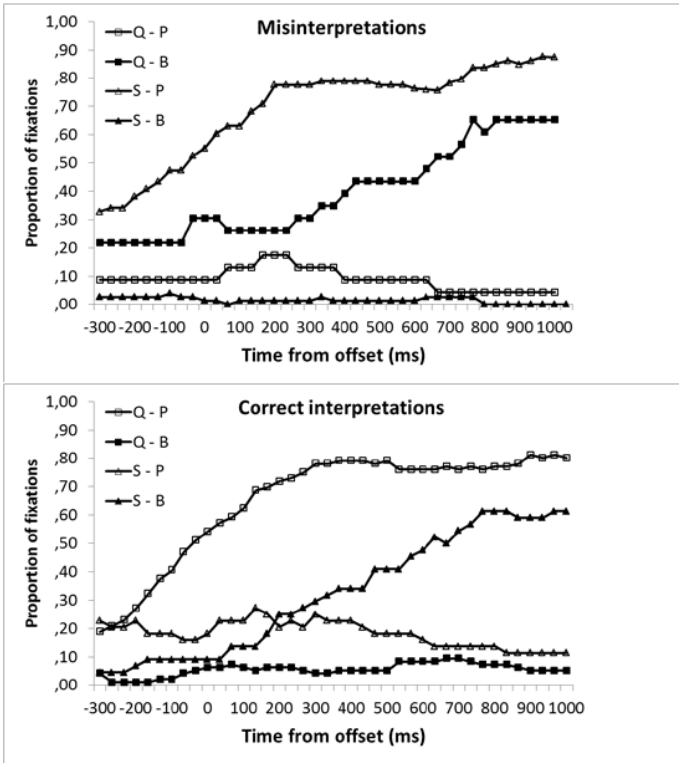

Figure 2: *Proportions of fixations to the playing cards (P) and block card (B), in the case of intended questions (Q) and statements (S). Misinterpretations and correct interpretations are plotted separately.*

Out of 240 trials, 140 were correctly interpreted (58%), 99 were misinterpreted (41%), and one trial was misunderstood. Misinterpretation means that intended questions were interpreted as statements, and the other way around. When looking at the division of correctly versus incorrectly interpreted trials per speech act, 76 out of 120 statements were misinterpreted, but only 23 out of 120 questions. On average, questions, but not statements, were correctly recognized above chance level.

Because of the large number of misinterpretations, eye movements to both correctly interpreted and misinterpreted trials were analyzed separately (see Fig. 2). For questions and statements the ratio of targets divided by the sum of targets and distractors, T/(T+D), was computed and compared in a two-tailed paired samples t-test, see [11]. This was done for two intervals, one before target offset (-300 ms to 0 ms) and one after target offset (0 ms to 300 ms). These intervals were chosen because they represent the regions before and after where the earliest effects of boundary tones are expected.

For correctly interpreted trials, no significant difference between the speech acts was found during the first analysis interval, $t(7)=0.8$, n.s, whereas during the second interval, a significant difference was found, $t(12)=2.7$, $p=0.020$. This pattern is in principle consistent with sensitivity to prosodic cues. When looking at the questions, however, there is an early preference for the playing cards that does not seem to be time-locked to the boundary tone (< 0 ms). In statements, the pattern of fixations is consistent with interpretation of the boundary tone, showing an increase in looks to the block card once the boundary tone becomes available (> 0 ms).

For misinterpreted trials, both analysis intervals showed a significant difference between the speech acts, $t(6)=-5.2$, $p=0.002$ and $t(8)=-5.1$, $p=0.001$, respectively. Eye-movements therefore do not seem to be time-locked to the prosodic events. In the case of misinterpreted questions (as statements), there is an initial bias to look at the blocking card early in the utterance, followed by a later increase in looks to the blocking card which is too delayed to reflect a time-locked response to the boundary tone. In the case of misinterpreted statements (as questions) there is an initial bias to look to the playing cards which begins to increase well before the final syllable.

The results show only a weak reliance on prosodic cues in whisper. Firstly, many trials were misinterpreted which indicates that prosodic cues to speech act were not correctly used or not used at all. Secondly, in correctly interpreted questions the proportion of fixations to the target increased well before boundary tone information became available. Only in correctly interpreted statements, does the time course of fixation proportions suggest that prosodic cues were used. Because of the predetermined order for moves in the game, the majority of statements occurred during the second half of the game. We used a mixed-effects logistic regression to explore the effect of trial number and speech act type on participants' answers. The model with the fixed and random effects structure most justified by the data (as accessed by model comparison) did not contain a significant intercept ($B=0.19$, $z=0.80$, $p=0.42$) nor a main effect of trial number ($B=0.057$, $z=0.60$, $p=0.55$), but it did show a significant main effect of speech act type ($B=-1.21$, $z=-6.54$, $p<0.001$); questions were more likely to be answered correctly than statements. The interaction between type and trial number was also significant ($B=0.22$, $z=5.25$, $p<0.001$). Separate logistic regressions by speech act type revealed that participants improved in performance across trials only on statements, $B=0.28$, $z=3.89$, $p<0.001$. On questions listeners actually became worse across trials ($B=-0.21$, $z=-2.99$, $p=0.003$), but remember that overall participants performed better on questions than on statements.

Earlier research [e.g. 6,7] and Table 1 suggest that acoustic cues to speech act type were present. There are several explanations as to why this information was not fully used. Listeners may either be relatively insensitive to the prosodic information that the speaker attempted to convey, perhaps because whisper as a speech mode is not used very often and the cue that normally carries boundary tones, f0, is absent. Listeners might also find it difficult to extract prosodic information because speakers may not provide consistent cues to intonation in whisper. These possibilities were addressed further in section 3.0.

3. Variation in boundary tone realization

Gotta-utterances from three additional speakers were recorded and speaker strategies for signalling prosody were compared to explore if the listeners' difficulty with prosodic cues in whisper may be explained by varying speaker strategies.

3.1. Method

Two male and one female native speaker of American English were recorded [Shure SM57 microphone, mono 44.1 kHz, 16 bit] using a script that took speakers through a game scenario intended to elicit each target utterance twice. Participants were told the outline of the game and then asked to imagine themselves as best as possible in the game scenario, saying the sentences how they would say them if they were really playing. They were not asked to make the questions and statements as acoustically distinct as possible; they were just told to be as clear as possible given that they would be whispering. They were also told to take their time and read the scenario descriptions carefully so that they would be in the right mindset for producing the utterances.

Recordings were annotated at the segment level, and for all final-syllable vowels we measured the relative syllable duration, mean intensity, and the first through third formants over the vowel's mid 50 ms using the Burg method implemented in PRAAT. Formant measurements were visually verified in the spectrogram (some F1s, mainly of [u], could not be determined). These acoustic characteristics were selected as they have been put forward as cues to whispered tones and/or intonation [12-15]. Comparisons between the speech acts were done per speaker, using paired samples Wilcoxon signed ranks tests.

3.2. Results and discussion

Relative vowel duration was longer in questions than statements for Speaker 1 only, $Z=-2.5$, $p=0.012$. The difference was marginal for Speaker 2 ($p=0.058$), and non-significant for Speaker 3 ($p=0.16$). Mean vowel intensity showed no significant differences between statements and questions for any of the speakers. Due to data sparsity, effects in F1 were hard to measure, but no significant differences were found, and no consistent trends were observed. For F2, Speaker 3 produced a significantly higher second formant (F2) in questions compared to statements ($Z=-2.1$, $p=0.036$). The mean difference was 82 Hz. Speaker 2 showed a tendency in the same direction with a 119 Hz mean difference ($p=0.077$). As for F3, speakers 1 and 3 had a higher value in questions than statements, with mean differences of 120 Hz and 96 Hz, respectively (both $Z=-2.5$, $p=0.012$). Speaker 2's data showed a comparable trend with a 92 Hz mean difference.

The results show that speakers vary in the acoustic dimensions that they use to signal different speech acts, along three dimensions that have been proposed as potentially contributing to the expression of intonation in whisper. Speakers provided both durational and spectral cues, but not in exactly the same way. Spectral differences, which are assumed to provide the most direct cue, were also present in the productions of Experiment 1's speaker. Duration may be taken as a secondary cue, through lengthening of the speech act that requires most production effort, the question. Two out of three speakers made a durational difference, but this had not been the case for the speaker of Experiment 1. Whereas that speaker seemed to vary vowel intensity with speech act, a comparable intensity difference was not found for the other three speakers.

4. Tuning in to whispered prosody

Taken together, results of Experiment 1 and the analysis of multiple speakers suggest that listeners' difficulty with the extraction of prosodic information from whispered utterances may arise because different speakers provide different cues to prosody in whisper. Therefore listeners require exposure to a particular speaker to learn the relevant cues that remain when f0 is absent. The fact that 'tuning in' took place is supported by the increased number of correctly interpreted trials in the second half of Experiment 1. To further investigate if participants are in fact tuning in to prosodic information or

were just making lucky guesses, listeners were exposed to different patterns of acoustic cues to test the hypothesis that they adapt to and use the cues in each case.

4.1. Method

A Web survey was conducted in which participants provided responses to whispered audio samples of statements and questions produced by one of the three speakers from Experiment 2. Participants were instructed that they would hear a whispering speaker play a simple card game, and that they would be asked to indicate whether they heard the player make a match (=statement response) or ask for a card (=question response), by clicking one of two buttons. Feedback on the correctness of their answers was provided, both during practice and testing. During practice, sentences from Experiment 1's fillers were used (i.e. different speaker, no elliptical structure). During testing, there were 16 trials: 2 repetitions of each target word (4) in each speech act (2).

Using the online crowd-sourcing service Amazon's Mechanical Turk, 258 Human Intelligence Tasks (HITs) were posted for (self-reported) American English participants (253 unique participants). Per speaker, four lists were used, each with a different order for the response options. In a pretest it was established that listeners' home equipment was set up to perceive whispered speech well. Ten participants were eliminated because sound files did not play properly during the pretest. Three additional participants were eliminated due to experimenter error, leaving 240 participants (80/speaker, 20/list). Participants were paid $2 for their efforts.

4.2. Analysis, results and discussion

The data were analysed with a hierarchical mixed-effects logistic regression with Trial Number, Speech Act Type, and Speaker as predictors using the maximal random effects structure as justified by the model, which included random intercepts by subject and by item, as well as random slopes by item over trial. The main effects of trial, type, and speaker were entered first, followed by the two-way interactions, followed by the three-way interaction.

We used model comparison to select the model most justified by the data. The final model included the intercept, and the main effects of trial, type, and speaker. This model accounted for a significant portion of the variance above and beyond the model with just the intercept $\chi^2(4)=22.62$, $p<0.001$. The intercept itself was significant ($B=0.22$, z=2.53, $p<0.05$), indicating that on average listeners performed above chance. The main effect of trial was significant ($B=0.056$, z=2.82, $p<0.01$); on average, as trial number increased, performance improved. The main effect of type was also significant ($B=-0.22$, z=-2.67, $p<0.01$); on average questions were more often answered correctly as compared to statements. The intercepts for Speakers 1 and 3 were significantly different from each other ($B=0.10$, z=3.27, $p<0.01$). The intercepts for Speakers 1 and 2 were not significantly different ($B=0.050$, z=1.57, $p=0.12$). The intercepts for Speakers 2 and 3 were marginally different ($B=0.052$, z=1.71, $p=0.088$). Separate logistic regressions for each speaker revealed a significant intercept for speaker 1 ($B=0.33$, z=2.67, $p=0.008$), a marginal intercept for speaker 2 ($B=0.199$, z=1.66, $p=0.097$), and a non-significant intercept for speaker 3 ($B=0.043$, z=0.31, $p=0.76$).

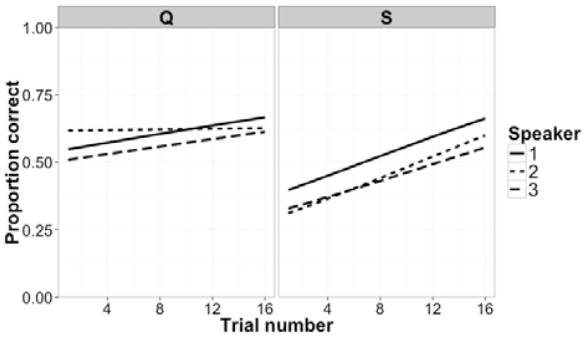

Figure 3: *Proportions of correct answers across trials plotted for the three speakers separated by questions (left panel) and statements (right panel).*

First, as Figure 3 shows, there was an overall trend across all speakers for listeners to improve performance as trial number increased. Thus, while it is true that different speakers signal prosody differently in whisper, listeners are able to adapt to those differences. This result contrasts with Experiment 1 where a main effect of trial was not found. Recall, however, that only one ordering for question and statement moves was used in Experiment 1, whereas four lists were used here. Second, there was a trend for listeners to perform better on questions than on statements (see Fig. 3), just as in Experiment 1. This difference seems to indicate a bias to interpret the "got a" construction as a question as opposed to a statement, see [16]. Third, we have some evidence that productions of different speakers have different effects on how listeners are able to interpret their intentions in whispered speech. The listeners who received Speaker 1's stimuli performed above chance overall (61% correct), in comparison to the listeners receiving Speaker 2, who were marginally above chance (58%), and Speaker 3 who were not statistically different from chance (54%). Possibly, listeners tuned in more quickly to Speaker 1 because that speaker significantly changed two acoustic dimensions, spectral and durational, between the speech acts rather than just one, spectral or durational.

5. Conclusion

We have replicated the effect that listeners can distinguish boundary tones in whispered speech. In addition we have provided provisional evidence that speakers can incorporate information about the boundary tones in real time processing of whispered sentences. This effect is complicated by the fact that listeners also appear to take into account cues from the lexical content of the utterance (a question bias for "got a"), and by the fact that cues to boundary tones are more difficult to distinguish in whispered speech. In addition, speakers have different strategies for how they signal boundary tones in whisper. Therefore, compared to the more systematic f0 cue in regular speech, listeners may need more exposure before they can utilize (speaker-dependent) systematic cues to prosody in whispered utterances. We note that there is emerging evidence that listeners adapt to the reliability of different prosodic cues for individual speakers even in normal speech [17]. Therefore, the mechanisms used by listeners to process prosody in whispered speech might partially be similar to those used when processing normal speech.

"A little more ironic" – Voice quality and segmental reduction differences between sarcastic and neutral utterances

Oliver Niebuhr

Department of General Linguistics, ISFAS, Kiel University, Germany
niebuhr@isfas.uni-kiel.de

Abstract

The presented production experiment analyzes the phonetic differences between neutral (i.e. sincere) and sarcastically ironic utterances in German. Results show in line with previous studies that sarcastic irony is expressed by longer utterance durations, lower and flatter F0 contours, and a lower intensity level. Moreover, extending previous findings, sarcastic irony is also characterized by a more variable (in tendency breathier) voice quality and a higher degree of segmental reduction, probably reflecting the speakers' dissociation from the wording of their utterances.

Index Terms: irony, sarcasm, intonation, emphasis, reduction

1. Introduction

Ironic statements convey the opposite of what the speaker has put into words. Even in this admittedly oversimplified common sense definition (e.g., [1,2]), irony is anything else but a marginal aspect of speech communication. For example, estimated on the basis of spontaneous dialogue corpora [8,23], one hour of speech contains about 10-15 instances of ironic expressions. They represent a type of emphasis at the utterance level. Such utterance-level types of emphasis can be distinguished from other word-level types of emphasis [3,4,5]. While lexical means like extreme exaggerations or question tags are optional irony signals, prosodic signals seem to be a constant companion of ironic utterances. Typically, and particularly in lexically unmarked ironic utterances, prosodic meanings are selected such that they clash with the verbal meanings. In this way, they can indicate irony and express at the same time what the speaker actually wants to say (in combination with the communicative and visual contexts).

Since there is an infinite number of different ironic utterances, and since the prosodic meanings have to be adjusted to clash with each of their verbal meanings, it is obvious that *the* prosody of irony cannot be determined. Therefore, phonetic studies trying to pinpoint specific prosodic exponents of irony have either failed or – implicitly or explicitly – investigated a particular subtype of irony. The most frequently investigated subtype of irony concerns the clash between positive verbal and negative prosodic meanings. It is often referred to as sarcasm, although sarcasm is actually just an attitudinal concept of a provocatively negative kind, which can in principle also be directly expressed in speech without being exploited for an ironic meaning clash [1].

The general aim of the present paper is to continue the line of phonetic research on this sarcastic subtype of irony. However, for the sake of simplicity and because irony is the determining concept, the more accurate term 'sarcastic irony' will be used interchangeably with 'irony' in the following. Detailed experimental-phonetic analyses of sarcastic irony have begun only about a decade ago, which makes sarcastic irony a relatively young field of research. The phonetic picture that has emerged so far from analyses of English, Italian, French, German, and Cantonese can be condensed as follows: Compared with neutral utterances, utterances with sarcastic irony are produced longer (i.e. at lower speaking rates) and with clear changes in the levels and ranges of F0 and intensity [6,7,8]. F0 patterns seem to be lowered and narrowed in Western Germanic languages like English and German [9, 10,11,12], but raised and/or widened in Cantonese and Roman languages like Italian or French [13,14,15]. Findings on intensity changes were a bit less consistent, but typically went in the direction of a lower, flatter intensity contour [13,16] (cf. [9,12] for exceptions).

The summarized findings call for an extension in two directions. (1) What about voice quality whose relevance as "the fourth prosodic dimension" as recently been stressed and promoted by [17]? (2) Since modern phonetic research also stresses the strong linkages of segments and prosodies (e.g. [18]), what about the segmental characteristics of sarcastic irony? The present study addresses these two questions on the basis of Standard Northern German.

As regards question (1), there are impressionistic indications from [19] that sarcastic irony is produced with a softer, i.e. breathier voice quality. With respect to question (2), one may expect a higher degree of speech reduction in ironic utterances for the following reason. It has recently been argued in [20,21] that the degree of speech reduction in an utterance is not just the result of an articulatory balance between the competing demands of economy and comprehensibility in a given communicative situation, cf. [27]. Rather, the articulatory effort invested by the speaker also signals his/her attitudes towards the dialogue partner or the content of the message. For example, utterances like "good morning", "I do not know" (cf. also [22]), "I am sorry", or "thank you" are less reduced when they not just function as routine statements, but sincerely serve to initiate a conversation, or express compassion, cooperativeness, remorse, or gratitude, cf. also [29]. Since irony requires that speakers distance themselves from the semantic con-tent of their utterances, it is reasonable to assume that they mark this distance by a higher degree of segmental reduction.

In summary, the hypotheses tested in this study are that ironic utterances in Standard Northern German are longer, breathier, more reduced, and have lower and flatter F0 and intensity contours than their neutral counterparts. Design and procedure of the corresponding production experiment will be outlined in the following section.

2. Method

2.1. Target Sentences

The study was based on 20 target sentences. They were designed to meet three criteria. First, they were plain and syntactically simple constructions of four to eight frequent German words. This allowed the sentences to be produced fluently and with a clear and consistent prosody. Second, in order to facilitate speech reduction processes, each sentence contained at least two so-called phonetically weak forms in the

sense of [24], i.e. function words like pronouns, auxiliary verbs, modal particles, articles, prepositions, or conjunctions, which are by default unstressed. Third, the sentences were formulated such that they can be directed towards an interlocutor. In addition, they made positive statements about this interlocutor or a third party and in this way lay the ground for realizing the sentences not only in a neutral fashion, but also with sarcastic irony by inverting their positive propositions. The 20 target sentences are provided in the Appendix.

2.2. Speakers and Recording Procedure

The target sentences were produced by 10 speakers of Standard Northern German, 5 males and 5 females. They were students at Kiel University and 23-29 years old.

The recordings were conducted at the speakers' homes in rooms which were silent and as anechoic as possible (i.e. typically in the speakers' living rooms). It was assumed (and supported by feedback after the recordings) that familiar surroundings would make it easier for the speakers to get into the kind of mood that is needed to express sarcastic irony. For the same reason, the recordings were conducted by a student of phonetics – DT – who was a good friend of all of the speakers.

Each speaker had a few minutes time prior to the recording to familiarize him/herself with the target sentences. Then, the speaker received the oral instruction to produce each target sentence in an informal everyday fashion while addressing his/her friend DT. The target sentences were presented separately on file cards in order to avoid any list effects on speech production. The speakers were free to repeat each sentence until they were satisfied with the result; and in fact most speakers made use of this possibility several times due to unsatisfactory expressions of irony or insufficient informality.

The group of 10 speakers was divided into two subgroups. One subgroup produced the target sentences first in a neutral fashion and then with sarcastic irony. The other, equally large subgroup started with the expression of sarcastic irony and then uttered the target sentences again in a neutral way. The sentence order was re-randomized after each round and for each new speaker. The concept of sarcastic irony was explained to the speakers on request by means of instances in comic strips, i.e. without using auditory examples.

The elicited ironic and neutral target sentences were recorded digitally with a HiFi speech recorder (Zoom H2n). Instead of using the built-in microphone, recordings were made with a head-mounted microphone so that the relative distance between mouth and microphone was constant during the recording. An entire recording session took about 15 minutes.

Pitch accents in the neutral and ironic sentences fell on the same words and were free from additional positive or negative emphatic intensification [3]. Spot checks just revealed a slightly greater number of high-tone (H* or L+H*) accents in the neutral set, reflecting the positive sentence semantics.

2.3. Filtering out Unclear Cases

Phonetic analyses were preceded by a small perception experiment. It served to cross-check whether the target sentences selected by the speakers to convey sincerity (neutrality) and sarcastic irony would in fact be clearly associated with these functions by independent listeners.

To that end, all target sentences were cut out of the recorded sound files and normalized in amplitude with Adobe Audition (www.adobe.com/Audition) to 90% of the possible dynamic range. Then, they were arranged in four differently randomized orders in which the sentences were separated from each other by a pause of five seconds and a beep. The so-assembled stimulus lists were finally handed over as a single sound file to four naïve German listeners together with a corresponding response sheet.

The naïve participants were informed that they would hear a set of isolated sentences from 10 speakers of Standard Northern German. They were furthermore asked to play the sound files in a silent room and judge spontaneously for each sentence whether it was meant sincerely or ironically. Conducting the perception experiment took about 45 minutes.

Based on the retrieved response sheets, target sentences were excluded from further analyses if they were not correctly identified as neutral or ironic in at least 75% of the cases. Although sentences of both types were affected by this filtering, it was primarily the ironic sentences that failed to meet the 75% threshold. Therefore, in order to create equally large samples for the phonetic analyses, additional sentences were randomly excluded from the neutral sample. In summary, the perceptual filtering procedure resulted in 142 target sentences, subdivided into two samples of 71 clearly neutral and 71 clearly ironic tokens.

2.4. Phonetic Analyses

The phonetic analyses of the remaining, clear target sentences included acoustic as well as auditory measurements. The acoustic measurements covered all four prosodic dimensions, i.e. F0, intensity, duration, and voice quality. F0 and intensity were represented by four parameters each. In summary, the following ten parameter values (a)-(j) were determined for each target sentence:

- (a) F0 minimum of the sentence, measured in semitones relative to 100/200 Hz for male/female speakers,
- (b) F0 maximum of the sentence, measured in semitones relative to 100/200 Hz for male/female speakers,
- (c) F0 range in semitones, i.e. (b) subtracted by (a),
- (d) average F0 level, calculated in semitones relative to 100/200 Hz for male/female speakers,
- (e) intensity minimum in dB within a non-silent sound section of the target sentence,
- (f) intensity maximum in dB,
- (g) intensity range in dB, i.e. (f) subtracted by (e),
- (h) average intensity level in dB, disregarding silent (sound) sections of the target sentence,
- (i) voice quality in terms of the amplitude difference in dB between the first and the second harmonic (H1-H2), measured in the midpoints of all vowels of a target sentence and then averaged across these vowels,
- (j) tempo, represented by the total sentence duration.

All measurements except for (i) were conducted with PRAAT [28], using the default settings. The F0 measurements (a)-(b) and (d) omitted octave errors and, as far as possible, also microprosodic perturbations. Intensity measurements were not normalized as the use of head-mounted microphones assured a constant speaker-microphone distance. The voice-quality measurements for (i) were made with WaveSurfer (www.speech.kth.se) on the basis of narrow-band FFT spectra.

The acoustic-prosodic analysis was complemented by a careful auditory analysis targeted at the degree of segmental reduction in a target sentence. This degree was measured by successively playing short sections of the target sentence and counting the number of assimilations, elisions, and lenitions of sound segments in these sections relative to their canonical full form in Standard German according to [25]. The reduction countings of the individual sections were then summed up for each target sentence. Assimilations could, for example, concern voice and place of articulation. Lenitions included vocalizations of consonants, centralizations of vowels, and changes of obstruents to approximants. The auditory analysis was performed with headphones by DT in a silent room and subsequently cross-checked by a trained phonetician (ON). DT and ON were Standard German listeners. Cases of disagreement were supplemented by visual inspections of spectrograms and/ or waveforms and discussed until a final decision was reached.

3. Results

The acoustic-prosodic measurements made within the selected 2x71 target sentences were analyzed with a multivariate ANOVA. It was based on the 2-level fixed factor Sentence Type (ironic vs. neutral); and since the sentences of the ironic and neutral sample were not equally distributed across the 10 speakers, possible differences between the two samples were analyzed in terms between-subject effects. The MANOVA resulted in a highly significant main effect of Sentence Type ($F[10,131]= 69.696$; $p<0.001$; $\eta_p^2= 0.842$). All dimensions of acoustic-prosodic parameters contributed to this main effect.

As regards the F0 parameters (a)-(d), the largest difference between the ironic and neutral sentences and thus the strongest effect in terms of partial eta-squared lies in the height of the F0 maximum ($F[1,140]= 193.416$; $p<0.001$; $\eta_p^2= 0.580$). As is illustrated in Figure 1, this maximum was produced considerably (i.e. 3 semitones) lower for the ironic than for the neutral sentences. The same, though less clearly, applied to the F0 minimum ($F[1,140]= 12.816$; $p<0.001$; $\eta_p^2= 0.084$), and in accord with the lowering of these two extreme F0 values, the overall F0 level was also about a major third lower for the ironic than for the neutral sentences ($F[1,140]= 116.366$; $p<0.001$; $\eta_p^2= 0.454$). In addition, the sentences expressing irony were also characterized by a significantly narrowed F0 range, representing the second strongest F0 effect ($F[1,140]= 163.532$; $p<0.001$; $\eta_p^2= 0.539$).

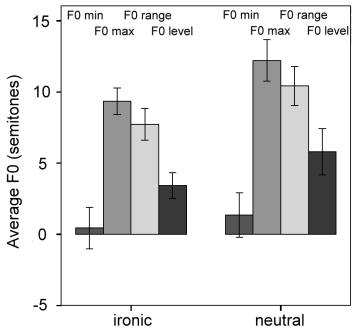

Figure 1: *Means and standard deviations of the four F0 parameters (a)-(d), measured in ironic (left) and neutral (right) target utterances; n=71 for each bar.*

The biggest intensity contributions to the significant main effect of Sentence Type come from the intensity minima and maxima. Figure 2 shows that both clearly decrease (between 4-9 dB) from the neutral to the ironic sentences (Int-min: $F[1,140]= 72.334$; $p<0.001$; $\eta_p^2= 0.341$; Int-max: $F[1,140]= 71.643$; $p<0.001$; $\eta_p^2= 0.339$). The intensity range does not differ significantly between the ironic and neutral sentences. However, parallel to the change in F0 level, the intensity level was also significantly lower for the ironic than for the neutral sentences ($F[1,140]= 37.594$; $p<0.001$; $\eta_p^2= 0.212$).

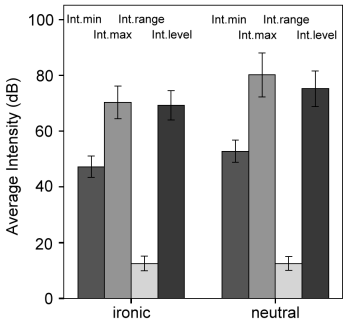

Figure 2: *Means and standard deviations of the four intensity parameters (e)-(h), measured in ironic (left) and neutral (right) utterances; n=71 for each bar.*

From the remaining two prosodic parameters (i)-(j), i.e. harmonic amplitude difference H1-H2 (voice quality) and sentence duration, only the latter differed significantly between the ironic and neutral sentences ($F[1,140]= 58.589$; $p<0.001$; $\eta_p^2= 0.288$), cf. Figure 3. Sentence durations were on average about 25% longer in the ironic than in the neutral productions. Importantly, this effect is not due to the fact that the 20 sentences occurred with different frequencies in the ironic and neutral samples. Even when the sentence durations were normalized and recalculated in terms syllables per second, a separate t test (for unpaired samples and homogeneous variances, based on a prior F test) showed that the duration difference between the ironic and neutral sample persisted, also with regard to its magnitude ($t[140]= -10.683$; $p<0.001$). The average syllable per second rate in the ironic sentence set was 5.5. This is about 30% slower than the average rate of 7.1 syllables per second in the neutral set.

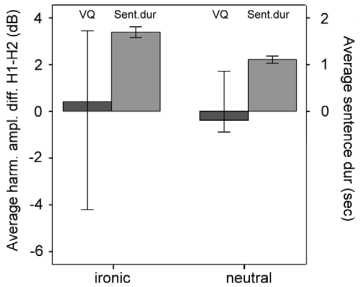

Figure 3: *Means and standard deviations of voice quality (dark gray, i) and sentence duration (light gray, j), measured in ironic (left) and neutral (right) target utterances; n=71 for each bar.*

The voice quality measure only yielded a trend towards higher H1-H2 values in ironic sentences $F[1,140]= 2.796$; $p<0.097$; $\eta_p^2= 0.020$). Next to this trend, however, there is a much more salient and statistically significant difference between the voice-quality measurements of the ironic and neutral samples. As can be seen in Figure 3, this difference concerns the standard deviation of the H1-H2 values, which were much larger

in the ironic than in the neutral sample. It is not surprising in view of this observation that the H1-H2 parameter clearly stood out highly significantly in the Levene tests of the MANOVA ($F[1,140]= 70.073$; $p<0.001$). So, while the overall voice quality in the neutral sentences was mainly constant and modal, the ironic sentences were produced with either breathier or tenser voice qualities. This interpretation of the measurements is in accord with an auditory inspection of the data.

The results of the auditory reduction analysis are summarized in Figure 4. It shows firstly that both the neutral and the ironic target sentences were subject to reduction processes such as assimilation, elision, and lenition. Secondly, however, the degree of reduction in terms of the mean frequency of reduction processes looks overall higher in the ironic than in the neutral sentences. This impression was confirmed in a one-way ANOVA. That is, the ironic set showed on average 4.8 reductions per sentence, which is significantly more than the 3.6 reductions that occurred on average in the neutral set of target sentences ($F[1,38]=10.464$; $p=0.003$; $\eta_p^2=0.216$). However, it must also be noted that this overall difference was not equally present for each target sentence. While sentences like 8, 15, 16, and 19 were realized with about twice as many reductions in the ironic condition, other sentence like 1, 3, 7, 12, and 17 were produced with a similar or even slightly higher number of reductions in the neutral condition.

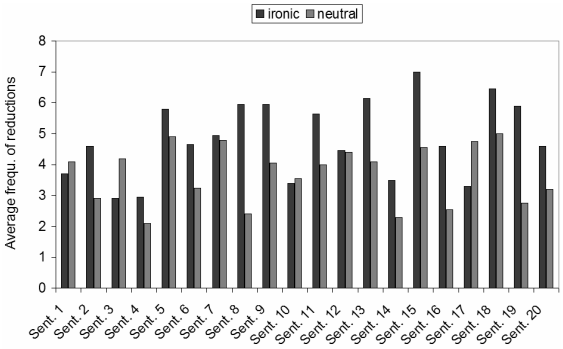

Figure 4: *Mean frequency of reductions found across the 10 speakers in the ironic (dark gray) and neutral (light gray) productions of the 20 target sentences.*

4. Discussion and Conclusions

The present findings support the conclusion of previous studies that sarcastic irony has a separate phonetic profile in comparison to neutral (i.e. sincere) speech. This profile involves extended utterance durations due to a reduced speaking rate, as well as changes in the F0 and intensity patterns. In accord with previous findings for Western Germanic languages, sarcastic irony was characterized in the present study by a lower and flatter F0. Intensity findings for sarcastic irony have always been less consistent both within and across languages. For example, expressing sarcastic irony in varieties of English was associated with an *in*crease in intensity parameters in [9], but with a *de*crease in intensity parameters in [13]. Similarly, for Standard German the intensity level was raised in [12], but lowered in the present study of the same language variety. Moreover, in contrast to [13,16] the present findings do not include a narrowed intensity range, as the intensity minima and maxima were both lowered to the same degree. The lack of a narrowed intensity range is also the only deviation of the results from the hypotheses put forward in the introduction. All other hypotheses were confirmed.

One possible explanation for the inconsistencies in intensity is that the direction of intensity changes – unlike those of F0 and speaking rate – does not reflect sarcastic irony itself, but rather the arousal level on which the expression of sarcastic irony is based. That is, similar to cold and hot anger [26], there may be different degrees or subtypes of sarcastic irony (in addition to higher-level types of irony like kind and sarcastic irony, cf. [15]). It fits in with this explanation that [16] introduced on an impressionistic basis the distinction between dry and dripping sarcasm and found that their intensity patterns differed relative to neutral utterances. This attempt of [16] stresses the need for a separate line of research on the sub-structures of the irony concept, which can then complement and guide our growing phonetic understanding of irony.

As for this growing phonetic understanding, the present study showed for the first time that changes away from modal voice quality and a higher degree of segmental reduction can also be a part of sarcastic irony. It is argued here with reference to [20,21,22] that the higher reduction level is supposed to signal that the speaker distances him/herself from the wordings of the sentences; in the same way as "I'm sorry" or "good morning" are more strongly reduced when they are used (insincerely) for routine matters. Looking at Figure 4, it seems that not all ironic target sentences differed in terms of reduction from their neutral counterparts. Target sentences like 1, 7, and 12 showed about the same absolute number of reductions in the two Sentence Type conditions. However, even for these sentences it can be argued that the *relative* degree of reduction was still higher in the ironic condition, since sentences in the ironic condition were produced (consistently) longer, i.e. at a slower speaking rate. So, speakers had basically more time in the ironic sentences to reach the respective articulatory targets, but obviously made no use of this possibility. This fact, in combination with the significant effect of reduction on Sentence Type, challenge an important assumption in the modelling of speech production. It has often been claimed with reference to the H&H theory [27] that slower speech is automatically also less reduced. The present study shows there is no such automatism. The degree of reduction is not just the passive result of time, speaker economy and listener demands. Rather, reduction is also actively varied to convey different kinds of function in speech communication.

The changes in voice quality went in both directions tense voice and breathy voice. It seems that the direction of the change was determined by the sentence semantics. For example, target sentences like 1, 10, and 15 were more often realized with a tense voice, whereas the majority of sentences like 2, 4, 8, 14, and 20 typically showed a breathier voice. Thus, like for intensity, and maybe even shaping the latter, the heterogeneous voice quality findings may reflect different degrees or subtypes of (sarcastic) irony. For example, it is striking that statements in which the irony is used to point to future alternatives were tenser, whereas ironic statements pointing to the lack of alternatives were mostly breathier.

In any case, it can be concluded from the present study that sarcastic irony is a four-dimensional rather than just a three-dimensional prosodic phenomenon, which moreover extends beyond the prosodic layer into the traditionally separated segmental layer of the speech signal. Both of these new insights must be further investigated and put into a cross-linguistic perspective. It seems also worth looking for speaker-specific differences, even though the only differences found here were those between sentences, probably caused by uncontrolled degrees or subtypes of (sarcastic) irony.

Is breathing sensitive to the communication partner?

Abstract

This paper investigates breathing profiles in eleven female speakers (subjects) when talking successively with the same two females (partners). Breathing kinematics of the two interlocutors was recorded synchronously by means of two Inductance Plethysmographs. In order to understand the implication of breathing in dialogue, we analyzed changes in breathing pauses according to the main dialogue events (listening, backchannels, turns start and turns continuation). Breathing and syllable rates were also compared among partners and subjects. The duration of inhalations and related pauses was reduced before a turn continuation in comparison to a turn start. The delay between speech offset in a breathing cycle and the onset of the next inhalation increased when a speaker and a listener swap roles as compared to a speaker who continued the turn. This was observed for both partners and subjects. The partners differed in their breathing and articulation rates but the two rates were not clearly correlated. In agreement with previous works, the current study shows that breathing kinematics is strongly linked to dialogue events. However, it doesn't show any clear effect of partner on speaker's breathing. This last result is discussed relative to methodological aspects.

Index Terms: Breathing, Respiration, Spontaneous dialogue, Interpersonal adaptation, Breathing rate, Syllable rate, Inhalation pauses

1 Introduction

Breathing is actively involved in speech production as it provides the airflow required to generate speech sounds. The vital need of air is also a constraint that organizes the discourse into inhalation pauses and speech intervals. Several studies have analyzed breathing in reading tasks and to a lesser extent in spontaneous speech. These studies consistently showed that speech production is achieved by a specific control of breathing, visible in the clear reduction of the inhalation duration relative to the exhalation phase, and as compared with quiet breathing [1-3].

In text reading, the inhalation pauses consistently occur at syntactic boundaries [4]. The duration and amplitude of inhalation are mainly related to the syntactic constituents of the text (e.g. more air is inhaled before a new paragraph than before a sentence inside a paragraph) [5-7]. The properties of inhalation are also related to the length of the upcoming utterance [2, 8-10]. Similar behavior can be found in spontaneous speech, with greater inhalation before a main than an embedded clause, but more inhalation pauses occurring at non-syntactic locations as compared to read speech [11-13].

Analyses of breathing noises showed that they may play a role to indicate continuity between two related speech groups in text reading [14], and could improve the quality of synthetic speech [15]. This indicates that breathing noises are useful for speech perception. Furthermore, when listening to read speech, the listener breathing changes according to the properties of the speech signal, suggesting some influences of the speaker on the listener breathing and interaction between the control of breathing and perceptual processes [16-18].

Few studies have analyzed interpersonal influences of breathing in verbal collaborative tasks. During collaborative reading, readers coordinate their breathing. They breathe in-phase when reading synchronously, and in anti-phase when reading in alternation [19]. During choir singing, singers synchronize their breathing, especially when singing in unison [20].

In dialogue, breathing pauses have to be coordinated with interpersonal constraints and in particular with turn taking events. Despite hypotheses about the implication of breathing in conversation [21], few behavioral studies have analyzed the breathing profiles in spontaneous dialogue. Preliminary analyses of inhalation pauses in spontaneous dialogue were based on short recordings and single dyads [22-23]. They showed adaptation of breathing to dialogue constraints. A more systematic investigation of breathing in scripted and spontaneous dialogue was provided in [24]. This study found evidence for interpersonal alignment of breathing related to turn taking and laughter. Yet, no study addressed changes in breathing profiles during dialogue according to the conversational partner, nor the potential role of breathing in communication.

Several studies found interpersonal adaptations during verbal interactions. These adaptations may occur at different levels. For example, interlocutors involved in a dialogue may converge in speech rate or intensity, f0 or formants values [25-27]. The same speaker may thus behave differently when talking to two different partners. As breathing is specifically involved in speech production and verbal interaction, it could also be involved in interpersonal adaptation. We tested potential changes in speakers' breathing according to their interlocutor by analyzing breathing profiles during spontaneous dialogue. In addition, we tested how breathing pauses durations were linked to the main communicative events of the dialogues (listening, backchannels, turns continuation vs. turns start).

2 Methods

2.1. Subjects

The participants were eleven subjects (S01-S11, age: 31 years (mean) ± 7 (standard deviation), body mass index 21.3 ±1.5) and two partners (P01, age 42, BMI: 20.4, and P02 age 28, BMI: 20.8). Subjects and partners were all native female speakers of German, students or academics with a university degree. The subjects were naïve to the purpose of the study while the partners were not.

2.2. Procedure and data acquisition

Partner and subject were sitting and facing each other with a distance of ~1.5 m. They were instructed to keep their hands on their legs in order to avoid torso and arm movements that could strongly affect the recording of breathing. Subject and

partner's task was to talk with each other about a topic chosen in agreement with one another (holidays, sports, cooking, or movies). In total, each subject had five short conversations with each partner (2.5 min, for each trial), starting with P01 or P02. The topic of the conversation could change or remain the same over the five trials.

The acoustic signals were recorded using two directional microphones (Sennheiser HKH50 P48). The rib cage and the abdominal kinematics were recorded by means of two Inductance Plethysmographs (RespitraceTM). One band was positioned at the level of the axilla (rib cage) and the other band at the level of the umbilicus (abdomen). The acoustic and the breathing signals were recorded synchronously for the two speakers by means of a six channels voltage data acquisition system. All signals were sampled at 11030 Hz.

2.3. Post-processing and labeling

After the recording, the breathing data were sub-sampled at 100 Hz and pass-band filtered (1-40Hz). The onset and offset of inhalation movements were detected automatically from the sum of the rib cage and the abdomen displacements, and manually corrected when required. The breathing cycle was defined from the onset of an inhalation to the onset of the next inhalation (*I+PI* on Figure 1).

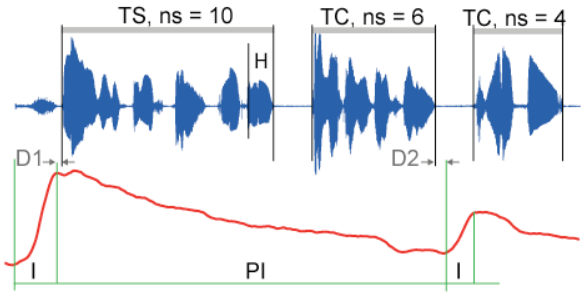

Figure 1. Top: The acoustic signal and the corresponding labeling of speech groups (*TS*: turn start, *TC*: turn continuation, *ns*: number of syllables, *H*: hesitation). Bottom: corresponding breathing kinematics and labeling of the breathing cycle (*I*: inhalation + *PI*: post inhalation). D1: *delayOnset* and D2: *delayOffset* are delays between the main breathing and speech events (see text for details).

Speech productions were labeled in Praat [28] by a trained phonetician. The boundaries of the inter-pausal units (IPUs) were detected. The vocalized hesitations (*uh, uhm mmm*,...) and the non-verbal communicative noises (laughter, mouths noises) were also delimited. Hesitations were distinguished from backchannels (*mhm*) easily as the first ones occurred during speaking and the second ones during listening phases. The spoken productions were transcribed for each IPU. On the basis of this transcription, the number of syllables was derived automatically from the output of the BALLOON toolkit [29]. The vocalized hesitations were considered as one (*uh, uhm*) or two syllables (*mmm*). IPUs were also labeled according to their main function in the dialogue as: turn start, turn continuation or backchannel (Figure 1). A turn start (*TS*) was defined when one interlocutor became the speaker and her interlocutor became the listener. This initial turn could be followed by one or several continuation (*TC*) separated by silent pauses. When the turn holder held the floor, the listener could produce short utterances like "mhm", "okay", "yes", "aha" that did not intend to take the floor, but rather signal to the speaker to continue talking. These utterances were labeled as backchannels (*BC*) [30].

2.4. Data selection and analyses

Each breathing cycle (*I+PI* on Figure 1) was characterized by its total duration (*durC*) and the duration of inhalation (*durI*). For each trial, we computed the breathing rate (as the number of labeled breathing cycles divided by the sum of the durations of these breathing cycles) and the articulation rate (total number of syllables in the speech groups divided by the sum of their durations). Vocalized hesitations were not considered in the computation of articulation rate.

The breathing cycles were classified according to their function in the conversation (*cycle_type*): listening cycle (*LI*, the subject is not speaking while her interlocutor is); backchannel cycle (the cycle included only one or more *BC* units); turn start (the cycle started with a *TS* IPU), and turn continuation (the cycle started with *TC* IPU).

The inhalation noises could be used to signal the continuation of a theme or major thematic breaks during text reading [14] : their amplitudes, durations and phasing relations with speech contribute to encode thematic structure. We investigated if similar strategies could also be found in unconstrained face-to face dialogues to signal turn start or continuation by analyzing pauses related to inhalation. For *BC, TS* and *TC* cycles, we computed the delay between inhalation offset and the onset of the first IPU (*delayOnset*) and between the end of the last speech unit and the onset of the next inhalation (*delayOffset*).

The changes in breathing and syllable rate according to the partner were tested using ANOVAs. The dataset was separated for subjects and partners, with partner as a within subject factor. This allows testing the effect of the partner on subjects' behaviors, and differences between the two partners. The results were considered as significant when $p<.01$.

The effect of partner and task (*TS*, *TC*, *BC*, *LI*) on the duration of inhalation was tested using Linear Mixed Models (lme4 & languageR packages in R version 2.14). The dataset was split between the partners and subjects' data. The subjects and dialogue trials were taken as random factors. The inhalation duration was log-transformed to obtain normally distributed residuals. The results were considered significant with $p<.01$. Additionally we run lmer for the *delayOnset* and *delayOffset*, but the residuals were nonlinear, even when transformed. We will therefore only provide descriptive statistics.

3 Results

3.1. Global description of the dialogue

We first characterized the dialogue at a global level. On average, speech intervals represented 37% of the total duration for P01, 40% for P2, 39% for subjects talking with P01 and 43% for subjects talking with P02. The effect of partner on the duration of subjects' speech failed to reach significance ($F(1, 10)=3.9$, $p=.08$), due to variability in subjects' behaviors. For example, some subjects were talking more than the partners while the reverse was observed for other subjects.

3.2. Relationships between breathing and syllable rates

The breathing and syllable rates were globally smaller for P01 as compared with P02 ($F(1, 10)=18.4$, $p<.01$ and $F(1, 10)=67$, $p<.0001$), see Figure 2. By contrast, subjects' breathing and syllable rates were not different when either talking with P01 or P02. Positive correlations were observed between the average syllable and breathing rates for subjects ($r=.61$ when talking with P01, .43 when talking with P02) and for partners ($r\sim.3$

for P01 and P02). For subjects, the correlation was significant only when talking with P01 ($p<.05$).

No clear correlation was observed between subjects and partners' breathing and syllable rates (Figure 3).

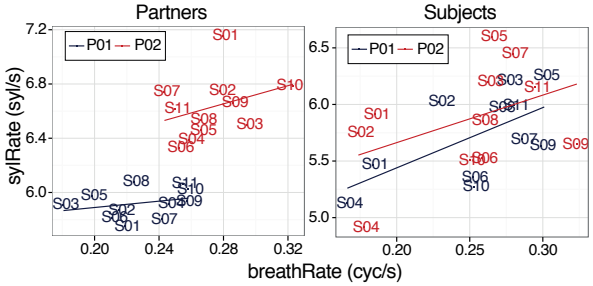

Figure 2. Average syllable rate according to average breathing rate for partners (left) and subjects (right).

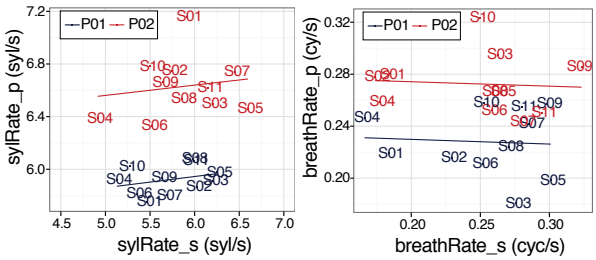

Figure 3. Partner's vs. subject's parameters, left: average syllable rate, right: average breathing rate

3.3. Duration of inhalation

Globally, inhalations were shorter for P02 than P01 (here we used lmer since our dataset was unbalanced, t=-7.3, pMCMC=.0001), while subjects did not show significant changes in *durI* according to the partner (t=-2.3). Inhalations were significantly shorter before turn continuations than before turn starts, backchannels and listening cycles (all $|t|>2.7$, pMCMC<.004). This was observed for both partners and subjects (Figure 4). The difference between *BC* and *LI* was significant for partners (t=2.7, pMCMC=.004) but not subjects (t=2.3).

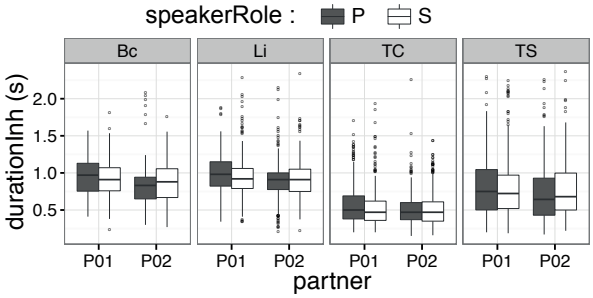

Figure 4. Duration of inhalation (*durI*) according to the function of the first speech group on the breathing cycle (*BC*, *TC*, *TS*) and for listening cycle (*LI*), for dyad involving P01 and P02 and for partners (*P*) and subjects (*S*).

3.4. Delay between inhalation offset and speech onset

The duration of pauses between inhalation offset and speech onset (*delayOnset*) were shorter for turn continuations than turn starts and backchannel cycles (see Figure). P02 may also initiate backchannels earlier on the breathing cycle as compared with P01.

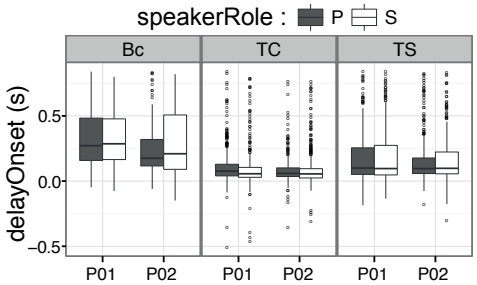

Figure 5. Delay between the offset of inhalation and the beginning of speech according to the dialogue event (*BC, TC, TS*) for the dyads involving P01 and P02 and for the partners (*P*) and the subjects (*S*).

3.5. Delay between speech offset and next inhalation

When speakers talked and then inhaled again, the delay between speech offset and the inhalation onset was shorter when the speaker continued the turn than when she started a new turn. This was observed for both subjects and partners (Figure). *delayOffset* was generally longer when the speaker switched her role and became the listener. This was particularly the case for P02 as compared with P01, while no clear change in subjects' behaviors was observed according to the partner.

The distribution of *delayOffset* is given in Figure 7 when the next breath group started with a turn continuation, a turn start (black and gray bars) or a turn start only (blue bars). The duration of *delayOffset* was in most of the cases shorter than 200 ms. The probability of the next speech group to be a turn start increased with the increase of the duration of *delayOffset*. This was particularly evident for the two partners. Additionally, P02 produced longer *delayOffset* than P01. The distribution was comparable between P01 and subjects who talked to her, but an asymmetry was observed between P02 and subjects talking to her, with a larger number of observations with shorter *delayOffset* for subjects than for P02.

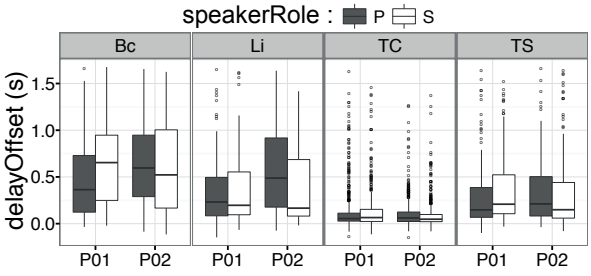

Figure 6. Delay between the offset of the last speech group on the breathing cycle and the onset of the next inhalation according to the dialogue event (*BC, LI, TC, TS*) for the dyads involving P01 and P02 and for the partners (*P*) and the subjects (*S*).

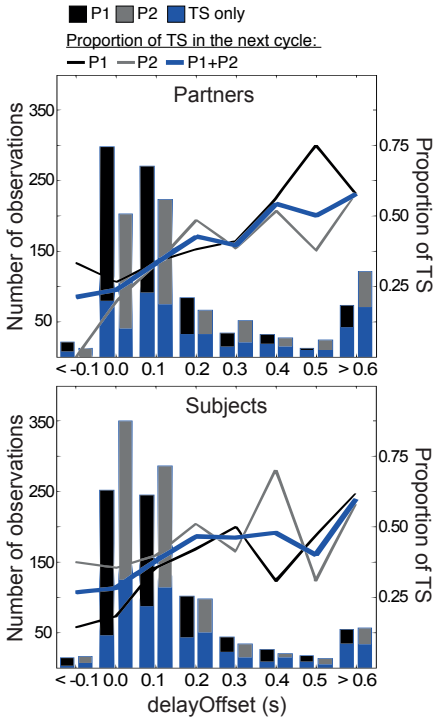

Figure 7 Distribution of the breathing cycles according to the delay between speech offset on the breathing cycle and the onset of the next inhalation. The results are given for the partners (*top*) and the subjects (bottom). The superimposed curves represent the proportion of turn start (*TS*) in the next breathing cycle (*TS*/(*TS*+*TC*)) for each lag.

4 Discussion and conclusion

The aim of the current study was to investigate changes in breathing profiles with respect to the conversation partner during spontaneous dialogue. We observed differences in the two partners' behaviors. P02 was breathing and speaking faster than P01. If breathing would determine dialogue rhythms [21] and if interlocutors were systematically adapting their physiological rhythms to each other through the verbal exchange (as observed before in more controlled tasks [19-20]), we could expect an increase in subjects' syllable and breathing rates when talking with P02 as compared to P01. This was yet not the case: the current analyses of breathing and syllable rate did not provide clear evidence of subjects' adaptation to partners' behaviors. This could be explained by the fact that the recordings were relatively short (2.5 mins * 5 recordings for each dyad) and that longer and continuous interpersonal interactions may be required to generate adaptations in physiological rhythms. Moreover, familiarity with the interlocutor may play a role in conversations. For example, romantic partners or members of a same family may display stronger adaptation of physiological rhythms [31] than persons who did not know each other very well as in the current study.

Our experimental paradigm involved two non-naïve partners. This choice allows testing the same partners for all subjects, similarly as in our previous work on breathing adaptation during listening [18]. However, for dialogue, this choice introduced an asymmetry in the interlocutors' roles: partners were aware they should maintain the dialogue, ending in conversations globally balanced between subjects and partners. Some variability was yet observed according to the subject: some subjects were talking more than the partners, some others less, with some interaction between subjects and partners. This suggests that the partners were not fully controlling the dialogue and that a better understanding of interpersonal adaptation of breathing may require a better description of socio-cultural and human factors [32]. It is also possible that partners were adapting more to the subjects than the reverse, as they were non-naïve, which could have preserved the subjects' rhythms.

The main difference in subjects' behaviors according to the partner was observed in the delay between speech offset and the onset of the next inhalation. Even if the effect was not statistically tested, it seems that subjects reduced this delay when talking with P02 as compared with P01. By contrast this delay was longer when talking with P02. Detailed analyses of turn types in the current dataset [33] showed that P02 was interrupted more often than P01, which could explain the longer delay at the end of the breathing cycle. The reverse could also be true: P02 could be interrupted more often due to longer pauses before inhalation. Despite the variability in subjects and partners' behaviors, and complex profiles due to inter-individual interactions, inhalation pauses during dialogue also showed strong and consistent patterns related to the dialogue events. The duration of inhalation was shorter when inhalation occurred inside a turn than before the start of a new turn. This "compression" of the breathing gap was also observed in the delay before the inhalation onset and after the inhalation offset. It suggests that partners and subjects avoid gaps inside turn by strongly reducing inhalation. This cue could signal to their interlocutor that they want to keep the floor. Such a strategy may limit the chance of the interlocutor to take the turn. It may also have physiological consequences such as hyper- or hypo-ventilation [3].

As readers used their breathing to indicate thematic changes or continuations [14], interlocutors of a dialogue may control the characteristics of their breathing noises – timing, amplitude and duration – to take or maintain their turn. Because the position of the microphone relative to the speakers' mouth was not precisely controlled in the current study, breathing noises could not be reliably analyzed. Faster inhalation may yet be related with louder noises, indicating to the interlocutor that the speaker wanted to keep or take the turn. By contrast, one could expect silent inhalations during listening, as inhalation noises produced by the listener may interfere with the perception of her interlocutor's speech.

Breathing during dialogue is a complex stream that alternates between different control levels of breathing, partially explained by the switching between speaking and listening [24]. Previous work found a tendency of interlocutors to breathe in-phase or in anti-phase at turn taking [24]. A similar analysis of interpersonal coordination in breathing has been carried out using the current dataset. Results showed no clear coordination of breathing profiles at a global level, but specific coordination patterns according to the type of turn [33]. Together with the current analyses, this seems to confirm the idea that during dialogue, breathing is strongly shaped by the communicative constraints [23]. However more studies are now required to understand the participation of breathing to these communicative constraints, the relationship between breathing changes and mutual accommodation in general [34] and the consequences of dialogue constraints on ventilation.

Abstract

Co-occurrence restrictions on tones and consonants in Yuhuan Wu Chinese syllables provide a powerful illustration of the phonetic basis of phonological contrasts, with sonorant contexts allowing more tone contrasts than other contexts. Interestingly, the language also reveals that the phonetic implementation of tones depends on the phonological contrast it is involved in. Such phonetic enhancement may be the opposite of what could be expected on the basis of speech ergonomics. Moreover, the language has a tone deletion rule that exempt tones in the context with the largest number of contrasts, showing a phonological version of enhancement.

Index Terms: tone, enhancement, Wu

1. Introduction

The relation between phonetics and phonology is bidirectional. On the one hand, phonetic considerations determine the structure of phonological systems, because the interacting ergonomics of speech production and speech perception will be reflected in them (e.g. [1],[2],[3]). We will refer to this connection as the ergonomic relation between phonetics and phonology. On the other hand, the articulatory implementation of phonological forms will reflect the phonological contrasts in them [4]. Speech production is biased towards enhancing specific contrasts and the articulation of the same feature will therefore vary across languages as a function of the contrasts it is involved in ('phonetic knowledge' [5]). In turn, phonetic measures to protect contrasts may be incorporated in the language's phonological systems, either as 'transphonologizations', whereby an enhancement feature takes over the contrastive role of a phonological feature, or distributionally, whereby exceptions arise in otherwise general rules [6]. These situations will be referred to as enhancement, where the phonetic behavior has not been incorporated in the phonological structure, and phonologized enhancement [7], when it has, whether as a transphonologized contrast or as a distributional restriction.

2. Segments, syllables and tones

We present the case of the lexical tones of Yuhuan Wu Chinese as one that particularly clearly illustrates these relations. The variety is spoken in Yuhuan County in the southeast of Zhejiang Province and has some 300,000 speakers. Like other Wu Chinese dialects, notably Shanghainese, Yuhuan Wu has a number of co-occurrence restrictions on consonants and tones in the same syllable.

2.1. Segmental structure

The language's consonant system is given in Table I.

Table I. Contrastive consonants of Yuhuan Wu Chinese

	labial	coronal	velar	glottal
plosive	b p p^h	d t t^h	g k k^h	ʔ
affricate		dz ts ts^h		
nasal	m	n	ŋ	
fricative	f v	s z	x	ɦ
lateral		l		

Onsets and codas are optional. All consonants can occur as onsets, except /ʔ/. Only /ʔ/and /ŋ/ can occur in the coda. The vowels that occur in open syllables are given in Table II. In addition, syllabic /z̩/ occurs after onset /s, z/, while syllabic /ŋ/ occurs more generally.

Table II. Contrastive vowels of Yuhuan Wu Chinese in open syllables

	Front unround	Front unround	Back unround	Back round
high	i	y		u
mid	ɛ	ø		o
diphthong	ei			əu
low			ɑ ɑ̃	ɔ ɔ̃

Additionally, the vowel /ə/ appears in closed syllables. Rimes ending in /ʔ/ have /i, ɛ, ø ,o/ or /ə/, while rimes ending in /ŋ/ have /i, o/ or /ə/. Discounting the onset consonant, some rimes may begin with [j, w], which we interpret as prevocalic /i, u/. Prevocalic /i/ appears before /u, ɛ, ø, ɔ, ɑ, ɑ̃/ and /oŋ/, while prevocalic /u/ appears before /ɛ, ei, ɔ̃, ɑ, ɑ̃, əŋ/ and /oʔ/. The syllable structure is thus (C)(G)V(C), where G stands for the prevocalic glide. The labiovelar prevocalic glide appears only after velars and the glottal /ɦ/ as well as syllable-initially; the palatal prevocalic glide appears syllable-initially and after all onset consonants except /f, v, x, ŋ/.

2.2. Tones and consonants

The first distinction to be drawn is that between sonorant rimes, those containing just a vowel or a vowel-plus-/ŋ/, with or without prevocalic glide, and glottal rimes, those ending in /ʔ/, again with or without prevocalic glide. The number of tone contrasts in sonorant rimes is five, H, L, HL, ML, LH. However, the presence of a glottal coda restricts that number to two, H and L, notated as Hq and Lq to indicate their occurrence in glottal rimes. This is shown in Table III. The explanation for this restriction is the short duration of the voiced portion of glottal rimes [7]. The reason for the reduced number of contrasts is the short duration of the sonorant portions of glottal rimes. Over five randomly chosen words with H-tone in each category, sonorant portions of glottal

rimes average 122 ms, against 438 ms for sonorant rimes. This is evidently a connection between phonetics and phonology of the first kind.

Table III. Tone contrasts in sonorant and glottal rimes

li	H	*plum*
li	HL	*surname*
li	L	*plough*
li	LH	*pear*
li	ML	*separate*
loʔ	Hq	*sway*
loʔ	Lq	*fall down*

Sonorant consonants have a constriction in the vocal tract that allows the air pressure levels on either side to be relatively equal [8]. Despite the higher air pressure behind the constriction, the relatively open constriction prevents a build-up of air pressure, and the interference by these consonants with the process of vocal fold vibration as occurring during vowels is therefore small or absent. Voiced obstruents, by contrast, have a constriction behind which the air pressure builds up, and any voicing during the constriction will be made difficult, because of the impedance the constriction offers to the air flow and the resulting reduction in the pressure difference below and above the glottis. As a result, the rate of vocal fold vibration during and after voiced obstruents is reduced. During voiceless obstruents, the vocal folds are abducted to prevent voicing. When voicing sets in after them, the tenser vocal folds will tend to vibrate faster than after the voiced sonorants; for references see [9, p. 8]. These considerations explain two features of the Yuhuan tone system. First, after obstruent onsets the number of tone contrasts is smaller than after sonorant onsets. Second, the tones that appear after voiced obstruents form a lower selection than those that appear after voiceless obstruents. This is shown in Table IV, which should be compared with Table III. Again, we are dealing with a connection between phonetics and phonology of the first kind.

Table IV. Tone contrasts after obstruent onsets

pʰi	H	*fart*
pʰi	HL	*drape over shoulder*
pʰi	LH	*semi-finished product*
pɔ	H	*leopard*
pɔ	HL	*precious things*
pɔ	LH	*bag*
bɔ	ML	*hug*
bɔ	L	*carpenter's plane*
bɔ	LH	*robe*

This restricted distribution not only applies to plosives and affricates, with their three-way laryngeal contrast, but also to fricatives, which have a two-way laryngeal contrast. As predicted, in glottal rimes, voiceless onsets can only be followed by H, while voiced obstruents can only be followed by L.

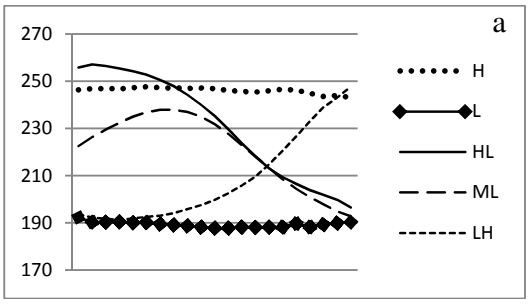
An apparent deviation from the distribution shown in Tables II and IV concerns syllables that begin with phonetic [w] and [j], after which six tones appear. Closer inspection of the beginnings of these syllables, however, indicates that such syllables with H and HL are onsetless, while those with L and ML begin with /ɦ/. The two rises, which differ in pitch range, are to be analyzed as LH occurring after onsetless syllables and syllables beginning with /ɦ/. In the onsetless syllables, a weakly released glottal closure often occurs, which never occurs in the syllables beginning with /ɦ/. Moreover, weak breathy voice may attend syllables beginning with /ɦ/. Strikingly, however, neither of these features appears to be obligatory. Table V presents the contrasts in sonorant rimes after onsetless syllables and syllables beginning with /ɦ/ which contain a prevocalic glide. Two tones appear in glottal rimes, H after onsetless syllables and L after /ɦ/-initial ones.

Table VI. Tone contrasts in onsetless and /ɦ/-initial rimes

uei	H	*fed up*
uei	HL	*bowl*
uei	LH	*hello*
ɦuei	L	*meeting*
ɦuei	ML	*refuse*
ɦuei	LH	*(proper name)*

The distribution in Table VI shows that the prevocalic glide is not an onset. If it were, it would have to be classed as a sonorant consonant. That is, there would have been five tones after a phonetic [w] or [j], not six. As it is, onsetless syllables pattern with voiceless obstruents, while /ɦ/-initial rimes pattern with voiced obstruents. Phonetically, this makes sense, since a glottal closure involves vocal fold tensing. Phonologically, there is a problem with the characterization of voiceless obstruents and zero as a natural class. Analyzing empty onsets as containing /ʔ/ would not work, since the glottal stop is not [-voice], nor are voiceless obstruents [+constricted glottis].

We recorded isolated syllables with all five tones and onset and coda conditions as illustrated in Tables III and IV from three speakers. Average time-normalized f0 tracks for one speaker are given in Fig. 1, pooled over onset conditions, for sonorant rimes (panel a) and glottal rimes (panel b). The pitch range is approximately 60 Hz, small for a female speaker; the values for H and L are fairly constant across tones; ML differs from HL in having a lower starting point.



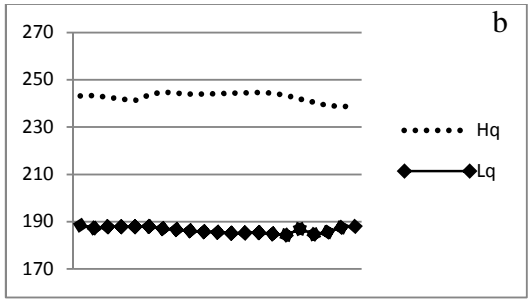


Figure 1: *F0 tracks on normalized times scales for H, L (n=24), HL (n=56), ML, HL (n=36) (panel a) and Hq (n=20) and Lq (n=16) (panel b). Speaker WL.*

3. Phonologized enhancement

Varieties of Wu have prosodic words, aka tone units, whose tonal pattern tends to be determined by the leftmost or rightmost syllable. On the basis of an investigation of disyllabic prosodic words, we find that Yuhuan preserves the tone on the rightmost syllable, and as such provides the mirror image of Shanghainese [10, 11]. That is, tones on non-final syllables are deleted. This is illustrated in Fig. 2, which shows the five (seven) tones before final LH. Thus, the final tone(s) don't spread left; rather, the preceding syllable is pronounced at mid or low pitch, a default pitch for what we take to be toneless syllables. Middish pitch appears in the case of H and LH (approx. 193 Hz), low pitch in the case of underlying L, ML, Hq and Lq (approx. 178 Hz). Differences of that magnitude are found in many cases of phonological identity in the data, and we cannot at this point say if the difference between the two groups of tones is systematic.

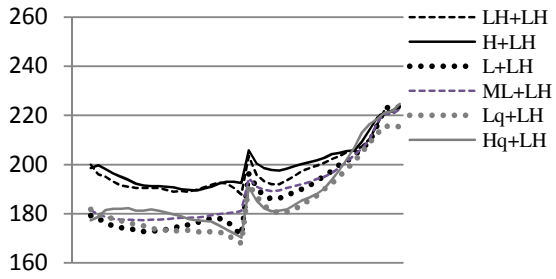

Figure 2. *F0 tracks on normalized times scales for LH, H, L, ML before final LH. Speaker WL.*

There is, however, a striking exception to this tone deletion rule. HL in syllables with a sonorant onset consonant does not delete. This non-final tone deletion rule is given in (1). Fig. 3 presents the fate of HL before LH and L.

(1) Pre-final tones are deleted, except HL in a syllable with a sonorant onset.

There are two questions that this exception raises. One is why HL is preserved after sonorant rather than obstruent onsets. The answer lies in the number of contrasts that are neutralized by the deletion. After obstruents, the reduction is from three forms to one, a loss of two; after sonorants, it is from five forms to two, a loss of three. A loss of four would place a greater strain on the system, which is apparently enough for it to be prevented. The other question is why it is HL rather than one of the other four tones that is preserved. One possible answer is that it provides the clearest phonetic contrast with mid or low pitch, another that it is the most frequent tone in this kind of syllable. In a corpus of 80 random syllables, the highest number is for L (23), followed by ML (20), HL (16), LH (10) and H (9). This suggests that only the first answer is correct. Relative to mid pitch, neither H nor L are very distinct, while because of their smaller pitch range, both ML and LH are closer to mid pitch than is HL. We show HL preservation in syllables with sonorant onsets before LH and L in Fig. 3.

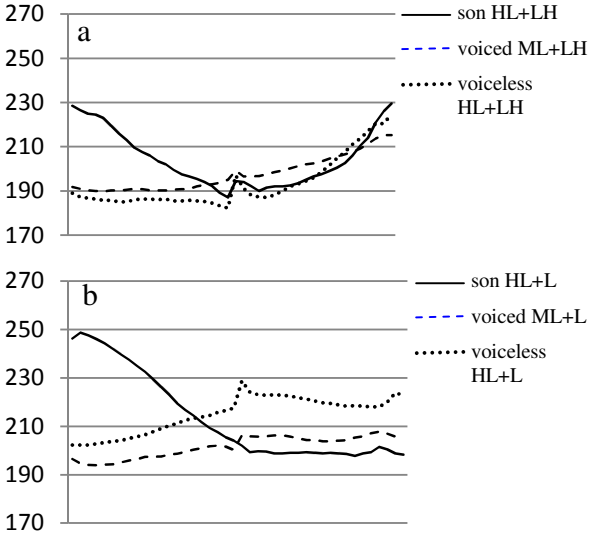

Figure 3: *F0 tracks on normalized times scales for HL before final LH (panel a) and L (panel b) broken down by the phonological specification of the onset (sonorant, voiceless obstruent and voiced obstruent). Speaker WL.*

Summarizing, because onset sonorants have no appreciable physiological effect on the f0 of the rime, Yuhuan Wu has more tone contrasts after sonorant onsets than after obstruent onsets. This distribution presupposes an analysis of initial glides as pre-nuclear glides in the rime, as opposed to onset glides. The observation illustrates the effect of phonetic ergonomics on phonological structure. Second, because there is a larger number of tones after sonorant onsets, an otherwise general tone deletion rules exempts HL from deletion if it occurs in rimes preceded by a sonorant onset. The exception illustrates that phonetic implementation will respect and preserve phonological contrasts, which tendency may in turn lead to distributional restrictions.

4. Phonetic enhancement

Phonetic enhancement can be observed in the way ML is pronounced in syllables with sonorant onsets as compared with voiced obstruents. If things were left to the phonetic implementation without regard for the place of the phonological representation in the system of contrasts, sonorant onsets would have no effect on the f0 of the initial part of the rime, while after voiced obstruents, the f0 of the first part of the rime would be depressed somewhat due to the impedance of offered by the constriction. After voiceless obstruents, the initial f0 after HL would be elevated relative to the situation for HL after sonorant onsets. In reality, the elevation after voiceless obstruents is negligible. Panel (a) of Fig 4 shows that there is no difference in the pronunciation of HL in the two onset conditions. This suggests that the tendency for raised f0 after voiced obstruents is counteracted

by a similar raising of the pitch after sonorants. Since it is only after sonorant onsets that the contrast between HL and ML exists, a comparison for ML should reveal the policy behind the lack of a perturbation effect in panel (a). Panel (b) in fact shows that the initial pitch after sonorant onsets in considerably *lower* than after voiced obstruents, against expectation, if expectation is based on speech ergonomics. By contrast, if we take into consideration that speech behavior is guided by contrast enhancement as well as speech ergonomics, the pattern in panel (b) can be understood as a manifestation of 'phonetic knowledge' [5].

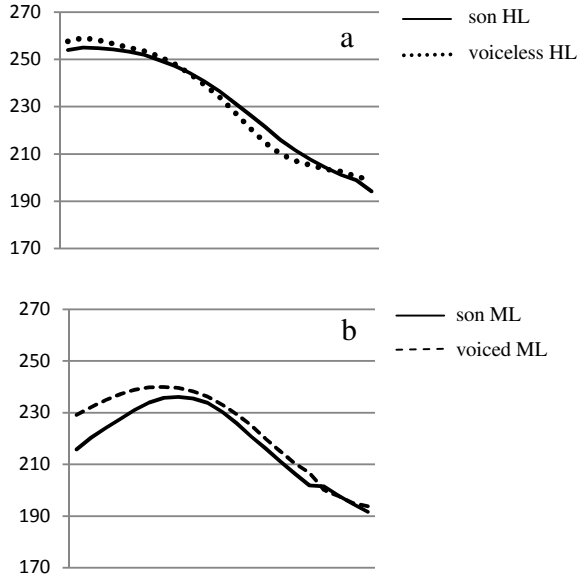

Figure 4: *F0 tracks on normalized times scales for HL with sonorant and voiceless obstruent onset (panel a) and ML with sonorant and voiced obstruent onset (panel b). Speaker WL.*

5. Discussion

Yuhuan Wu appears to be a textbook case for the illustration of the complex relation between phonetics and phonology. On the one hand, phonological systems reflect the opportunities afforded by the speech production and perception systems for creating phonological contrasts, the speech ergonomic connection [1, 2, 3]. In particular, patterns of f0 perturbation by onset consonants explain why there are five tone contrasts after sonorant onsets and three after onsetless or obstruent onsets. Similarly, the large difference in duration between sonorant and glottal rimes explains why glottal rimes have two tone contrasts and sonorant rimes five [7]. On the other hand, contrast enhancement is illustrated by the exceptional retention of HL in pre-final position just in the situation that the onset is sonorant, whereas H, L, ML and LH are deleted in all onset conditions. This suggests that exhaustive deletion of the five-way tone contrast would have jeopardized the maintenance of a comfortable level of lexical distinctions.

Finally, the rationale behind the distributional pattern arising from post-sonorant tone retention is suggested by the phonetic enhancement of the ML tone after sonorant onsets. It consists of a lowering of the initial part of the pitch contour which is more extreme that the physiologically induced lowering due to onsets consisting of voiced obstruents. This shows the enhancement of the contrast between HL and ML in the only context in which it exists, in sonorant rimes after sonorant onsets.

Phonetic enhancement, therefore, may lead to new phonological contrasts ('transphonologization'), but may also lead to restrictions in the distribution of phonological features. Having said that, we cannot be certain about the developmental path that led to the exceptional retention of HL in prefinal sonorant-initial syllables [12]. The deletion may have started gradually, with the retained tones lagging behind as motivated by contrast preservation, which pattern ultimately became phonologized. Alternatively, the deletion may have involved one tone first, which rule then expanded its focus tone by tone, stopping short at HL.

6. Conclusions

The tone grammar of Yuhuan Wu reveals a bidirectional relation between phonetics and phonology. While it has five lexical tones after sonorant onsets in sonorant rimes, lower numbers of tone contrasts appear after obstruent onsets and in glottal rimes. This pattern, variants of which can be found in many languages, in particular Wu dialects of Chinese, is explained by speech ergonomics (f0 perturbation and rime duration). The opposite direction in the relation between phonetics and phonology is shown by a tone deletion rule. Pre-final tone deletion preserves HL if it occurs in a syllable with a sonorant onset. This exception is explained by phonological contrast preservation. Third, the language shows that the contrast between HL and ML, which only appears in sonorant rimes with sonorant onsets, is enhanced, such that the beginning pitch of ML is lower than after voiced obstruents, quite against ergonomic phonetic considerations. After voiced onsets, ML does not contrast with HL, so that less differentiation between the tone sis called for here than om syllables with sonorant onsets.

Abstract

This paper investigates how prosodic elements such as prominences and prosodic boundaries in Hindi are perceived. We approach this using data from three sources: (i) native speakers of Hindi without any linguistic expertise (ii) a linguistically trained expert in Hindi prosody and finally, (iii) classifiers trained on English for automatic prominence and boundary detection. We use speech from a corpus of Hindi narrative speech for our experiments. Our results indicate that non-expert transcribers do not have a consistent notion of prosodic prominences. However, they show considerable agreement regarding the placement of prosodic boundaries. Also, relative to the non-expert transcribers, there is higher agreement between the expert transcriber and the automatically derived labels for prominence (and prosodic boundaries); this suggests the possibility of using classifiers for the automatic prediction of these prosodic events in Hindi.

Index Terms: Hindi prosody, perception study, automatic labeling of prosodic events in Hindi.

1. Introduction

Hindi is one of the most widely spoken Indo-European languages in the world with over 200 million native speakers in northern parts of India. There have been a sizeable number of studies on intonation in Hindi. Many early works studied the phenomenon of lexical stress in Hindi words which manifests itself as prominence via a designated syllable [1, 2, 3, 4] and acoustic evidence for lexical stress in Hindi [1, 2, 4, 5]. There are two consistent observations regarding prosody in Hindi across previous work (refer to [1, 3, 6, 7] among others): 1) every content word (i.e. a prosodic word), except for the phrase-final one, is associated with a rising pitch contour and 2) focus induces post-focal pitch range compression.

Prior work confirms the presence of pitch accents on content words with a rising pitch contour. However, there are varying opinions regarding the reason these pitch contours are triggered [8, 9, 10]. Most recently, Féry and colleagues [6, 9, 11] claim that Hindi does not have prominence-lending pitch accents and uses only prosodic phrasing to structure an utterance, with edge-marking phrase tones. As evidence for this claim, they note that Hindi speakers do not produce a consistent pattern of pitch movement on a stressed syllable, and in general have very weak intuitions about the location of stress prominence at the word level.

A question of particular interest to us, and one of the objectives of this paper, is to investigate whether ordinary untrained native listeners of Hindi consistently perceive prosodic elements in Hindi speech (specifically, prosodic prominence and prosodic phrase boundaries). This technique of involving ordinary listeners to derive prosodic transcriptions (the latter will henceforth be referred to as *non-expert transcriptions*) was successfully implemented by Cole et al. [12] for English. This is categorically different from most of the previous work on Hindi prosody; the latter is predominantly based on production studies where trained experts analyzed sentences spoken by native Hindi speakers for evidence of various prosodic elements. To our knowledge, there has not been a systematic enquiry into ordinary listeners' perception of prosody in Hindi speech. We use a corpus of Hindi narrative speech to conduct our perception study, described in more detail in Section 2.

This paper also attempts to initiate the discussion about whether we can automatically detect prosodic elements such as pitch accents and prosodic boundaries in Hindi speech. There is a large body of research that studies the identification and classification of prosodic events in English ([13, 14, 15, 16, 17] are a sampling of some of the important works in automatic labeling of English prosody). Automatic prosody labeling is a relatively unexplored area for Hindi. Many of these studies make heavy use of the ToBI Standard [18] – a formalized notation developed to describe the intonation of Standard American English. Recently, a publicly available toolkit called AuToBI [19] has been developed to automatically detect and classify prosodic events (using ToBI labels) in English. As a first step, we use models of prosody trained on English obtained via AuToBI to automatically label prosodic pitch accents and phrase boundaries in Hindi speech. We hope this investigation informs us of what would be needed to build improved models of Hindi prosody. This could also prove to be useful for the design of automatic speech recognition systems in Hindi.

To summarize, the objectives of this paper are two-fold:

1. *Perception of prosody in Hindi by ordinary listeners*: What is the untrained, ordinary listener's perception of prosodic prominence and phrase boundaries in Hindi? How does this compare to the prosodic transcription by a linguistically trained expert Hindi listener? Do native listeners consistently identify pitch accents in Hindi speech? What about phrase boundaries? These are some of the questions we try to address; the experiments are detailed in Section 3.

2. *Automatic labeling of prosody in Hindi*: How do trained models of prosody in English perform when evaluated on Hindi data? Is the automatic labeling of prosodic events more consistent with the non-expert transcriptions or the expert transcription? What can be deduced from the Hindi evaluation task to build better prosody models for Hindi? These questions are discussed further in Section 4.

We conclude this paper with a closing discussion along with scope for future work in Section 5.

Figure 1: A screenshot of the user interface for the study. Prosodically prominent words turn red on being selected.

2. Speech materials

The speech material used in our experiments was drawn from the "OGI Multi-language Telephone Speech Corpus" [20]. This corpus consists of telephone speech in eleven languages, including Hindi; the corpus has recorded speech from 198 Hindi speakers. The Hindi speech was collected in narrative form by asking volunteers to talk about any topic for up to a minute. Sixty-eight of these one-minute audio clips have corresponding hand-labeled phonetic transcriptions.

Out of the sixty-eight audio clips with phonetic transcripts, we selected ten and extracted excerpts, one from each clip, averaging 24.10 secs in length and averaging 59.2 in the number of words per excerpt; there are a total of 592 words over all excerpts. Since the speech in the OGI corpus was collected from volunteers speaking impromptu, it contains many occurrences of conversational elements such as disfluencies, hesitations and repetitions. Our ten excerpts were chosen such that the utterances in each excerpt were relatively free of disfluencies and the usage of English words were kept to a minimum.[1]

3. Perception of prosody in Hindi by non-expert transcribers

3.1. Method and Experimental Setup

Ten adult native speakers of Hindi participated in this study.[2] All the participants were English-speaking students living in the United States. Most of them could speak and write only Hindi and English (and not other languages); three of them could additionally understand other Indian languages such as Kannada, Oriya and Bhojpuri. Information about their language background was retrieved via a questionnaire administered along with the main study.

The entire study was conducted with the help of a web-based software [21]. The interface of the experiment and the instructions for the prosody transcription tasks were worded in Hindi. This was done in order to, hopefully, make the participants more receptive to prosodic elements in the Hindi excerpts.

The non-expert transcribers were shown the ten excerpts described in Section 2 in a randomized order. For each audio file, a participant was asked to complete two tasks – firstly, listen to how the speaker breaks up the text into chunks and mark the location of chunk boundaries (*prosodic phrase boundaries*) and secondly, mark the words that are emphasized or stand out relative to the other words in the utterance (*prosodic prominence*). The participants were explicitly informed that the phrase chunks do not necessarily have to coincide with any punctuation. In order to get acquainted with the two tasks, the experiment was preceded by a training session using one speech excerpt.

On identifying a chunk, the participant was asked to select the final word in the chunk and a "/" delimiter was inserted after the word to mark the phrase boundary. For the second task of identifying emphasized words, the participants' boundary markers from the previous task were kept visible for them to refer to. Figure 1 shows a snapshot of the interface for an excerpt during the prominence marking task. There was no limitation on the response times. The entire experiment was set up such that it would not exceed an hour. However, the participants could listen to each excerpt any number of times and they could choose to devote any amount of time to each excerpt.

As a second set of experiments, this entire run of two tasks per excerpt for all ten excerpts was repeated – only this time the transcripts were displayed without any accompanying audio clip. Each participant was asked to 'listen' to their own inner speech while reading the excerpt text and mark the word chunks and emphasized words. By removing the associated speech clips, the participants would have to rely entirely on lexico-syntactic cues to guide their annotation.

Finally, we also asked an expert in Hindi prosody to transcribe the same data using ToBI.[3] The expert transcriber was provided the audio signals, along with pitch and intensity tracks and phonetic and word alignments (the annotations were done using the Praat [22] toolkit). We note here that the conditions under which the expert interprets prosody is positively different from the conditions for ordinary listeners. Our experimental results also point to this difference, as detailed in Section 3.2.

3.2. Experimental results and discussion

We first compute Cohen's kappa agreement coefficients [23] between the ordinary listeners' and the expert's transcriptions of prominences and boundaries. This is a fairly standard measure of agreement that takes into account the chance probability of agreement. Values of 0.01 to 0.2 indicate slight agreement, 0.21 to 0.4 is fair agreement and 0.41 to 0.6 indicates moderate agreement. Fig. 2 shows the distribution of agreement coefficients across all the participants for both prominence and boundary labels. This shows that ordinary listeners perceive boundaries (with a moderate $\kappa = 0.41$) much more similarly to the expert than prominences (with a slight $\kappa = 0.15$). The slight agreement for prominence marking in Hindi has a parallel in English. In English, prominences that are more closely tied to meaning (e.g., the nuclear prominence that marks focus) are more reliably marked by transcribers than pre-nuclear prominences, which may serve a rhythmic function ([24, 25]).

We also compute Fleiss' kappa statistics (typically used to compute agreement across multiple transcribers) across all listeners (ignoring the expert transcriptions). Fig. 3 shows Fleiss' coefficients for both prominences and boundaries; *With audio* and *Without audio* specify non-expert transcriptions obtained

[1] Most of the volunteers who helped collect Hindi data for the OGI multi-language corpus were graduate students in the United States and often made use of English words while speaking impromptu in Hindi.

[2] One participant listed "Marwari" as their native tongue but identifies themselves as a native Hindi speaker.

[3] The last author served as our expert. She is a native speaker of Hindi and a simultaneous English-Hindi bilingual (much like the non-expert transcribers).

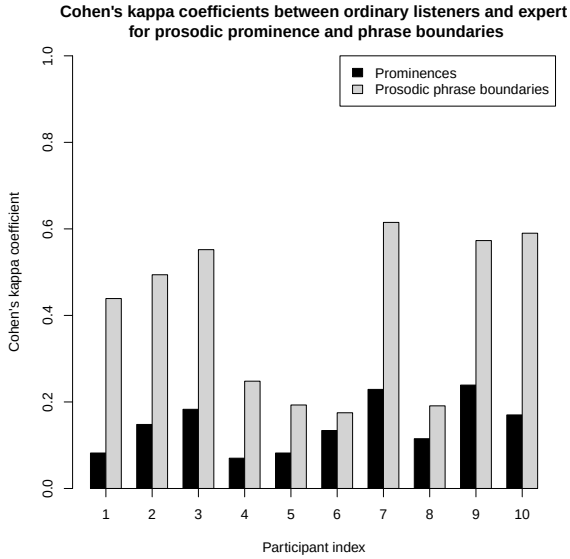

Figure 2: Cohen's kappa agreement coefficients for each participant against the expert for prominences and boundaries.

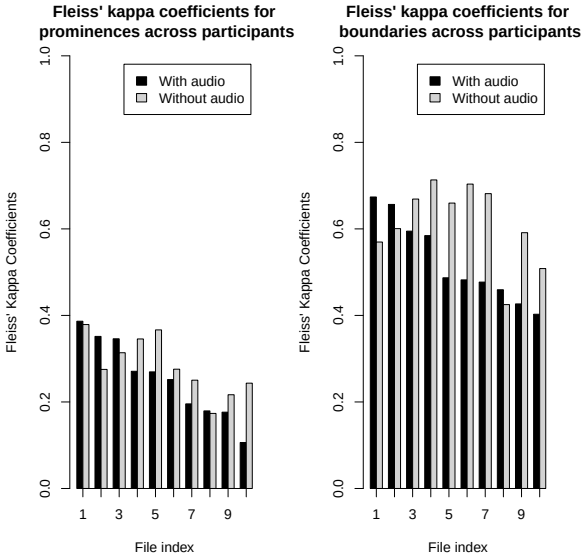

Figure 3: Fleiss' agreement statistics for prosodic prominences and boundaries across all the participants.

with audio and without audio, respectively.[4] We focus first on the non-expert transcriptions with audio. We observe that the non-expert transcribers agree on the location of boundaries well above chance (mean $\kappa = 0.524$) and agree with one another more than they agree with the expert ($\kappa = 0.407$). There is only a fair amount of agreement on prominences ($\kappa = 0.253$)). This partially supports Féry's [9] prediction that Hindi speakers will reliably and consistently perceive prosodic phrases in Hindi utterances and will not reliably perceive prosodic prominence as distinct from phrasing in Hindi utterances.

Comparing the non-expert transcriptions with and without audio, the mean κ values for both prominences and boundaries are comparable (0.25 vs. 0.28 and 0.52 vs. 0.61, respectively). The distributions of non-expert transcriptions with and without audio in Fig. 3, however, suggest that the transcribers may not be getting cues from the same information structure.

Finally, we compute the rate of occurrence of prominences and boundaries. The mean length of intervals (in words) between prominences range from 5.4 – 11.4 for each audio clip, across all transcribers. This indicates the speaker dependent variation of the rate of prominences. Similarly, for boundaries, this range is 5.3 – 8.4. We also compute the mean prominence and boundary intervals for each listener averaged over data across all the clips: 5.0 – 14.0 and 4.6 – 18.5, respectively. This corresponds to listener dependent variation. We note that the listener dependent variation is larger than the speaker dependent variation as previously observed for American English [26].

4. Automatic prosody detection in Hindi

4.1. Method and Experimental Setup

AuToBI [19] is a publicly available toolkit to automatically detect the presence and type of prosodic events, from the ToBI standard, present in a speech sample. The toolkit is accompanied by a number of trained models[5] of pitch accent and phrase boundary detection (and classification using ToBI labels); we use models for pitch accent detection and intonational phrase boundary detection, trained on three spontaneous speech corpora of Standard American English. The classifications are performed using the logistic regression algorithm with a range of pitch, intensity and duration input features [19]. The trained models were evaluated on all ten Hindi excerpts to derive labels indicating pitch accents and prosodic phrase boundaries.

4.2. Experimental results and discussion

Fig. 4 shows the kappa values for the automatically derived labels against the expert for both prominences and phrase boundaries; a confusion matrix with details of the insertion and deletion errors of AuToBI relative to the expert are also shown. We see that AuToBI almost never (only for 2 words) predicts a boundary when the expert does not. However, there are many instances (126 words) where AuToBI does not predict a boundary after the word while the expert does. These errors mainly stem from instances where a new prosodic phrase begins even when there is no preceding silence; this silence is an important feature for AuToBI to detect a boundary. For prominences,

AuToBI\Expert	Accent	No accent
Accent	74% (130/175)	37% (156/417)
No accent	26% (45/175)	63% (261/417)

Kappa coefficient: **0.311**

AuToBI\Expert	Boundary	No boundary
Boundary	43% (95/221)	0.5% (2/371)
No boundary	57% (126/221)	99.5% (369/371)

Kappa coefficient: **0.479**

Figure 4: Confusion matrix of AuToBI predictions against expert predictions, along with the kappa agreements, for both prominences and phrase boundaries.

[4] The speech files were sorted in descending order according to the Fleiss' coefficients of the "with audio" case.

[5] The toolkit and trained models are available at the following website: `http://eniac.cs.qc.cuny.edu/andrew/autobi/`.

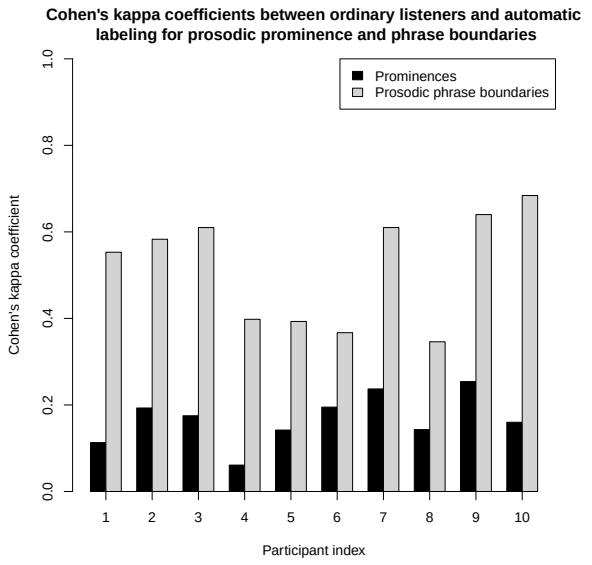

Figure 5: Cohen's kappa agreement coefficients for each participant against the automatically derived transcriptions for prosodic prominence and prosodic phrase boundaries.

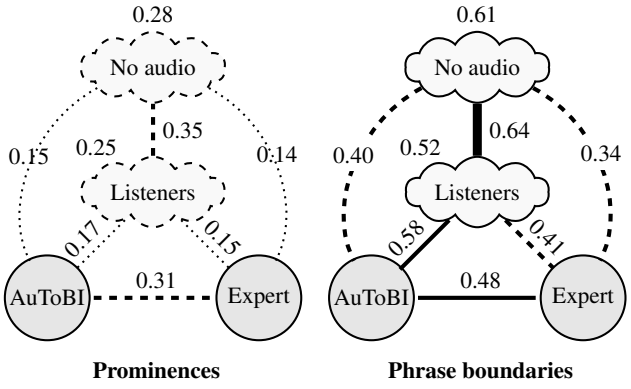

Figure 6: Kappa agreements between the non-expert transcribers, both using audio (*Listeners*) and without audio (*No audio*), AuToBI and the expert, for prosodic prominence and boundaries (shown on the left and right, respectively). The dotted lines indicate no agreement, the dashed lines indicate fair agreement, the bold lines indicate moderate agreement and the thick bold line indicates substantial agreement (according to the interpretation of the kappa statistic in [27]).

the false-positives result from words with a rising pitch accent which get classified as being prominent due to the pitch excursion (but are actually not prominent according to the expert).

Fig. 5 shows Cohen's kappa coefficients for each participant against the AuToBI predictions. As observed in Fig. 2, the listeners show a much higher value of agreement for phrase boundaries (mean $\kappa = 0.582$) than for prominences (mean $\kappa = 0.167$). Fig. 6 summarizes the agreement statistics between the non-expert transcriptions (both with and without audio), the expert transcriptions and the automatically derived transcriptions. We emphasize the following points:

1. The automatically derived labels for both prosodic events show fair to moderate agreement with the expert. This suggests the possibility of using AuToBI in the future for automatic prominence and boundary labeling in Hindi.

2. AuToBI predicts the non-expert transcribers' boundary scores better, but for prominence it is a better prediction of the expert's labels. This reaffirms the claim that ordinary Hindi listeners (unlike experts and machines) do not have a consistent internal definition of prominence.

3. The listeners are more in agreement with each other than with the expert; κ between the listeners and the expert for prominences fall within $[0.07, 0.24]$ while κ of the listeners with each other is in $[0.04, 0.49]$. This suggests that both are possibly tapping into different criteria for prosody perception.

4. In perceiving prosodic boundaries, the *Listeners* and *No audio* groups show moderate and substantial agreement with each other ($\kappa = 0.524$ and $\kappa = 0.612$, respectively). Further, for each participant, there is substantial agreement between the boundaries perceived with and without audio (κ is in the range $[0.55, 0.86]$). This suggests a fairly consistent bias amongst the listeners regarding what is expected of the task.

5. Listeners have much lower agreement for prominence than for boundaries. But the findings also show that, relative to the non-expert listeners, there is higher agreement between the expert transcriber and AuToBI on prominence (κ between listeners and AuToBI fall in the range of $[0.06, 0.25]$ showing that none of the listeners agree with AuToBI as much as the expert does, with $\kappa = 0.31$). This suggests that there are acoustic patterns in Hindi speech that are similar to the acoustic patterns that mark prominence in English, and further, that a trained Hindi speaker can discriminate among words on the basis of these acoustic patterns, as a basis for identifying prominence.

5. Conclusions and future work

We observe that non-expert listeners have much lower agreement for prominence than for boundaries amongst themselves as well as with the expert. On the other hand, AuToBI is more in agreement with the expert on prominence, relative to the non-experts. The fact that non-expert listeners fail to identify prominence on the basis of the same cues used by the expert and the machine suggests that either the patterns of acoustic prominence do not function to mark important linguistic information in Hindi, or they may serve multiple functions that are not easily lumped together in a single percept. Future research on Hindi is needed to investigate prominence under a wider range of pragmatic conditions (beyond contrastive focus), in production and perception.

We have found that automatic models of prosody for English make fairly good predictions about prosody in Hindi. We hope to improve on these models by fine-tuning them using labeled Hindi data; this would allow us to use relatively limited amounts of labeled Hindi data as opposed to building models of Hindi from scratch. We also propose to make use of these models in automatic speech recognition systems for Hindi.

6. Acknowledgements

Abstract

This study investigates prosodic marking of focus in Bai, a Sino-Tibetan language spoken in the Southwest of China, by adopting a semi-spontaneous experimental approach. Our data show that Bai speakers increase the duration of the focused constituent and reduce the duration of the post-focus constituent to encode focus. However, duration is not used in Bai to distinguish focus types differing in size and contrastivity. Further, pitch plays no role in signaling focus and differentiating focus types. The results thus suggest that Bai uses prosody to mark focus, but to a lesser extent, compared to Mandarin Chinese, with which Bai has been in close contact for centuries, and Cantonese, to which Bai is similar in the tonal system, although Bai is similar to Cantonese in its reliance on duration in prosodic focus marking.

Index Terms: focus, prosody, duration, pitch, Bai

1. Introduction

This is a study of prosodic focus marking in Bai. The Bai language is spoken in the Southwest of China by more than one million people of the Bai ethnic group. It has eight lexical tones from three tonal categories: level (55, 44, 33), rise (35), and fall (42, 21, 32, 31) [1, 2, 3]. The term 'focus' refers to the part of a sentence that conveys new information on a topic, following [4] and [5]. Focus can differ in the size of the focused constituent and contrastivity. In terms of size, focus can be on a whole sentence (broad focus), or on a lexical word (narrow focus). If narrow focus also conveys an explicit contrast to alternatives in the context, it is termed as contrastive focus [6]. There is some debate on the position of Bai within the Sino-Tibetan group [2], but this discussion is not crucial for the topic of our paper. Pertinent to the current study is that Bai has been in close contact with Mandarin Chinese for centuries [7].

Pitch is used to encode focus in many non-tone languages [6, 8, 9]. Previous studies have shown that pitch also plays an important role in signaling focus in some tone languages. For example, in Stockholm Swedish, a lexical pitch accent language with two contrasting lexical accents, a separate high tone is added to the lexical accent to mark focus, making pitch relevant for both lexical and post-lexical distinctions [10]. In Mandarin Chinese, a tone language with four lexical tones, pitch is used as a major prosodic cue to realize focus in addition to duration [11]. According to [11], the pitch range at the focus is substantially expanded; the pitch range after the focus is lowered as well as compressed; and the pitch range before the focus does not really deviate much from the neutral focus condition. In addition to that, in Mandarin Chinese, syllable duration increases significantly under focus, regardless of the position of the syllable in the utterance. The data presented in [11] reveals that the pre-focus constituents undergo little change in pitch and duration compared to the same constituents in focus in Mandarin. The same is true for Vietnamese, a tone language with six lexical tones [12, 13]. However, other tone languages do not use pitch to mark focus. For example, in Cantonese, a language with six lexical tones, pitch variation is not systematically modified to mark focus. According to [13], duration and intensity are the main acoustic correlates of focus in Cantonese; both are increased significantly in the on-focus words in any word location for all lexical tones. Besides, no decrease in mean pitch range is found in the post-focus words. In Yucatec Maya, a language with two lexical tones, pitch is only used at the lexical level and focus is not prosodically encoded [15, 16, 17].

Such differences in prosodic focus marking among tone languages suggest that which cues are used to what extent can vary from language to language and is not related to the total number of lexical tones in a language. Against this background, we investigate how pitch and duration may be used to mark focus in the southern variety of Bai by adopting a semi-spontaneous experimental approach. The southern dialect of Bai is chosen because it is well studied at the segmental and lexical level compared to other varieties of Bai [1, 2, 3, 18, 19]. The southern variety of Bai is hereafter referred to as Bai.

2. Methodology

2.1. Experimental materials

The production experiment aimed to elicit SVO sentences in five focus conditions: narrow-focus on the subject NP in sentence-initial position (NF-i), narrow-focus on the verb in sentence-medial position (NF-m), narrow-focus on the object NP in sentence-final position (NF-f), broad focus (BF) and contrastive-focus on the verb in sentence-medial position (CF-m). The focus condition was set up by a WH-question or a statement from the experimenter, as illustrated in examples (1) to (5), where focused constituents appear in square brackets.

Target sentence: *ɕo*^{42} *tɯ*^{21} *kɯ*^{21} *tsɯ*^{33}.

Bear one (quantifier) *sell* *tree.*

The bear sells the tree.

(1) Experimenter: Look! The tree. There is also a price label. It seems someone sells the tree. Who sells the tree?

Participant: [THE BEAR] sells the tree. (NF-i)

(2) Experimenter: Look! The bear and the tree. It seems like that the bear does something with the tree. What does the bear do with the tree?

Participant: The bear [SELLS] the tree. (NF-m)

(3) Experimenter: Look! The bear, it stands behind a shelf. It seems like that the bear sells something. What does the bear sell?

Participant: The bear sells [THE TREE]. (NF-f)

(4) Experimenter: Look! This picture is very blurring. I can't see anything clearly. What has been depicted in the picture?

Participant: [THE BEAR SELLS THE TREE]. (BF)

(5) Experimenter: Look! The bear and the tree. It seems like that the bear does something with the tree. I guess the bear wipes the tree.

Participant: The bear [SELLS] the tree. (CF-m)

Each focus condition was realized in 30 SVO sentences. The lexical tones of verbs were strictly controlled. The verbs were the items for acoustic and statistical analysis, as they can have multiple roles played in the five focus conditions. For example, the verb could be a focused constituent in the BF, NF-m and CF-m conditions; it can also be a pre-focus constituent in the NF-f condition and a post-focus constituent in the NF-i condition. The property of the verbs in the present setting thus provided us with an opportunity to investigate effects of both focus (focused vs. unfocused) and focus type (narrow focus vs. broad focus vs. contrastive focus) on pitch and duration in Bai.

In order to keep the experiment within a feasible length, three lexical tones were included, representing the three tonal categories existing in Bai: level, falling, and rising tones. Tone in Bai can be considered as a complex combination of pitch, phonation type, and degree of tenseness [2]. The present study has selected lexical tones that were well spread over the tonal space of Bai's tone system. Specifically, 55 was selected as a representation of level tones, 21 as a representation of falling tones, and 35 as the rising tone.

The target sentences were constructed in such a way that each was a unique combination of a subject-noun and a VP (verb + object-noun). Six verbs were included, two in each tonal category. In Bai, the noun needs to be followed by a quantifier to form an NP as a subject in a sentence, but the quantifier of the NP can be omitted when the NP is an object in a sentence [20]. Four subject-nouns were selected, which followed by a same low fall-tone quantifier in all the target sentences. Four level-tone object-nouns were selected. The six verbs and four object nouns formed 24 VPs, each of which appeared in each focus condition. This gave us 120 VPs. The subject nouns were evenly distributed over the 120 VPs to form 120 target sentences. To make sure that the duration of the experiment was manageable and reasonable for the participants, the 120 target sentences were split into two lists. Each list contained all the five focus conditions realized on different sentences, and all the six representations of the tones, but only half of the V+O combinations. This results in 60 items per list and participant.

2.2. Data elicitation

In the picture-matching game, three piles of pictures were used: the experimenter and the participant each held a pile of pictures ordered in a certain sequence; the third pile of pictures were scattered around on a table. In the experimenter's pictures (the first pile), there was always something missing, like a subject, an action (verb) or an object. The participant's pictures (the second pile) all contained a complete event. The participant's task was to help the experimenter with sorting out pictures from her own pile and the third pile that went together. Here is a detailed example of a trial eliciting a target sentence in the NF-i condition: First, the experimenter took a picture (e.g. a tree) from her own pile, drew the participant's attention to the picture and established what the picture was by saying, e.g. *"Look! The tree! There is also a price label. It seems like that someone sells the tree."* This was done to make sure that the entity in the picture was referentially given to the participant before the utterance of the question. Second, the experimenter asked a question about the picture (e.g. "*Who sells the tree?"*). Third, the participant took a complete picture from his or her pile and looked at it. The experimenter then repeated the question, followed by an answer from the participant (e.g. "*[THE BEAR] sells the tree.*"). Fourth, the experimenter found the picture containing the missing information in the third pile and pairs it up with her own picture. The participants were explicitly instructed (1) to respond in full sentences and (2) not to show their own pictures to the experimenter. Prior to the picture-matching game proper, the experimenter conducted six practice trials with the participant to familiarize him or her with the game.

In order to ensure the consistency in the participants' word choice, the picture-matching game was preceded by a picture-naming task, which was designed to familiarize the participants with the target words and the entities in the pictures used in the game.

2.3. Participants and procedure

Five native speakers of Bai (four male and one female, aged between 23 and 25) took part in the experiment. The participants all met the following criteria: (1) using Bai on a daily basis with self-estimated daily use exceeding 60%; (2) not having lived outside the Bai speaking community for the past 10 years; (3) not having used Chinese or other languages for a long period on a daily basis; (4) having no self-reported speech and hearing impairments.

Every participant was randomly assigned to one of the two lists. The game lasted 20 to 25 minutes per participant. The participants were tested individually by a female experimenter, who was a native speaker of Bai, in a quiet room in a villager's private home. The experiments were recorded using a portable ZOOM H1 digital recorder at a 44.1 kHz sampling rate and 16 bit accuracy. Each session was also video-taped.

3. Analysis and Results

3.1. Analysis

The auditory recordings from each participant were first orthographically annotated so that the participant's responses could be selected. A strict selection criterion of the usable data was applied, i.e. a sentence was considered usable only if it contained no self-correction and hesitation and was uttered as a response to the target question. In total 80.3% of the obtained responses (N=241) were included in further analysis. The usable sentences were subsequently acoustically annotated in Praat [21]. A textgrid with four interval tiers (word, tone, sentence, comment), and two point tiers (pitch, duration) was created for each target sentence. Every sentence was segmented into words in the 'word' tier, then landmarks demarcating verb onset and offset, and the locations of pitch-maximum and pitch-minimum within the verb were added to the 'duration' and 'pitch' tiers. The landmarks for the onset and offset of verbs were determined according to the information in the waveform and spectrogram.

The pitch values of the pitch landmarks and the time values of the word boundaries were subsequently extracted via Praat scripts. Two measures from these values were calculated: word duration (i.e. offset time minus onset time) and pitch range (i.e. the difference between the maximum pitch and the minimum pitch). In 55 of the usable responses, the pitch values could not be reliably measured. These responses were thus excluded from the analysis on pitch range.

In order to investigate how focus is prosodically realized in Bai, several analyses were done to find out the effect of focus (focused vs. unfocused), focus type, and the interaction between these variables and the tone of the verb on the duration and pitch range of the verbs. To find out the effect of focus and its interaction with tone, we compared the duration and pitch range of the focused verbs with these measures of the verbs in the unfocused conditions: NF-m (focus) vs. NF-i (post-focus); NF-m (focus) vs. NF-f (pre-focus). To find out the effect of focus type and its interaction with tone, we compared the verbs in the NF-m condition with the same verbs in the BF and CF-m conditions.

3.2. Results

3.2.1. Duration

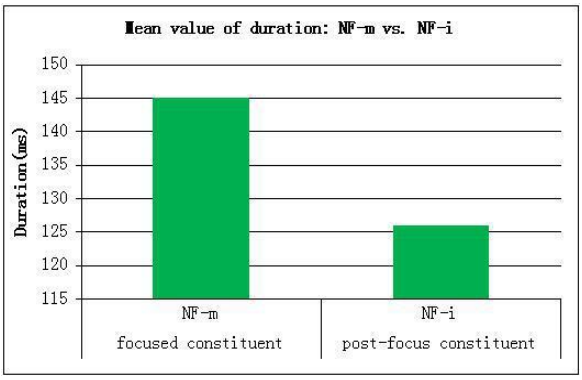

Figure 1: *Mean duration (in ms) of verbs in focus vs. non-focus position. (NF-m=verb in sentence medial focused position, NF-i=verb preceding a focused constituent)*

The duration data obtained from the verbs in the NF-m and NF-i conditions showed that the verbs were on average 19.1 ms longer when focused (NF-m) than when not focused and following a focused constituent (NF-i). To assess the effect of focus (focused vs. unfocused) on the duration of the verbs, we built a mix-effect model with 'focus' as the fixed factor (independent variable), 'speaker' and 'verb' as the random factors; and another mix-effect model with only the random factors. The variation between speakers was corrected in the models per focus condition. A statistically significant difference between the two models was taken as the evidence for a main effect of the fixed factor at issue. In the comparison between NF-m and NF-i, the model including the fixed factor differed significantly from the model with only the random factors ($p<0.01$). This indicated that the speakers used duration to distinguish focus from non-focus when the unfocused verb was in post-focus position. Furthermore, we also used mixed-effect-modeling to assess the effect of the interaction between 'focus' and 'lexical tones of verbs'. The model involving the interaction did not differ significantly ($p=0.31$) from the model without the interaction. Thus, the speakers used duration to distinguish focus from non-focus regardless of the tonal category of the verbs.

The duration data obtained from the verbs in the NF-m and NF-f conditions showed that the verbs were on average 12.5 ms longer when focused (NF-m) than when not focused and preceding a focused constituent (NF-f). Mixed-effect modeling was used to assess the effect of 'focus' on the duration of the verbs, as described above. It did not reveal a main effect of 'focus' ($p=0.13$). Furthermore, the model involving the interaction did not differ significantly ($p=0.31$) from the model without the interaction. This indicated that there was no main effect of 'focus', i.e. the speakers did not use duration to distinguish focus from non-focus (i.e. pre-focus in NF-f). This suggested that the duration in the pre-focus constituents hardly changed relative to the constituents in focus.

With regard to the effect of focus type, mixed-effect modeling revealed no main effect ($p=0.16$) of 'focus type' (referring to the three types of focus). Further, there was no interaction between 'focus type' and 'lexical tones of verbs' ($p=0.49$). Thus, duration was not used to differentiate the three focus types regardless of the tones of the verbs. To find out whether duration was used to distinguish NF-m and CF-m, two focus types with a smaller focus-constituent size, from BF, we grouped NF-m and CF-m and built new models. The models showed that NF-m and CF-m did not differ from BF in the duration of the verbs regardless of the tone of the verbs ($p=0.33$). Finally, models were built to see whether NF-m and CF-m could differ in duration. Again we found no significant difference in duration.

3.2.2. Pitch range

The mean pitch ranges hardly differed across conditions, i.e. 8.78Hz in the BF condition, 7.99Hz in the CF-m condition, 7.89Hz in the NF-f condition, 10.78Hz in the NF-i condition, and 9.12Hz in the NF-m condition. Mix-effect-modeling confirmed that pitch range was not used in any way in focus marking in Bai.

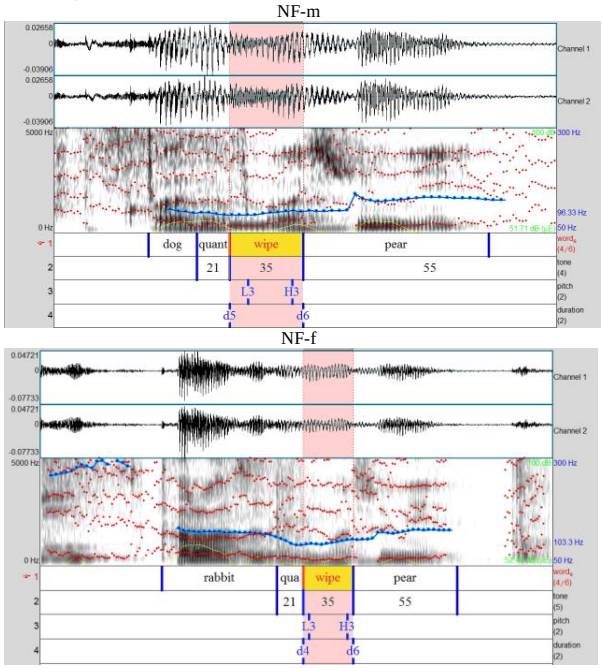

Figure 2: *Pitch contour (in Hz) of verbs in focus vs. non-focus position. (NF-m=verb in sentence medial focused position, NF-f=verb following a focused constituent)*

4. Discussion and Conclusions

The present study shows that speakers of the southern variety of Bai increase the duration of the focused constituent and reduce the duration of the post-focus constituent to encode focus, similar to speakers of Mandarin Chinese [11] and Cantonese [14]. Further, they do not vary the duration of a pre-focus constituent compared to the same constituent in a focused position, again similar to speakers of Mandarin Chinese and possibly Cantonese. However, they do not use pitch variation in any way in focus marking, different from speakers of Mandarin Chinese but similar to speakers of Cantonese. In addition, speakers of this variety of Bai do not use duration distinguish focus types differing in size and contrastivity, different from speakers of Mandarin Chinese [11] and Cantonese [14], who use duration to distinguish focus types differing in the size of the focused constituent. These results suggest that Bai uses duration in prosodic focus-marking to a lesser extent than Mandarin Chinese and

Cantonese. Related to this is the fact that Bai also exploits word order and morphological topic marker to distinguish focal information from non-focal or topical information. Specifically, the canonical word order in Bai is SVO, the word order OSV can be used to highlight the topic status of the object. Further, the topical status of a subject can be optionally marked by topic markers, such as 'nɯ^{55}' and 'lɯ^{44}'[19]. The use of these non-prosodic cues may explain the modest use of prosody in focus marking in Bai. Furthermore, the results add to the existing findings on prosodic focus-marking in tone languages and show that there is no relationship between the cues used to mark focus prosodically and the number of lexical tones in a language.

Our study suggest two topics for future research. Bai has been in close contact with Mandarin Chinese for centuries [7], which has led to a large number of Chinese-loan words in Bai, and deep influence from Chinese syntactic structure on the syntax of Bai [2, 19]. However, in spite of the lexical and syntactic influence from Mandarin Chinese, Bai is by and large more similar to Cantonese in prosodic focus-marking in that both Bai and Cantonese, duration is the major prosodic cue rather than pitch. This puts forward an interesting hypothesis for future research. That is, prosodic focus-marking may not easily undergo changes as a result of language contact. Further, considering the dialectal differences in Bai language, it is not clear whether prosodic focus marking is similar across Bai dialects. Future research on the northern variety of Bai can shed light on this question.

5. Acknowledgements

We are grateful to Wenju He for collecting data in Xizhou County, and to the participants in the village. We also thank Liquan Yang and Yanzhen Zhao for their feedback on Bai, Paula Cox, Anqi Yang, Anna Sara Romøren for their help. Abstract

Although glottalization has often been associated with low pitch, evidence from a number of sources supports the assertion that this association is not obligatory, and is likely to be language-specific. Following a previous study testing perception of glottalization by German, English, and Swedish listeners, the current research investigates the influence of pitch context on the perception of glottalization by native speakers of a tone language, Mandarin Chinese. Listeners heard AXB sets in which they were asked to match glottalized stimuli with pitch contours. We find that Mandarin listeners tend not to be influenced by the pitch context when judging the pitch of glottalized stretches of speech. These data lend support to the idea that the perception of glottalization varies in relation to language-specific prosodic structure.

Index Terms: prosody, voice quality, perception, glottalization

1. Introduction

Glottalization, and in particular creaky phonation, is associated across languages with lowered amplitude, positive spectral tilt, and higher first formant values than modal voice (Gordon & Ladefoged [1]), and with low fundamental frequency (F0), damping, and aperiodicity (Gerratt & Kreiman [2]). Because of its low F0, creak/glottalization has been classically described as giving the impression of "a stick being run along a railing" (Catford [3]: 32). Glottalization, despite its acoustic complexity, can be identified with 95% accuracy by listeners (Blomgren, Chen, Ng & Gilbert [4]), and can therefore be considered a robust tool for phonetic signaling.

Glottalization's acoustic characteristics have often led to it being associated with low pitch, especially in intonation languages. However, associating glottalization with low pitch on the basis of its having low F0 is problematic. Many tone languages associate creakiness with high tones (Gordon & Ladefoged [1]; Gussenhoven [5]), and this can be the case even in intonation languages (Pierrehumbert & Talkin [6]; Pierrehumbert [7]; Dilley, Shattuck-Hufnagel & Ostendorf [8]; Redi & Shattuck-Hufnagel [9]). Dilley et al. [8] found, for example, more frequent glottalizations of word-initial vowels if the target words were pitch-accented. Since in their corpus L* accents were rare, they claimed that glottalization was influenced by pitch-accents per se and not by low F0 ([8]: 439). Pierrehumbert [7] also reported glottalization associated with pitch accents.

In intonation languages, creaky voice and other forms of glottalization have often been associated with prosodic boundaries. Henton & Bladon [10] and Redi & Shattuck-Hufnagel [9] reported that in English glottalization is likely in utterance-final position, while Pierrehumbert & Talkin [6] and Huffman [11] found its presence at prosodic boundaries. Ogden [12, 13] noted that glottal productions characterize possible turn transition locations in Finnish. Creak and/or glottalization have also been shown to occur in other positions. For example, the glottalization of word-initial vowels is a frequent word juncture marker in Czech and in German (Bissiri et al. [14]; Kohler [15]).

Tone languages may demonstrate some of the same intonational features as intonation languages, and this appears to hold true for glottalization features. Ding et al. [16] found glottalization at the beginnings of vowel-initial syllables in Mandarin Chinese, similar to the effects reported above in German, English and Czech. In Mandarin, tone itself can also have an influence on the occurrence of glottalization. Chao [17] observed glottalization in Mandarin's falling-rising Tone 3. Ding & Helbig [18] reported glottalization most frequently in the middle (i.e. associated with the pitch valley) of Tone 3 and sometimes at the end of the falling Tone 4. This would appear to contradict Silverman's [19] and Frazier's [20] proposals that tone and glottalization are perceived sequentially, at least in the case of Mandarin Chinese. It therefore remains the case, as Ní Chasaide & Gobl [21] pointed out, that studying pitch perception without analyzing the influence of glottalization is likely to lead to incomplete results.

Bissiri & Zellers [22] investigated the perception of glottalization in different pitch contexts by German, English and Swedish listeners. They found that long stretches of glottalization tended to be associated with low pitch by listeners in all three of these languages, although listeners could also associate glottalization with mid or rising pitch in a substantial minority of cases. The pitch contour preceding the glottalized stretch influenced English and German listeners' judgments: when the glottalization was preceded by a rising pitch contour, it was more likely to be perceived as falling pitch. Swedish listeners, however, did not show this perceptual effect. Bissiri & Zellers [22] proposed that this was because Swedish listeners' experience with the lexical pitch accent system in Central Swedish made them more sensitive to pitch in general, and therefore more likely to respond based on the actual F0 of the stimuli, than the English and German listeners, who may have relied more on their predictions about the continuing direction of the pitch contour.

If listeners from a pitch-accent language background are more sensitive to F0 than listeners from an intonation language background, it follows that listeners from a tone language should also be more sensitive to F0. The study reported below investigates Mandarin Chinese listeners' perception of glottalized stretches in different pitch contexts.

2. Perception experiment

The current study uses the same AXB forced-choice paradigm as Bissiri & Zellers [22] to investigate whether Mandarin Chinese listeners would consistently associate glottalization of a final syllable with a falling, level, or rising pitch contour in that position. Following Bissiri & Zellers' findings for Swedish versus German and English, we hypothesize that Mandarin listeners, coming from a tone language background, will not be influenced by the surrounding pitch contour.

2.1. Methodology

2.1.1. Stimuli

The stimuli used for this experiment were the same as those used by Bissiri & Zellers [22], and a more detailed account of their creation can be found there. Stimuli consisted of the syllable sequences /da'dada/, /la'lala/, and /na'nana/. Although /da/, /la/ and /na/ are acceptable Chinese syllables, the sequences are nonsense words in Chinese. By means of a Praat (Boersma & Weenink [23]) script, twelve versions of each syllable sequence were created. Nine of them were the Pitch conditions. A flat pitch contour of 220Hz was set over the whole syllable sequence. Then, four pitch points were added: at the onset of the first consonant, the onsets of the middle and final vowels, and the end of the final vowel. The second pitch point (onset of stressed vowel) was either raised 3 semitones above the initial pitch (fall), lowered 3 semitones below the initial pitch (rise), or kept level (mid). Similarly, the fourth pitch point (end of final vowel) was raised 3st, lowered 3st, or kept level. The third pitch point (onset of the final vowel) was held constant. In this way, 9 pitch contours were created (see Figure 1).

For each initial pitch condition (mid, rising, or falling), a further version was created with the final syllable containing glottalization instead of a smooth pitch contour; these stimuli constitute the Glottalization set. The glottalization was taken from naturally-produced tokens, and was matched in length to the final syllables of the Pitch conditions. In order to make sure that the consonant preceding the glottalization remained clear, the glottal stretches were spliced into the stimuli following the formant transitions. Using a Praat script, four additional pitch points were added in the transitions to create the impression of glottalization. These pitch points, with values of 35Hz, 220Hz, 35Hz, and 220Hz respectively, were equally spaced through the duration of the formant transitions. The amplitude of the entire glottalized part of the stimuli was then reduced in order to improve naturalness. All Pitch and Glottalization stimuli were then amplitude-normalized.

2.1.2. Participants

Participants in the experiment were native speakers of Mandarin Chinese (N=21) between 20 and 27 years old, students at the Tongji University in Shanghai.

2.1.3. Experiment procedure

The experiment was presented by means of Praat's ExperimentMFC. Participants heard sequences of three stimuli. Their task was to compare the second stimulus to the first and third, and to decide which it sounded most like. The

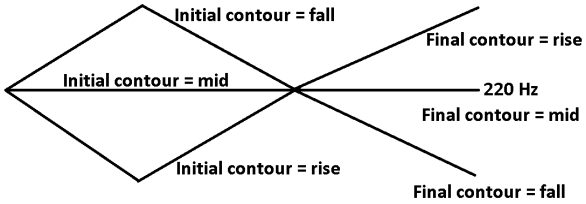

Figure 1: Schematic of pitch contours.

AXB paradigm was chosen instead of ABX because the target stimulus is adjacent to both options, thus putting fewer demands on memory. AXB sets were created from the same syllable set (/da/, /la/, or /na/), and also with the same initial pitch contour. The A and B options were always stimuli from the Pitch set, while the target item X was from the Glottalization set. Since participants in AXB tests tend to choose the more recent and thus better remembered B option, each critical pitch contour comparison was presented in both AXB and BXA format. Thus, each participant heard 126 stimuli in total: 54 test comparisons, in which the X item contained a glottalization, and 72 control comparisons, in which all the items were drawn from the Pitch set. For each participant, the order of presentation of all sequences was randomized by Praat.

The experiment was preceded by a practice session to get participants accustomed to the task. During practice, participants heard 3 control items with the syllables /ba'baba/. According to feedback from a pilot participant, optional breaks after every 32 items were included in the experiment. The time taken by participants to complete the task was between 17-20 minutes.

2.1.4. Data cleanup

Prior to the data analysis, participants' responses to control items were checked to make sure they had accurately matched pitch patterns. The control items always contained two identical contours and one that was different; any participants who failed to identify the identical contours in more than 10% of the control items were considered to have not performed the task correctly. One Chinese listener, who systematically gave the incorrect response in 93% of the control stimuli, was excluded on this basis. Of the 20 Chinese participants whose results were kept, 16 had an accuracy above 95%.

2.2. Results

The cases in which participants had to choose between a) fall and mid, b) fall and rise, and c) mid and rise pitch contours were analyzed separately in three subsets of 360 observations each. We found no statistically significant difference in any of the three data subsets on the basis of the three syllable sequences with /da/, /la/ and /na/; therefore, in the following analysis, the three syllable sets will be collapsed.

Glottalization was most frequently associated with falling pitch, but with a remarkable minority of non-fall responses (see Figure 2). When participants had to choose between fall and mid, fall responses were 65.8%, lower than the percentage of fall responses found by Bissiri & Zellers [22] for German (69.4%), English (73%) and Swedish (66.7%) listeners. Most Chinese listeners identified glottalization with falling pitch in over 50% of the cases; however, two of them gave a majority of mid responses and three gave 50% mid responses. When

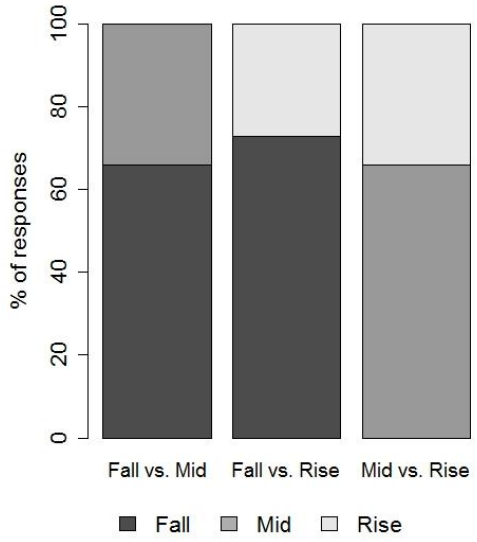

Figure 2: Responses by Chinese listeners.

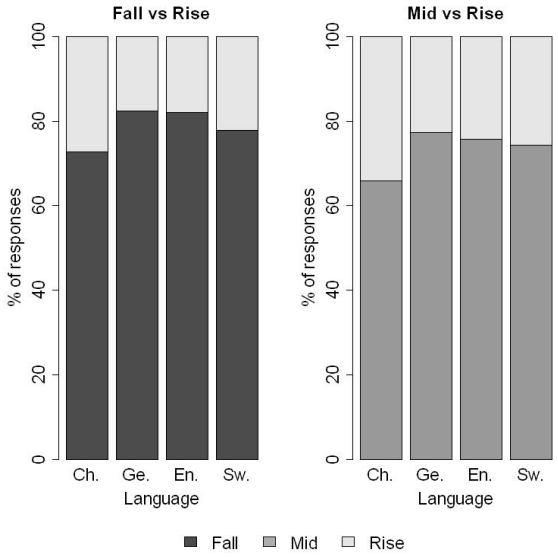

Figure 3: Responses by Chinese listeners and by Bissiri & Zellers' [22] German, English and Swedish listeners when rise was one of the options.

rise was one of the options, there was a substantial minority of rise responses: 27.2% in the fall and rise subset, and 34.2% in the mid and rise subset. The Chinese listeners gave significantly more rise responses than Bissiri & Zellers' [22] German, English and Swedish listeners: subset fall and rise χ^2 (1, N = 1368) = 10.9798, $p < 0.001$, subset mid and rise χ^2 (1, N = 1368) = 14.0703, $p < 0.001$ (see Figure 3). In the fall and rise subset, three Chinese participants had a majority of rise responses. Two of them had 50% rise responses in the mid and rise subset, while three other Chinese participants had a majority of rises.

For Chinese listeners, the initial pitch contour had no influence on the association of glottalization with a final pitch (subset fall and mid: χ^2 (2, N= 360) = 1.556, n.s.; fall and rise: χ^2 (2, N= 360) = 1.374, n.s.; mid and rise: χ^2 (2, N= 360) = 0.9633, n.s.). Figure 4 represents responses by Chinese across initial pitch when they had to choose between fall and mid, in comparison with Bissiri & Zellers' [22] Swedish, German and English participants. German and English listeners had significantly more fall responses when initial pitch was rise, while Swedish listeners, similarly to the Chinese listeners in the present study, did not.

3. Discussion

As with the English, German and Swedish listeners in Bissiri & Zellers' [22] analysis, the Mandarin Chinese listeners in the current study were most likely to associate glottalization with falling pitch rather than mid or rising pitch. However, to an even greater extent than Bissiri & Zellers' listeners, the Mandarin listeners were flexible in their association of glottalization with different pitch contours, with around 30% of responses preferring a mid or rising contour even when a falling contour was also presented. Furthermore, there was no statistically significant effect of the initial pitch contour on listeners' choice of final pitch contour to match the glottalization.

The lack of effect of initial pitch contour on Mandarin listeners' judgments seems most likely to be the result of the Mandarin tone system, in which every syllable is assigned a lexical tone. In the case of the current stimuli, there was no reason for the Mandarin listeners to make predictions about the pitch of the final syllable on the basis of the first two unless they adopted a strategy of assigning lexical meanings that could constrain the last syllable. Six of the Chinese participants reported after the experiment that the stimuli sounded similar to their native language. However, the stimuli did not constitute existing words in Chinese, and we can therefore reasonably exclude the possibility that a mapping of some stimuli to real Chinese words introduced a bias in the responses.

It was possible that an influence of tone sandhi from the preceding pitch contour could constrain perception of the pitch of the glottalized syllable, but this does not appear to have been the case in the current data. There are several possible reasons for this. The first is of course that the pitch percept in the glottalized stretches was too strong to allow for alternative interpretations. However, the substantial minority of non-falling responses suggests that this is not the case, since if the pitch percept was extremely strong, it seems unlikely that those non-falling responses would be possible. Therefore, we must look elsewhere for an explanation.

One possibility is that glottalization may be so firmly associated with Tones 3 and 4 that listeners' interpretation was constrained by the glottalization even if the pitch contours did not match the canonical form. The higher percentage of rise responses by the Chinese compared to Bissiri & Zellers' [22] German, English and Swedish listeners might be explained by an association of glottalization with the falling-rising Tone 3. Liu & Samuel [24] report that Tone 3 is perceived by Mandarin Chinese natives with the same accuracy even if its rising portion is missing. They also found that listeners could still perceive Tone 3 most of the time even if it consisted only of its rising portion, which is surprising given its redundancy for Tone 3 perception. These results indicate a) a possible flexibility in tone perception by Mandarin Chinese listeners allowing them to associate glottalization with rising pitch, if they relate both acoustic cues to Tone 3, and b) a possible relevance of other secondary cues beside F0 for tone perception. Liu & Samuel [24] propose duration and amplitude

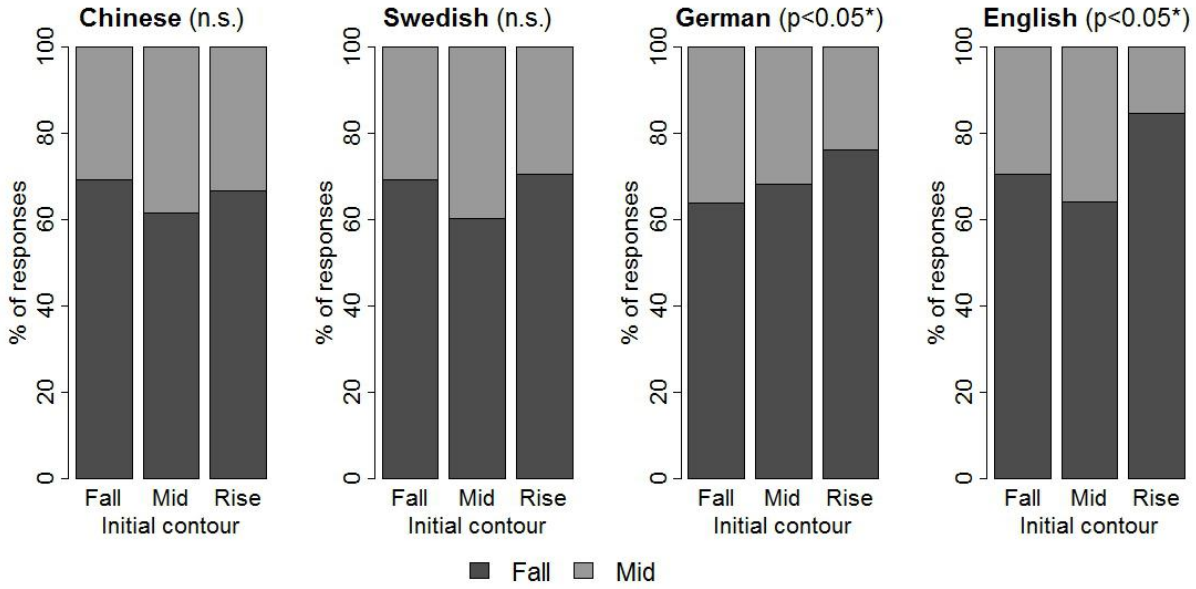

Figure 4: Responses by Chinese listeners and by Bissiri & Zellers'[22] Swedish, German and English listeners across initial pitch when choosing between fall and mid contours (Pearson's χ^2 test).

as possible candidates, and Lee et al. [25] also suggest voice quality or glottalization as a relevant perceptual cue for Mandarin tones.

Another alternative for the interpretation of our results is that listeners did not treat the syllables as Chinese lexical items at all. Since, as mentioned above, some participants treated the items as coming from a nonsense language, they could have potentially interpreted the pitch according to a tone-based system without being completely influenced by the form of the Mandarin tone system.

Combined with Bissiri & Zellers' [22] results, a consistent picture of the perception of glottalization begins to emerge from the data. Specifically, the different functional load of prosodic features across languages leads to different perceptual patterns. In Mandarin Chinese, where pitch is essential to lexical meaning, and every syllable has its own tone assigned, listeners were apparently not influenced by the pitch of preceding syllables but only made judgments about the pitch of the glottalized syllable itself. In Swedish, where pitch also contributes to lexical meaning but glottalization is not so firmly associated with either tone, listeners apparently were strongly inclined to seek a pitch interpretation of the stimuli, with most responses matching glottalization to the lowest available pitch contour in the pair. In German and English, where pitch is assigned on the intonational rather than a pitch-accent or tonal level, larger-scale contours appear to have a stronger influence on listeners' judgments, with listeners apparently making many of their pitch judgments on the basis of prediction of how a pitch contour would continue, rather than on calculation of the pitch of the glottalized stretch alone. It is important to note, however, that the current task intentionally influences listeners towards interpreting glottalization as having pitch, or being related to pitch variation. In other words, the task may have biased listeners towards a categorization of glottalization within the tonal/intonational system of their native language. A task which depended on a function of glottalization not (necessarily) tied to pitch variation – e.g. turn transition, as in Ogden [12, 13] – might lead to a different result.

4. Conclusion

Our data, combined with Bissiri & Zellers' [22] findings, give growing evidence for a language-specific link between perception of pitch and perception of glottalization in long stretches of creaky voice. It appears that listeners' experience with tone or intonation languages can lead them to focus on different prosodic information when judging the pitch of glottalized stretches. In particular, the influence of the surrounding pitch context is different across different languages. Mandarin Chinese listeners, similarly to Bissiri & Zellers' Swedish listeners, were not influenced by the previous pitch contour while associating glottalized syllables to the possible pitch alternatives. Their performance contrasted with Bissiri & Zellers' German and English listeners, speakers of intonation languages, who were influenced by the previous pitch contour in their responses. Creak may lead Mandarin listeners to a falling-rising Tone 3 interpretation as well as a falling Tone 4 one, while the one-syllable size of the tone domain apparently influences them to ignore the preceding pitch context when making their judgments. Thus the different sizes of pitch domains relevant in each language, and even the internal phonological structure itself, appear to influence listeners' expectations about the relevant interpretive context for glottalization.

5. Acknowledgements

The authors are grateful to Xinping Xu for conducting the experiment, and to all of the Chinese participants. This research was supported by the European Union grant MC-IEF GeCzEnGlott, by the postdoctoral research grant 'Perception of prosody in linguistic contexts' (VR-435-2011-6871) from the Swedish Research Council (Vetenskapsrådet) and by the National Social Science Foundation of China (13BYY009).

Cross-linguistic perception of Mandarin intonation

Robert Bo Xu, Peggy Pik Ki Mok

Abstract

This study investigated how phonological knowledge and psychoacoustic mechanism interact in intonation perception. In the experiment, Mandarin and Cantonese listeners identified Mandarin statement and question in both unfiltered and low-pass filtered contexts. The results show that the importance of different perceptual factors varies depending on the perception materials. Language background plays an important role even in processing low-level psychoacoustic materials.

Index Terms: cross-linguistic perception, intonation, Mandarin, the Frequency Code

1. Introduction

1.1. Intonation and the Frequency Code

This study investigates the interaction between psychoacoustic mechanism and phonological knowledge in intonation perception. The most relevant psychoacoustic mechanism to the perception of statement and question is the Frequency Code proposed by Ohala [1]. It explains the cross-linguistic correspondence between intonation contour and (para-)linguistic meaning, stemming from a biological basis [2]. Since the organ that produces a lower sound is usually larger, low-pitched individuals are associated with being dominant and aggressive, whereas individuals that produce a higher pitch are associated with being subordinate and submissive. As a result, the informational interpretations of the Frequency Code relate high or rising contour to "uncertainty", and thus questioning, and relate low or falling contour to "certainty", and thus being assertive, i.e., statements [1], [2].

1.2. Tone and intonation of Mandarin

1.2.1. Lexical tones in Mandarin

There are four lexical tones in Mandarin [3] (Table 1), all differ in pitch shape. There is a tone sandhi rule in Mandarin. In a T3-T3 sequence, the first T3 is produced as a high rising tone [4], perceptually indistinguishable from T2 [5] [6].

Table 1. *Lexical tones in Mandarin.*

	T1	T2	T3	T4
Tone Shape	Level	Rising	Dipping	Falling
Tone Letter	55	35	21/214	51

1.2.2. Production of Mandarin question intonation

While some studies suggested that questioning in Mandarin could be a local event at the final tone [5]–[8], other studies showed that the tone shape of the final tone remains very similar to the citation form acoustically [11]-[13]. Many studies have demonstrated that Mandarin questions were signaled by modification of the F0 contour of the whole utterance [14]-[21]. Yuan [13] showed that the global F0 of a question was raised and the whole sentence had a smaller declination slope compared with that of a statement. The final T2 of a question had a steeper rising and a higher ending, and the final T4 of a question had a higher beginning and a higher ending than those of a statement, and hence had a flattened falling contour. He concluded that a boundary tone is not necessary to model the distinction between statement and question in Mandarin. The essential mechanism of Mandarin questioning is its raised F0 contour over the scope of the whole utterance.

1.2.3. Perception of Mandarin question intonation

Studies on intonation perception of Mandarin revealed several asymmetries in their perception results. First of all, statements are easier to identify than questions. This bias towards statement shows that statement would be an unmarked sentence type [13], [22]. Second, the sentence-final lexical tone does not affect the identification of statements, but influences the identification of intonational questions (yes-no questions that are signaled by intonation only, without any sentence final particles). Questions with a sentence-final falling tone (T4) are easiest to be identified, and a question ending with a final rising tone (T2) is the most difficult to identify [9]. Yuan [13],[23] explained that this was due to the flattening of the falling tone at the end of a question. This is a language/tone specific perceptual pattern; and intonation perception was sensitive to the phonological tone identity at the end of an utterance. Third, question-final lexical tones are rarely affected by intonation perceptually. Each tone in statements or in questions can be easily recognized by listeners [23]. Jiang and Chen [24] showed that cutting off the final tone does not significantly influence perception. What is important to questioning is the last prosodic word of the utterance.

1.3. Intonation of Cantonese

This study includes Cantonese listeners because Cantonese intonation patterns are different from Mandarin. Cantonese yes-no questions are signaled by a final rising that change the canonical tone shape of any tone at the end of the questions [25]-[27]. In addition, global F0 contour does not play an important part in questioning [27], [28]. As a result, Cantonese listeners may have different interpretation of Mandarin intonation patterns from native listeners.

1.4. Cross-linguistic perception of prosodic features

An important theme in cross-linguistic perception is how phonetic forms are shaped in the perception with different language backgrounds [29], [30]. Huang and Johnson [31] showed that language experience was impactful in the perception of tonal contrasts even in low-level psychoacoustic processing. Burnham et al. [32] showed that tonal contrasts in musical sounds were better discriminated than in low-pass filtered speech, which in turn was better discriminated than in

normal speech, indicating that listeners were more sensitive to acoustic differences in non-speech signal than in speech.

While some studies showed that language background played an important role in perceiving intonation [33], [34], Gussenhoven and Chen [35] showed that listeners with different native languages associated question intonation with a later or a higher F0 peak and higher end pitch in a made-up speech, concurring with the Frequency Code that a high or rising pitch contour is associated with questioning. Grabe et al. [29] suggested that experience with a native language was added to the universal auditory mechanism in shaping listeners' perception of intonation.

1.5. Summary

Previous studies have shown that the Frequency Code plays an important part in intonation perception [35], but intonation perception is also shaped by listeners' first language intonation phonology[33], [34]. However, no previous studies have systematically demonstrated the interactions between these factors. This study aims to fill in this research gap.

2. Method

2.1. Materials

Nine-syllable sentences in Mandarin shown in Table 2 were designed for the experiment. The final two syllables of each sentence share the same lexical tone. With the final syllable cut off, the utterances still remained meaningful, and the ending tone remained the same (with the exception of T3 because of unavoidable tone sandhi).

Table 2. *Mandarin utterances used in the experiment*

Finals	Sentences (Chinese, pinyin and English translation)
T1	妈妈今晚炖的是鸡(汤)。 ma1 ma jin1 wan3 dun4 de shi4 ji1 (tang1). 'Mommy cooked chicken (soup) for tonight'
T2	亚马逊是最长的河(流)。 ya3 ma3 xun4 shi4 zui4 chang2 de he2 (liu2). 'Amazon is the longest river.'
T3	他最大的缺点是懒(散)。 ta1 zui4 da4 de que1 dian3 shi4 lan3 (san3). 'His biggest shortcoming is laziness.'
T4	工人在修公园的路(面)。 gong1 ren2 zai4 xiu1 gong1 yuan2 de lu4 (mian4). 'The workers are repairing the road in the park.'

Two native speakers, both professional Mandarin teachers, (male aged 30 from Shaanxi, female aged 26 from Hubei) were recorded reading the sentences for the experiment. The recording took place in a sound-treated room. The speakers were instructed to read the sentences focus-neutrally.

After screening the naturalness of the recordings, four presentation sentence conditions (complete statement and question, statement and question with the final syllable cut-off) were prepared for the perception test for two experiment contexts (normal speech and low-pass filtered speech). All cutting points were at zero crossing following the offset of the penultimate syllables of the utterances. The average amplitude of all the utterances was also normalized. Low-pass filters were applied with 100 Hz bandsmoothing. The cutoff frequency was determined by the highest pitch each speaker produced in their T2 questions, being 250 and 400 Hz for the male and female speakers respectively. Informal tests showed that native speakers of both languages could not understand the content of the low-pass filtered sentences They reported only hearing some low frequency humming.

2.2. Listeners and procedure

20 Cantonese and 20 Mandarin listeners participated in the perception experiment. All the Cantonese listeners were native Hong Kong Cantonese speakers, speaking Mandarin with varying proficiency. All the Mandarin listeners came from Northern China. They all spoke English as a foreign language. None of them have received any systematic training in linguistics when they participated in the experiment. None had a reported history of speech or hearing disorder.

The perception experiment was carried out in a sound-attenuated room. The materials were presented to them using the software E-Prime. After a practice session, the listeners finished the section with low-pass filtered speech before the section with normal speech, to prevent them from guessing the content of the filtered materials. In the filtered section, two blocks of filtered Cantonese utterances were used as fillers to conceal the identity of language the listeners heard. The blocks and the tokens within each block were randomized. Each of the 64 stimuli (4 sentence conditions × 2 contexts × 2 genders × 4 tones) was repeated twice. Listeners listened to each trial only once before they decided whether the utterance they just heard was a statement or a question by pressing a button on the keyboard.

2.3. Data analysis

Average identification accuracy (IA) were calculated. Three-way (Intonation type × Condition × Final tone) repeated measures ANOVAs were conducted on the identification scores. Corrections for violations of sphericity were made, where appropriate, using the Greenhouse–Geisser estimates of sphericity. Bonferroni correction was applied for pairwise comparisons.

3. Results

3.1. Mandarin listeners: Normal speech

Figure 1 shows the identification accuracy for Mandarin listeners listening to normal utterances. The main effects of Intonation type [$F(1,19)=23.02$, $p<0.001$], Condition [$F(1,19)=148.52$, $p<0.001$] and Final tone [$F(3,57)=18.65$, $p<0.001$] are all significant. In the complete utterance condition, statements were well identified across different tones. T3 ($M=78\%$, $SD=0.26$) complete question has the lowest IA, significantly lower than T2 and T4 ($p<0.05$ in each comparison). In the cut-off condition, while T1, T2 and T4 statements remain well identified, T3 statement has the lowest IA ($M=74\%$, $SD=0.29$), probably due to the penultimate high rising pitch contour induced by tone sandhi. The IA of T3 cut-off statement is significantly lower than T2 and T4 statements ($p<0.05$ in each comparison). Among the cut-off questions, T4 question remains almost unaffected by the elimination of the last syllable, while the IA for T1 and T2 questions become much lower than their complete counterparts. The identification accuracy for T4 is significantly higher than all the other tones ($p<0.05$ in every comparison). The results suggest that T3 is a difficult tone to identity in Mandarin

questions in the compete condition. In contrast, T4 may be the easiest ending tone for Mandarin questions. Cutting off the final syllable influences the perception of intonation, but the exact influence depends on different tones.

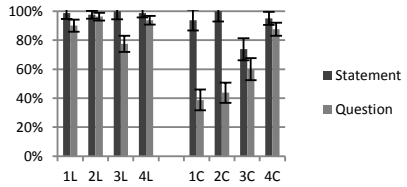

Figure 1: *IA of normal utterances by Mandarin listeners. (L: complete utterances; C: cut-off utterances)*

3.2. Cantonese listeners: Normal speech

Figure 2 shows that Cantonese listeners had lower IA than native Mandarin listeners, especially for questions. The main effect of Intonation type [$F(1,19)=71.31$, $p<0.05$], Condition [$F(1,19)=55.50$, $p<0.05$] and Final tones [$F(3,57)=13.10$, $p<0.05$] are all significant. For the complete utterances, listeners performed well for statements with all ending tones. This is not the case for questions, as T3 complete question is poorly identified (M=43%, SD=0.20, below chance level). The IA is significantly lower than complete questions with the other tones ($p<0.05$ in every comparison). For the cut-off statements, T3 statements is the worst identified (M=71%, SD=0.34), with IA significantly lower than the other tones ($p<0.05$ in every comparison). For the cut-off questions, T1 and T2 questions (both identified below chance level) are identified significantly more poorly than T3 and T4 questions ($p>0.05$ in every comparison). There are no significant differences between the IAs of T1 and T2 ($p>0.05$) or between those of T3 and T4 ($p>0.05$). The result shows that Cantonese listeners also found T3 to be a difficult ending tone. They also found questions ending with T1 and T2 in the cut-off condition confusing.

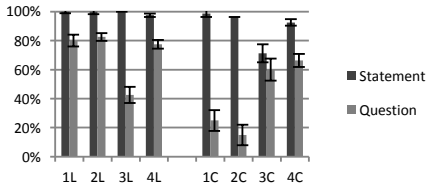

Figure 2: *IA of normal utterances by Cantonese listeners.*

3.3. Mandarin listeners: Filtered speech

Figure 3 shows the identification accuracy for Mandarin listeners listening to low-pass filtered utterances. The main effect of Intonation type [$F(1,19)=57.39$, $p<0.001$], Condition [$F(1,19)=173.57$, $p<0.001$] are significant. Although the main effect of Final tone is not significant [$F(3,57)=1.73$, $p>0.05$], the significant interactions Final tone × Intonation type [$F(2.29,43.59)=15.94$, $p<0.001$] and Final tone × Condition [$F(3,57)=6.74$, $p<0.01$] suggest that tones affect listeners' identification depending on the intonation type and condition. For example, complete question ending with T3 (M=76%, SD=0.23) is the least well identified by listeners among the complete questions, significantly poorer than T1 (M=93%, SD=0.14, $p<0.05$). Among the cut-off utterances, T3 statement is significantly more poorly identified than statements in all other tones, whereas T3 question is significantly better identified than the other tones ($p<0.05$ in all comparisons), both owing to the rising penultimate tone due to tone sandhi. Besides, within the cut-off condition, T4 question (M=51%, SD=0.37) is significantly better identified than T1 question (M=25%, SD=0.26, $p<0.05$), suggesting that for Mandarin listeners, questions ending with T4 are still easier to identify than some other tones, even though the original final tone is cut off.

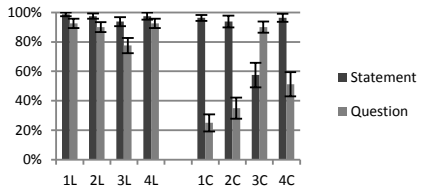

Figure 3: *IA of filtered utterances by Mandarin listeners.*

3.4. Cantonese listeners: Filtered speech

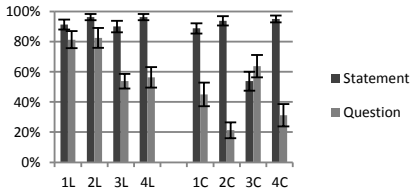

Figure 4: *IA of filtered utterances by Cantonese listeners.*

Figure 4 shows the patterns of Cantonese listeners' identification accuracy for filtered Mandarin utterances. The main effect of Intonation type [$F(1,19)=40.69$, $p<0.001$], Condition [$F(1,19)=69.82$, $p<0.001$], and Final tone [$F(3,57)=5.28$, $p<0.005$] are all significant. In the complete condition, the identification accuracy of T3 (M=54%, SD=0.22) question is significantly lower than T1 (M=81%, SD=0.25) and T2 (M=83%, SD=0.29) questions ($p<0.05$ in each comparison). In the cut-off condition, the T3 utterances end with the sandhi-ed T3 with a rising contour. As a result, the T3 cut-off question (M=64%, SD=0.33) was better identified than the other tones (comparisons with T2 (M=21%, SD=0.23) and T4 (M=31%, SD=0.33) questions were significant, $p<0.05$). The T3 cut-off statement (M=54%, SD=0.28) was identified most poorly among all the tones (significant compared with every other tone, $p<0.05$). Furthermore, unlike the patterns of Mandarin listeners, the T4 complete question (M=56%, SD=0.30) was poorly identified by Cantonese listeners, with the accuracy significantly lower than that of T1 and T2 questions ($p<0.05$ in each comparison). The identification of T2 cut-off question (M=21%, SD=0.23) was also not successful, significantly poorer than T1 and T3 ($p<0.05$ in each comparison). The perceptual patterns suggest that Cantonese speakers mainly use the final tone in their judgment, much like the way they identify intonation type in their own language. Final high level and high rising pitch contours (in the case of complete T1, T2 utterances and cut-off

sandhi-ed T3 utterances) seem to be a strong indicator for question, while a dipping tone and a falling tone (complete T3 and T4 utterances) were associated with statements.

4. Discussion

This study examined the perception of three kinds of materials: native speech as a baseline, non-native speech, and filtered-speech. In general, the listeners from both groups performed well in the complete utterance condition. There is no significant difference in IA among different tones in complete utterances, except that the IA of T3 complete question was significantly lower than the other tones. On the other hand, eliminating the last syllable affects listeners' judgment of questions, but not so much of that of statements. With the exception of sandhi-ed T3, the IA of the cut-off questions is lower than that of complete questions across listener groups and experiment contexts.

Our data show that perception of intonation is influenced by phonological knowledge. For example, Mandarin final T4 benefits question identification because native listeners are sensitive to the identity of final tone in questions [13] (Cantonese listeners also have experiences in speaking Mandarin). This seems to be the case in the normal speech context. In the cut-off condition, T4 question was hardly influenced by the loss of the final tone, and was significantly better identified than questions with all the other tones. However, when the identity of language and lexical tone were concealed from the listeners by the low-pass filter, listeners were unable to use the knowledge of tone-intonation interaction to identify questions. Therefore, the IA of T4 questions decreased for both groups of listeners, especially in the cut-off condition, suggesting that the absence of phonological knowledge affects the identification of questions.

When perceiving non-native speech, Cantonese listeners' identification of Mandarin intonation was facilitated by different tools that interacted with each other. In most cases, they used the phonological knowledge of intonation in Cantonese by locating the perceptual cue for question at the end of the utterances, as this is where the cue for their native language is placed. Then they made use of the Frequency Code to associate a high rising tone with questions and a low tone with statements. For example, they performed well in T3 cut-off questions but performed poorly for T3 complete questions. Finally, the experience in knowing Mandarin also helped them to identify questions with T4.

In the low-pass filtered speech, segmental information was eliminated and F0 became the main resource of information left in the stimuli. Therefore, the use of native phonological knowledge was restricted and the Frequency Code might have become the most, if not the only, available and useful tool for intonation perception. The listeners performed generally quite well in perceiving the low-pass filtered speech, indicating that F0 provided most information for intonation perception. The role of the Frequency Code can be observed from the results. On the one hand, the canonical T3 (low tone) is associated with a statement. On the other hand, the cut-off T3 statement ending with a rising tone was identified significantly less successfully than the other tones; and the cut-off T3 question was identified more accurately than the other tones, especially in the low-pass filtered speech, where the Frequency Code dominated the process of the perception.

To sum up, listeners process different materials differently. When listening to native speech, they primarily use their phonological knowledge of the language. For non-native speech, both the Frequency Code and some phonological knowledge were used. For filtered-speech (or non-speech), the Frequency Code becomes the most useful tool. In other words, the biologically-based universal Frequency Code lays the foundation for perception, while phonological knowledge comes into play when native speech materials are used. When phonological knowledge and the Frequency Code contradicted with each other, the former takes advantage in the perception of native language.

However, although the Frequency Code is shown to have dominated the perception of intonation in the filtered context, the perceptual patterns of the two groups of listeners were not identical. For example, the IA of T1 cut-off question is not significantly different from T3 question for Cantonese listeners, but is significantly lower than T3 questions for Mandarin listeners. T4 complete question was well identified by Mandarin listeners but not so by Cantonese listeners. These differences stem from the different language backgrounds the two groups of listeners have, suggesting that language experience shapes prosodic perception even in the low-level processing of unintelligible filtered speech. This finding echoes previous study in cross-linguistic perception of lexical tone by Huang and Johnson [31].

Finally, the results further the insights into question-statement bias previously observed in individual languages [13]. For both groups of listeners, the IA of questions was constantly lower than that of statements, especially in cut-off utterances. The fact that both groups of listeners showed the same preference towards statements suggests that the bias towards statement being an unmarked sentence type may be universal.

5. Conclusions

In conclusion, the results demonstrate that two interactions in intonation perception. One of them is the interaction between tone and intonation: no matter how intonation modifies F0 contour, at the final tone or on a sentential level, listeners are sensitive to the identity of lexical tone at the end of the utterance. Therefore, the processing of tone and intonation in tone languages is interdependent. More importantly, phonological knowledge and the Frequency Code co-direct listeners' perception of intonation, especially when listeners are given a less familiar language or filtered speech. Listeners follow the Frequency Code when phonological knowledge is not applicable. When the linguistic resources are rich in the speech signal, and when phonological knowledge and the Frequency Code conflict with each other, phonological knowledge would override the Frequency Code. As a result, listeners could perceive intonation patterns that seemingly contradict the Frequency Code in their native/familiar language. Furthermore, language background is an important and robust factor in intonation perception even with filtered speech materials, as different patterns arose from the two groups of listeners because of their language background. The results also confirm that statements are generally identified better than questions. This tendency applies to intonation perception cross-linguistically.

Segmental and prosodic cues to vowel identification: The case of /ɪ i iː/ and /ʊ u uː/ in Saterland Frisian

Abstract

Saterland Frisian has a complete set of closed short tense vowels. Together with the long tense vowels and the short lax vowels they constitute series of phonemes that differ by length and/or tenseness. We examined the cues that distinguish the front unrounded and the back rounded series of short lax and short and long tense vowels in triplets by eliciting 'normal speech' and 'clear speech' in a reading task from two speakers. Short and long vowels were distinguished by vowel duration, and lax and tense vowels by their location in the F1-F2 space. The durational difference between short tense and long tense vowels, however, was largely restricted to the 'clear speech' condition. In 'clear speech', f0 dynamics and centralization in the F1-F2 space were used as additional means to make short tense vowels more distinct from long tense vowels. These results suggest that length and tenseness are used as distinctive features, while f0 dynamics and centralization in the F1-F2 space were optionally used to enhance the contrast between short and long tense vowels.

Index Terms: f0 dynamics, f0 excursion, formants, Saterland Frisian, tenseness, vowel duration

1. Introduction

Saterland Frisian is spoken in three small villages – Strücklingen, Ramsloh and Scharrel – in the north-western corner of the district of Cloppenburg in Lower Saxony. It is the only remaining living variety of Old East Frisian, which was spoken along the coasts of the Netherlands and Lower Saxony. Saterland is believed to have been colonised by Frisians from the coastal areas in the eleventh century. According to the most recent count, Saterland Frisian is spoken by 2250 speakers [1].

Saterland Frisian has a complete set of closed short tense vowels: /i y u/ [2], [3], [4]. Together with the short lax vowels /ɪ ʏ ʊ/ and the long tense vowels /iː yː uː/ they constitute series of phonemes that differ by length and/or tenseness. Potential acoustic cues which distinguish the vowels in a triplet may be vowel duration, spectral features (F1, F2) as well as the timing and scaling of f0.

In this paper we investigate which acoustic cues distinguish the sounds within two triplets containing /ɪ i iː/ and /ʊ u uː/ respectively. For each of the two triplets we conducted a traditional reading task and a listener-directed task, which maximizes the discrimination between words and is an effective way to reveal potential segmental and prosodic cues.

Several studies show that vowels with stronger f0 dynamics are perceived as being longer. Lehiste [5] found that listeners perceived a falling-rising or rising-falling f0, as opposed to a flat f0 pattern, to be longer even when the stimuli have the same acoustic duration. Yu [6] found the same effect for dynamic versus flat f0 and also showed that syllables with higher f0 are heard as longer than syllables with lower f0. Cumming [7] was able to show the perceived lengthening effect of dynamic f0 for native speakers of Swiss German, Swiss French and French. This effect is likely language-specific [8].

The acoustic cues, which add to the distinction of vowels in Saterland Frisian triplets have not yet been fully studied. Siebs [9] distinguishes between tone accents in Saterland Frisian (*Stoßton* versus *Schleifton*) which suggests that f0 might play a role. In a more recent study Tröster-Mutz [10] [11] investigated the phonetics of Saterland Frisian vowels, but did not find any evidence for tone accent differences in present-day Saterland Frisian. In this paper, we focus on the question whether f0 dynamics have any systematic effect which may help to discriminate between the vowels of each triplet.

2. Method

2.1. Material

The two triplets used are still known by a restricted number of Saterland Frisian speakers. For the closed front vowels /ɪ i iː/ we used *Smitte* 'forge', *smiete* 'to throw' and *Smíete* 'throws' (pl.). The closed back vowels /ʊ u uː/ were elicited by the triplet *ful* 'full', *fuul* 'rotten' and *fúul* 'much'.

2.2. Procedure

For each of the triplets we conducted two experiments, one eliciting 'normal speech' and another eliciting 'clear speech'. The experiments were carried out by two female native speakers, aged 78 and 66 years, henceforth referred to as subject 1 and subject 2 respectively. The two speakers are born and raised in Ramsloh and have lived in this village most of their lives. We chose Ramsloh since it is located in the center of Saterland and its Saterland Frisian variety is considered to be the most conservative [3].

2.2.1. Normal speech

In this experiment Saterland Frisian words were presented in written form to the two native speakers on a computer screen, one word at a time. We used twelve different words: six triplet words (*ful*, *fuul*, *fúul*, *Smitte*, *smiete*, *Smíete*), and six filler words (*Pot*, *Paad*, *Kat*, *leet*, *Täk*, *Poot*).

A session consisted of four blocks in which each of the 12 words was presented four times. Within each block the order of the words was randomized, so that a word was never followed by the same word or by a word belonging to the same triplet. Three of the six filler words (*Pot*, *Paad* and *Kat*) were also used

as a short practice, preceding the first block. In sum, 195 words were presented in one session.

We obtained 16 samples per subject per triplet word. Looking for cues concerning the f0 dynamics, only samples with a clear f0 peak in the vowel can be used for the analysis. The number of word samples which satisfy this condition is given per triplet word and per subject in Table 1.

2.2.2. Clear speech

Saterland Frisian words were presented in written form to the two native speakers on a computer screen. In this condition, only the six triplet words were used. For maximum discrimination, a triplet word was always presented together with the two other triplet words. The word to be pronounced was encircled and displayed in blue (the other words were black). The three words of a triplet were located on the screen so that they were imaginary vertices of a triangle. Each 'triangle' was rotated over an arbitrary angle.

One session consisted of four blocks. Each of the triplet words was presented eight times per block. Within a block, 24 words of the /ʊ u uː/ triplet were presented first, followed by 24 words of the /ɪ i iː/ triplet. Thus, in each block 48 words were pronounced. In each part the words were presented in a randomized order so that a word was not followed by the same word.

In this experiment, the subjects were either speaker or listener and changed roles after each block. When one subject read the words aloud, the other subject marked the triplet word she thought she heard. The reader and the listener were separated by a screen during the experiment.

We obtained 16 samples per speaker per triplet word. Just as for 'normal speech' we limited the analysis to word samples with a clear f0 peak when looking for cues concerning the f0 dynamics. The number of word samples with f0 peak are given per triplet word and per speaker in Table 1.

Table 1: *Number of word samples with a clear f0 peak per triplet word and per subject.*

	Normal speech		Clear speech	
	sub1	sub2	sub1	sub2
Smitte	14	16	15	14
smiete	15	16	16	15
Smíete	13	16	16	16
ful	1	13	6	5
fuul	10	16	5	11
fúul	7	15	15	10

2.3. Acoustic variables

Segmental and prosodic variables were measured with PRAAT [12]. For each word belonging to the /ɪ i iː/ triplet we measured the duration of each of the segments: /s/, /m/, V, /t/ and the final schwa. The duration of /t/ was split into two parts: the time from the beginning of the segment to the burst (t1), and from the burst to the end of the segment (t2). We also measured spectral variables F1 and F2 at the center of the vowel.

We measured f0 variation in the interval from the beginning of /m/ to the end of V. When the f0 peak was somewhere in this interval, we considered a rise and a fall. F0 dynamics was operationalized by calculating the relative f0 excursion in semitones per millisecond, which was obtained by calculating the sum of the f0 rise size (pitch of f0 peak minus pitch at the beginning of the interval) and the f0 fall size (pitch of f0 peak minus pitch at the end of the interval) divided by the duration of the interval. A related approach was used by Grabe [13].

For each word belonging to the /ʊ u uː/ triplet we likewise measured the duration of each of the segments, /f/, V, and /l/, and F1 and F2 at the center of the vowel. When measuring relative f0 excursion, we focused on the interval starting at the beginning of V and ending at the end of /l/.

2.4. Statistical processing

We looked for acoustic cues that distinguish all of the sounds within a triplet. Per acoustic variable we used a Generalized Linear Model (GLM) where the stimulus was the independent variable and the acoustic variable the dependent variable. Since not all of the acoustic variables are normally distributed, GLM was the fitting test. The stimuli were the triplet words, therefore the stimulus variable was a three level factor. Two-tailed p-values obtained from pairwise comparisons were adjusted using the Bonferroni correction.

The variables were initially analyzed per subject and per triplet. However, in this paper the results of the subjects are combined by showing the consensus. For example, when we found $p < 0.01$ for the one subject, and $p < 0.001$ for the other subject, then the consensus is considered to be $p < 0.01$. When we do not find a significant effect for both of the subjects for a particular variable or a significant difference in opposite direction, no significance is reported. In the tables below, levels of significance are indicated by asterisks: $*< 0.05$, $**< 0.01$ and $***< 0.001$.

3. Results

3.1. Normal speech

3.1.1. Results /ɪ i iː/ triplet

Duration values for the /ɪ i iː/ triplet are shown in the upper panel of Figure 1. Vowel plots are found in Figure 2 and f0 contour plots in Figure 3. Statistical results are summarized in Table 2. *Smitte* is distinguished from *Smíete* by a shorter vowel duration, a higher F1, a lower F2, and smaller f0 dynamics. *Smitte* differs from *smiete* by a shorter vowel duration, a higher F1, a lower F2, a smaller fall size and smaller f0 dynamics. The triplet word *smiete* is distinguished from *Smíete* by larger f0 dynamics. Hence, tense short vowels have largest f0 dynamics.

3.1.2. Results /ʊ u uː/ triplet

Duration values for the /ʊ u uː/ triplet are shown in the lower panel of Figure 1. Vowel plots are found in Figure 2 and f0 contour plots in Figure 4. Statistical results are summarized in Table 3. In Table 1 we find that *ful* is represented by just one sample in the normal speech experiment. Therefore comparisons between *ful* and *fuul* and between *ful* and *fúul* are based on subject 2 only. The triplet word *ful* has a smaller vowel duration and higher F1 and F2 values than the other triplet words. Additionally, *ful* has a smaller /f/ duration then *fúul*. The triplet words *fuul* and *fúul* are not distinguished, i.e. short tense and long tense vowels are not distinguished.

3.2. Clear speech

3.2.1. Results /ɪ i iː/ triplet

Duration values for the /ɪ i iː/ triplet are shown in the upper panel of Figure 1. The clear speech graph shows a stronger contrast

between short vowels and long tense vowels than the normal speech graph. The vowel plots are found in Figure 2. Unlike in normal speech, short tense and long tense front vowels are separated in the acoustic vowel space in clear speech. Figure 3 shows that the difference between rise size and fall size in clear speech has decreased compared to normal speech. Statistical results are summarized in Table 2. The number of variables that distinguish triplet words is much larger in clear speech than in normal speech. When comparing *Smitte* and *Smíete* we find smaller values for the duration /m/, V, t2 and /ə/, a higher F1, a lower F2 and a smaller rise size. We get the same findings when comparing *smiete* and *Smíete*, but rise size is not significant and *smiete* has larger f0 dynamics than *Smíete*. *Smitte* has a smaller vowel duration, a higher F1, a lower F2, a smaller fall size and smaller f0 dynamics than *smiete*. V duration, F1 and F2 distinguish all of the triplet words.

3.2.2. Results /ʊ u uː/ triplet

Duration values for the /ʊ u uː/ triplet are shown in the lower panel of Figure 1. Again, the clear speech graph shows a stronger contrast between short vowels and long tense vowels. The vowel plots are given in Figure 2. Eventhough there is still some overlap in the acoustic vowel space for the long and short tense back vowels, the spread and the mean formant values show a clearer separation for the two sounds compared to the normal speech conditon. The f0 contour plots in Figure 4 show a longer f0 fall duration for the long tense vowel compared to the two other vowels. Statistical results are presented in Table 3. *ful* is distinguished from *fúul* by a smaller vowel duration and a higher F1 and F2. *fuul* has a smaller vowel duration, a higher F2, and larger f0 dynamics than *fúul*. *ful* is distinguished from *fuul* by a higher F1.

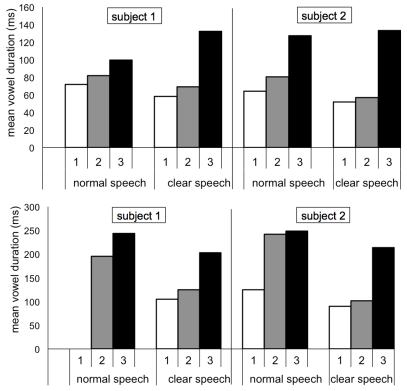

Figure 1: *Duration values for normal speech and clear speech. On top the /ɪ i iː/ triplet (1=Smitte, 2=smiete, 3=Smíete) and at the bottom the /ʊ u uː/ triplet (1=ful, 2=fuul, 3=fúul).*

3.3. Consensus of triplets

In Table 4 we show consensus results of the two triplets. For normal speech we find that lax vowels are distinguished from tense vowels by a higher F1 and a lower (/ɪ i iː/ triplet) or higher (/ʊ u uː/ triplet) F2. Additionally, short lax vowels are distinguished from long tense vowels by a smaller vowel duration. Short tense and long tense vowels are not distinguished by any variable in the normal speech data.

We find that lax and tense short vowels are distinguished only by a higher F1 in clear speech. Short lax vowels are

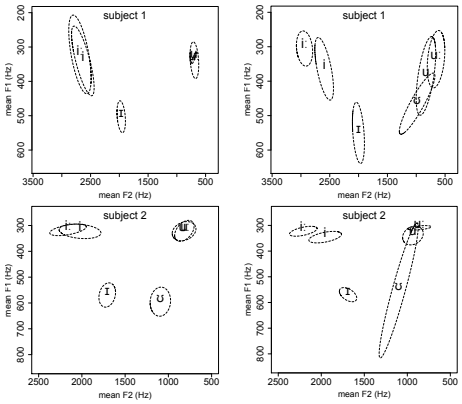

Figure 2: *Vowel plots show the mean formant values of the six triplet sounds for normal speech (left) and clear speech (right). Ellipses enclose two standard deviations.*

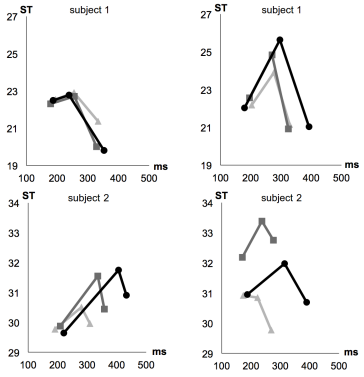

Figure 3: *f0 contours for the /ɪ i iː/ triplet in normal speech (left) and clear speech (right) for subject 1 (top) and subject 2 (bottom). Lighter gray lines with triangles represent short lax vowels, darker gray lines with squares represent short tense vowels, and black lines with circles represent long tense vowels.*

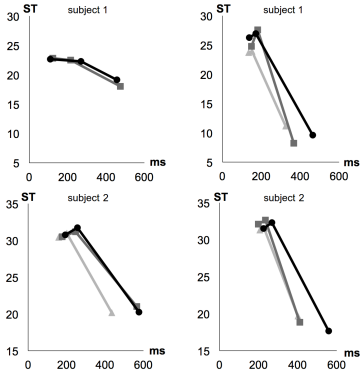

Figure 4: *f0 contours for the /ʊ u uː/. For graphical conventions see Figure 3.*

distinguished from long tense vowels by the same variables as for normal speech. In contrast to normal speech, short tense vowels and long tense vowels are clearly distinguished. Short tense vowels have a smaller vowel duration, a lower (/ɪ i iː/ triplet) or higher (/ʊ u uː/ triplet) F2, and larger f0 dynamics than long tense vowels.

Table 5 shows percentages of stimuli that were correctly predicted on the basis of V duration, F1, F2, and f0 dynamics, and which were obtained by Linear Discriminant Analysis. As expected, percentages for clear speech are higher than for

4. Conclusions

We found that vowel duration, spectral variables, and f0 dynamics are cues for the distinction of vowels in two Saterland Frisian word triplets.

Vowel duration. From Table 4 we conclude that vowel duration implements the phonological feature [± long]. In normal speech short lax and long tense vowels are distinguished by vowel duration, whereas in clear speech short tense and long tense vowels are also distinguished, suggesting a division in short and long vowels.

F1 and F2. Table 4 suggests that the feature [± tense] is implemented by spectral features. Lax vowels have a higher F1 and a lower (/ɪ i iː/ triplet) or higher (/ʊ u uː/ triplet) F2 than tense vowels, i.e. lax vowels are more centered than tense vowels (cf. Figure 2). Gussenhoven [14] observed that closed vowels are perceived as relatively longer than open vowels, which suggests that lowering of F1 may increase perceived vowel duration, which can be explained by a tendency of listeners to compensate for the intrinsically shorter duration of closed vowels. In view of this finding, the slight additional centralization of the short tense vowels (/i/ and /u/ cf. Figure 2) relative to /iː/ and /uː/ may be used to enhance the perceived durational contrast between the short and long tense vowels.

Table 5: *Discriminant percentages per triplet word and per subject. For each subject important variables contributing to discrimination are marked by 1 and/or 2.*

triplet	sp. type	V dur	F1	F2	f0 dyn.	sub1 %	sub2 %
/ɪ i iː/	norm.	1,2	1,2	1,2	2	90.5	91.7
	clear	1,2	1,2	1,2		100	100
/ʊ u uː/	norm.		1,2	1	2	55.6	65.9
	clear	1,2	1,2	1,2	1	92.3	96.2

F0 dynamics. Short tense vowels were found to have larger f0 dynamics than long tense vowels and, in case of [ɪ], short lax vowels (cf. Figures 3 and 4). According to [5] and [7], increased f0 dynamics may enhance perceived vowel duration. As shortening of /i/ and /u/ in clear speech resulted in vowels that were hardly longer than the short lax vowels [ɪ] and [ʊ], increased f0 dynamics may increase the perceived durational difference between short lax and tense vowels, at least in the case of [ɪ] and [i]. We found that f0 dynamics have a systematic effect which contributes to the tripartite vowel contrast. The most likely interpretation of this contribution is phonetic feature enhancement. The possibility that variation of tonal structure is involved as suggested by Siebs' terms *Stoßton* and *Schleifton* [9] cannot be determined on the basis of our current data, but we will investigate this in a later study.

Overall, our data suggest that the phonological contrasts between [ɪ i iː] and between [ʊ u uː] can be accounted for by the combination of two distinctive features, [± long] and [± tense]. The slight centralization of /i/ and /u/ relative to /iː/ and /uː/ in clear speech may be used to enhance the durational contrasts between the short and long tense vowels. Increased f0 dynamics of tense short vowels relative to lax short vowels, which was found for [ɪ] and [i], may be regarded as a means to make the short tense vowels sound more different from the short lax vowels.

Kohler [15] investigated triplets of closed vowels in High German and in Low German dialects spoken in Schleswig-Holstein and Lower Saxony. In some dialects he found that lax and tense vowels within a triplet differ qualitatively, and short and long tense vowels differ quantitatively. Just as Kohler we found that short lax and tense vowels are distinguished by spectral features only. The clear speech experiment revealed that short and long tense vowels are dinstinguished by vowel duration, F2, and f0 dynamics, being a combination of qualitative and quantitative variables.

5. Acknowledgements

We would like to thank the two Saterland Frisian informants for participating in our experiments. We are grateful to Darja Appelganz and Nicole Mayer for labeling the recordings in PRAAT. The research reported in this paper has been funded by the *Deutsche Forschungsgemeinschaft* (DFG), grant number PE 793/2-1.

Abstract

The present study investigates the prosody of yes/no questions (in comparison with statements) in Chinese learners and native speakers of Italian. Acoustic analyses and a perceptual test were performed, in order to identify the main trends in non-native productions. Results show the relevance of prosody, which differentiates elementary, intermediate and advanced Chinese learners of Italian. Listening tests based on prosody transplantation also suggest that non-native segments with a native Italian prosody are rated as less accented than are native Italian segments with a non-native prosody. Similar trends were found, overall, in terms of question/assertion discrimination, confirming the relative importance of prosody. These findings could be helpful for teachers and learners of Italian as a foreign language.

Index Terms: L2 Italian, yes-no questions, Chinese learners, prosody acquisition

1. Introduction

To acquire a good command of prosody in a second language (L2), it is crucial to identify the most salient patterns of the target language and to determine the main tendencies observed in the performance of L2 speakers. In L2 Italian, especially, the teaching of prosody often focuses on questions: this speech act is very important in everyday communication and it is introduced early in language classes [1].

A large body of research has concentrated on problems caused by question intonation. Ullakonoja [2] as well as Santiago-Vargas and Delais-Roussarie [3], for instance, were interested in the challenges posed by yes/no questions to Finnish learners of Russian and Mexican Spanish learners of French, respectively. The present study investigates problems faced by Chinese learners of Italian as an L2, when asking yes/no questions. It intends to better understand how speakers of a tone language perform in a non-tone language. Chinese questions have to preserve, to some extent, lexical tone pitch variations in order to keep the utterance meaning unchanged [4], whereas the Italian language distinguishes between questions and statements by intonation alone. Questions are usually marked by a rising-falling pitch movement on the last stressed syllable of the utterance (most often the penultimate syllable), at least in southern varieties of Italian [5] [6] [7]. Even though a common strategy is observed in the two languages under consideration in the present study, namely an overall higher pitch range in interrogative utterances [8] [9], interferences between the Italian and Chinese systems may affect the acquisition of prosody in the L2. For an overview on the prosody of yes/no questions, see [5] [7] for Italian, and [10] for Chinese.

This study compares statements and yes/no questions produced by both Chinese learners (of various proficiency levels in Italian) and native speakers of Italian. It combines acoustic analyses and a perceptual test using prosody transplantation. This paradigm [11] consists of copying prosodic parameters from a native Italian utterance to a non-native one and vice versa. Unlike previously used techniques such as low-pass filtering [12], the method preserves comprehensibility: it thus yields a more ecological speech material. It was applied to various language pairings [13] [14]: in particular, it was used so as to disentangle the contribution of prosodic features (melody and global timing) and segmental features to the perception of accentedness and intelligibility in German-accented English and English-accented German. Here, the same methodology was used in order to evaluate the contribution of prosody to the perception of Chinese foreign accent and to the discrimination between questions and statements in Italian. The method, materials and results are described below.

2. Corpus

2.1. Speakers and material

For this study, 4 native Italian speakers and 12 Chinese learners of Italian (all females, aged 24 on average) were recorded. The learners, all speakers of Mandarin Chinese, belonged to three groups (each composed of 4 students) according to their level of competence in Italian (elementary, intermediate, advanced). All speakers lived in the Naples region (southern Italy).

Native and non-native speakers were recorded while reading a short dialogue in Italian, including 7 yes/no questions. These questions varied in length (between 5 and 11 syllables each), but they all ended with a paroxytone (that is, a word stressed on the penultimate syllable). This choice was determined by the need to avoid stress-related variation and by the frequency of this stress pattern in Italian: the Italian vocabulary is mostly composed of paroxytone words (in over 75% of cases [15]). Speakers were then instructed to read the same questions in the declarative modality — word order does not change in Italian. The corpus analysed below was therefore made up of 112 questions and 112 statements. Examples of sentences are given in § 3.2.

2.2. Acoustic analysis

The 224 resulting utterances (as many questions as statements) were analysed to identify prosodic differences between native and non-native speakers of Italian, as well as across the three learner groups. For each utterance, mean pitch, the number and duration of inter-pause speech intervals, the number of syllables per inter-pause speech interval, the duration of silent pauses and disfluencies were computed. The speech articulation rate (excluding pauses), phonation rate (including pauses), tonal range (between maximum and

minimum defined pitch values) and the percentage of disfluencies were calculated. Furthermore, fundamental frequency (f0) values were measured at the midpoint of each of the last three syllables, for each utterance. These measurements were taken using the Praat software [16].

Mean pitch differences in semitones (ST) between questions and statements were averaged for each speaker group. In each group, questions are higher than statements: by 0.5 ST for elementary learners, 0.2 ST for intermediate learners, 1.7 ST for advanced learners and 0.8 ST for native speakers. Hence, no clear tendency seems to emerge.

Results of the other acoustic analyses are shown in Table 1. As expected, the speech articulation rate and phonation rate of elementary learners are lower than those of the other two learner groups and those of native speakers. Note that already at an intermediate level of language proficiency, Chinese learners are able to properly manage duration-related variations. Intermediate learners, together with the advanced learner group, show values very close to the native model, partly due to our native speakers' tendency to hyperarticulate.

Table 1. *Acoustic measurements: articulation rate (syll./s), phonation rate (syll./s), tonal range (semitones), % dis. (percent time of disfluencies) within questions (Q) and statements (S).*

Speaker group	Q	S
	Articulation rate	
Elementary L2	3.8	3.8
Intermediate L2	5.2	5.1
Advanced L2	5.5	5.0
Native Italian	5.4	5.3
	Phonation rate	
Elementary L2	3.3	3.7
Intermediate L2	5.1	5.0
Advanced L2	5.5	5.0
Native Italian	5.4	5.3
	Tonal range	
Elementary L2	12.6	8.3
Intermediate L2	7.2	7.9
Advanced L2	7.7	7.2
Native Italian	9.4	13.7
	% dis.	
Elementary L2	3.2	0.0
Intermediate L2	0.1	0.2
Advanced L2	0.0	0.0
Native Italian	0.0	0.0

As for the tonal range of both questions and statements, the three groups of Chinese learners seem to be unable to produce varied pitch movements as native Italian speakers do. On average, non-native speakers' tonal range is more reduced than that of native speakers — by 4 ST. Interestingly, the only exception stems from questions asked by elementary learners. Because of their linguistic insecurity (their uncertainty and lack of confidence in how to pronounce words properly), these speakers tend to produce creaky-voiced vowels and sometimes a high-rising terminal tune, resulting in a tonal range even wider than that of native speakers.

As far as disfluencies are concerned, they mainly come from elementary learners of Italian. Due to the use of read speech, they are very few (only 3% of utterance duration). They mainly consist of self-repairs and repetitions.

In addition to this, the final pitch contours of the 224 sentences of the corpus were analysed in detail. Results are displayed in Figure 1 in semitones calculated with respect to the minimum f0 measure (172 Hz). The comparison of Fig. 1a and 1b shows that the involved native Italian speakers' terminal pitch range is higher in questions than in statements (with a 3.6 ST difference). The average f0 range difference between questions and statements is 3 ST in the case of advanced learners. For the other two groups of Chinese speakers, f0 values are quite similar between the speech acts considered: the measured increase in questions is only 1.1 ST for intermediate learners and 0.7 for elementary learners.

In question-final syllables, the involved native speakers produced a slight upward-downward curve, which is the typical pitch movement of the Italian language (or at least its Neapolitan variety), as evidenced by the literature (e.g. [7]). The group of elementary learners, on average, displayed no movement at all but instead produced a flat pitch curve. It should be noted however that, in contrast with this general trend, several beginners' questions exhibit a rising pitch movement on the very last syllable, which sounds foreign as will be confirmed by the perception test. A flat pitch pattern can also be found in the intermediate speakers' productions, whereas the advanced learners' pitch rise on the penultimate (stressed) syllable is closer to the native Italian model (see Figure 1a).

In statements, a sharp pitch fall is noticeable only in native Italian speakers. The three groups of Chinese learners, on average, show gradual downstep towards the utterance-final syllable (see Figure 1b).

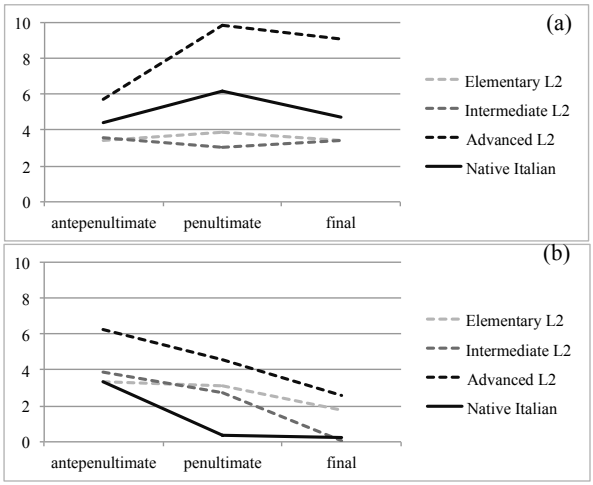

Figure 1: *Last three syllables (average values in semitones) of questions (a) and statements (b).*

3. Perceptual test

3.1. Protocol and listeners

A perceptual test was then conducted to check whether and to what extent there was an audible improvement of prosody from Chinese elementary, intermediate and advanced learners to native Italian speakers, in terms of native-likeness and communicative effectiveness. More precisely, this test aimed at evaluating speakers' degree of foreign accent and

possible difficulties encountered by Italian listeners in properly identifying questions and statements. These difficulties are expected to be primarily related to prosody, rather than to the segmental level. As regards the perception of a foreign accent, it may be due to both prosodic and segmental levels [11] [14]. For this purpose, the prosody transplantation technique was used so as to exchange native and non-native acoustic-prosodic features, phoneme by phoneme. It relied on the PSOLA algorithm implemented in Praat, which allows phoneme durations to be matched, between two realisations of a given utterance, before grafting the f0 curve of version 1 onto version 2 and vice versa.

The perceptual test was administered to 40 native Italian listeners (18 males and 22 females, aged 34 on average) with no reported history of hearing impairment, coming from various regions of Italy. Almost all of them (34 out of 40) were experts in the field of language and phonetics research. However, none of them could speak an Asian or a tonal language.

3.2. Material and tasks

Out of the 84 questions produced by Chinese learners of Italian (7 × 4 per group), 12 questions were used for the perceptual test. Nine of these sentences, uttered by 3 different speakers from each of the 3 learner groups, had the following structures: *È una cosa che si usa spesso?* 'Is it something often used?', *Questo oggetto si trova in casa?* 'Is this object in the house?', *Si usa quando si è stanchi?* 'Is it used when somebody is tired?'. Another 3 questions, uttered by another speaker from each of the 3 learner groups, had the following structure: *È un(a)* 'Is it a' + Noun, with Noun being *divano* 'sofa', *persona* 'person' or *oggetto* 'object'. In addition, 12 questions were selected among the native Italian speakers' corresponding renditions, in such a way that each learner group was associated with 4 different Italian voices producing each of the 4 selected questions. Prosody transplantation was then performed, thus generating 24 additional stimuli. The same type of selection and prosody transplantation procedure was carried out for statements. The question + statement samples finally used in the perceptual test were therefore composed of:

- 12 Q + 12 S original non-native Italian utterances (4 + 4 elementary, 4 + 4 intermediate and 4 + 4 advanced);
- 12 Q + 12 S original native Italian utterances, selected so as to never have the same voice repeating the same utterance and to have different voices associated with each of the three learner groups;
- 12 Q + 12 S utterances with native Italian segments and a non-native prosody;
- 12 Q + 12 S utterances with non-native segments and a native Italian prosody.

The 96 resulting stimuli were administered to the 40 listeners in different random orders, through an online interface (http://www.audiosurf.org/test_perceptif_marilisa/). Participants were informed that the experiment dealt with the Italian language spoken by native and non-native subjects, and that they would listen to excerpts of original or acoustically-modified speech. They were advised to use headphones or earphones.

Subjects first provided autobiographical information (age, education, place of residence, etc.). Also, they were asked very general questions, before a short familiarisation phase with the types of stimuli. They first listened to examples of native/non-native, original/manipulated statements and questions (not used in the actual test). For each utterance, they were then asked to:

- assess the degree of foreign accent on a continuous 0–5 scale (0 = no foreign accent; 5 = very strong foreign accent);
- identify the correct speech act, discriminating between "question" and "statement".

To accomplish the first task, a slider was provided (by default located in the middle of the scale); for the second task, participants had to click on buttons. They could listen to each stimulus as many times as they needed, but it was not possible to correct previous answers once a new stimulus was displayed.

At the end of the test, listeners were asked other questions (1) to indicate the speakers' most salient and characteristic linguistic cues and (2) to identify the native and non-native speakers' geographical and linguistic backgrounds.

3.3. Results

The results of the perceptual test are reported in Table 2. On the basis of original stimuli, analyses of variance (ANOVAs) were carried out separately on listeners' responses, in terms of rating and correct speech act identification, with the two fixed factors Modality (question or statement) and Level group (elementary, intermediate, advanced or native). On the basis of prosody-transplanted stimuli, a second series of ANOVAs was performed on listeners' responses, with the two fixed factors Modality (question or statement) and Type of stimulus (6 levels: see Table 2b).

The degrees of foreign accent attributed by listeners to the original stimuli gradually decrease from elementary learners to native speakers of Italian (Table 2a). The Italian pronunciation of Chinese speakers improves linearly, in both questions and statements, and L1 Italian speakers (with a 0.1 degree of foreign accent) are properly identified as native speakers. Differences related to Modality are not significant, but differences across Level groups are significant [$F(3, 1960) = 2387$; $p < 0.001$] — the interaction between the two factors is marginal. Tukey's HSD post hoc test shows that all differences across Level groups are higly significant.

Responses in terms of question/statement discrimination display slightly different patterns, with significant differences related to Modality [$F(1, 3928) = 10$; $p < 0.001$], significant differences across Level groups [$F(3, 3928) = 123$; $p < 0.001$] and a significant interaction between the two [$F(3, 3928) = 12.7$; $p < 0.001$]. As in accent ratings, a linear progression is observed in the speech act identification of statements. In contrast, beginners' questions are better recognised than are intermediate students' questions, probably due to the fact that the elementary level speaker group sometimes produces high-rising terminal tunes. These pitch rises on utterance-final syllable rather than on the last stressed syllable of the question do sound foreign but they may be effective from a communicative point of view.

The use of acoustically modified stimuli allowed us to tease apart the influence of prosodic (suprasegmental) level and segment articulation in terms of both foreign accent rating and question/statement discrimination. As shown in Table 2b,

the stimuli with non-native segments and a native Italian prosody are perceived as having a slight foreign accent, whereas the stimuli with native Italian segments and a non-native prosody are perceived as more strongly foreign accented. Differences related to Modality are not significant, but the Type of stimulus has a major effect [$F(5, 1908) = 101$: $p < 0.001$] — the interaction between the two being marginal. Post hoc comparisons (Tukey's HSD test) show that stimuli containing native Italian prosody form a homogeneous subset, but differ significantly from the other stimuli.

A similar trend is observed concerning the speech act identification of questions vs. statements. Differences related to Modality are still not significant, but the Type of stimulus has a major effect [$F(5, 1908) = 87.1$: $p < 0.001$] and the interaction between the two is here significant [$F(5, 1908) = 2.23$; $p < 0.05$]. Subsequent post hoc comparisons (Tukey contrasts) show that stimuli with non-native segments and a native Italian prosody are discriminated significantly better than stimuli with native Italian segments and a non-native prosody. Both questions and statements with the native Italian prosody turn out to be identified almost perfectly by the listeners, regardless of possible mispronunciations at the segmental level. By contrast, the superimposition of the non-native rhythm and intonation on native Italian productions dramatically reduced question/statement discrimination.

Table 2. *Average degree of perceived foreign accent and speech act identification of the original (a) and manipulated (b) stimuli Q = questions; S = statements.*

(a) Original stimuli		
Speaker group	Q	S
	Degree (/5)	
Elementary L2	4.3	4.1
Intermediate L2	3.7	3.6
Advanced L2	2.6	2.6
Native Italian	0.1	0.1
	% Q/S Id	
Elementary L2	59	48
Intermediate L2	41	72
Advanced L2	73	82
Native Italian	100	99

(b) Manipulated stimuli			
Prosody donor	Prosody receiver	Q	S
		Degree (/5)	
Elementary L2	Native Italian	3.6	3.5
Intermediate L2	Native Italian	2.4	2.7
Advanced L2	Native Italian	1.8	1.8
Native Italian	Elementary L2	1.6	1.4
Native Italian	Intermediate L2	1.8	1.6
Native Italian	Advanced L2	1.7	1.5
Prosody donor	Prosody receiver	Q	S
		% Q/S Id	
Elementary L2	Native Italian	59	56
Intermediate L2	Native Italian	62	73
Advanced L2	Native Italian	69	76
Native Italian	Elementary L2	98	98
Native Italian	Intermediate L2	97	98
Native Italian	Advanced L2	99	96

In their final comments, most listeners (about 30) mentioned intonation and rhythm among the features which helped them make their decisions. Also, 30 subjects properly identified the regional origin of native speakers (i.e. Campania) and the linguistic background of non-native speakers (i.e. Chinese). Most of them reported an average familiarity with Chinese-accented Italian, which suggests that their evaluations were relevant.

4. Conclusions

This study based on Chinese learners of Italian as an L2 included acoustic analyses and a perception test in which suprasegmentals took precedence over segmentals, as in a previous study focusing on Spanish-accented Italian [11]. It highlighted the importance of focusing on prosody in order to improve both native-likeness and communicative effectiveness, at least as far as the perception of questions and statements is concerned. Overall, the more proficient the speakers, the better their questions are judged. However, results suggest that Chinese learners of Italian, a non-tonal language, succeed in producing yes/no questions in an appropriate manner only if they have acquired an advanced level of proficiency in the L2. It therefore seems important to point out the main problems faced by Chinese speakers of Italian, in order to give them feedback when learning the Italian yes/no question prosody.

Primarily, the pitch range of questions and statements need to be differentiated, since it is usually more extended in the case of questions. When asking questions ending with paroxytone words (a frequent pattern in Italian), Chinese learners of Italian should also be taught to realise a rising-falling pitch movement on the penultimate, prominent syllable of the utterance. Particular attention must be paid to beginners' tendency to produce a pitch rise on the utterance-final syllable: even if this intonational movement is communicatively effective in the sense that it is prone to be interpreted as a question contour, it is far from the native Italian model and sounds foreign.

The Chinese speakers under investigation here were also recorded in their L1. Acoustic analyses of their native productions are currently in progress and provide interesting comparisons. Finally, the results presented here need to be validated by further studies on spontaneous speech, to provide a clearer picture of question intonation in Italian as a foreign language. The understanding of questions in conversational speech will undoubtedly be another challenge.

5. Acknowledgements

This work was done during the first author's stay at LIMSI-CNRS, financed by an Erasmus Placement grant. We are grateful to all the speakers and listeners who volunteered to take part in the experiments.

Abstract

To support text-to-speech with detailed prosody rules and to generate natural prosody, the paper studied the pitch variation near the end of sentences based on a Chinese Mandarin natural dialogue corpus. An additional lowering effect on the last prosodic word was found in both questions and statements, and proved to be independent of tone influence. Nevertheless, this effect, which is referred to as final lowering in other languages, was claimed to be absent in Chinese by some previous experimental studies. Such a contradiction is very likely to be caused by the difference between experimental speech versus natural speech. Based on this observation, the paper proposed a combination of the two methods in intonation studies, in which experimental speech served as an entry point to develop new topics, while natural speech served as a necessary extension to revise and apply prosody rules.

Index Terms: intonation, questions, final lowering, spontaneous speech

1. Introduction

In many languages, pitch within an utterance tends to drift down, especially in statements. There are many factors accounting for the pitch downtrend. One is the declination effect, which refers to the general tendency of pitch declination over the course of an utterance [4][6][9][12][14]. Another is final lowering, indicating an additional lowering effect near the end of the sentence [5][7]. Besides, there is also a downstep effect, which means that pitch lowering can be triggered by former syllables that carry low tones/accents [1]. Experimental studies of Mandarin showed the presence of declination and downstep [16][17][18], but the absence of final lowering [12]. In Chinese Mandarin, the downstep effect is supposed to be triggered by both low tone T3 and neutral tone T5 [12][16][17]. When it comes to questions, the downtrend is considered suppressed [14].

There have already been a considerable number of intonation studies on questions of Chinese Mandarin. Features of questions in Mandarin were put forward as: a) trends of top/base-lines, Shen, Jiong adjusted Gårding's grid model and suggested a gentle fall on the top-line and a slight rise on base-lines for questions [3][10]; b) starting point, Shen, Xiaonan suggested that all types of questions begin at a register higher than statements [11]; c) boundary tone, Lin, Maocan adopted AM theory and underlined the role of boundary tone in the distinction of interrogative and declarative moods [8]; d) phrase curve and strength, Yuan, Jiahong thought interrogation to be expressed by an overall higher phrase curve and higher strength on final syllables in Chinese [19].

However, the above conclusions cannot fully satisfy the needs of speech synthesis. For one thing, these studies mainly focused on the general intonation trend of questions [10][11][19], but neglected the concrete details of pitch variation within sentences. Is pitch variation distributed evenly over the whole sentence, or is it mainly realized by certain parts of the sentence? Such questions still remain disputable. For another, in order to generate natural prosody, conclusions from experimental works should be checked and revised in natural speech. Since Chinese Mandarin is a tone language, previous intonation research tends to adopt designed stimuli to arrange tone types [12][16][17][18][19][20], while research on spontaneous speech is relatively few. To make up for these inadequacies, we particularly studied the pitch variation near the end of questions and statements by using a large-scale natural dialogue corpus, with the purpose of providing speech synthesis with more detailed prosody rules, and thereby making contributions to generating natural prosody.

2. Corpus

Our research is based on a large-scale Q&A conversation corpus. The corpus contains more than 4000 sentences, i.e., more than 2000 turns of questions and answers, selected from interview programs. A wide range of topics are involved and sentences with less normal style were rewritten. These conversations were transliterated and then re-read by a trained male speaker in a professional recording studio to make sure that F0 values of different sentences come from the same speaker and are comparable. During the recording process, the speaker was required to maintain a natural speaking style without act or exaggeration. The corpus contains an annotation of four-level prosodic units, i.e., syllables, prosodic words, prosodic phrases and intonation phrases, which were manually checked by the first author.

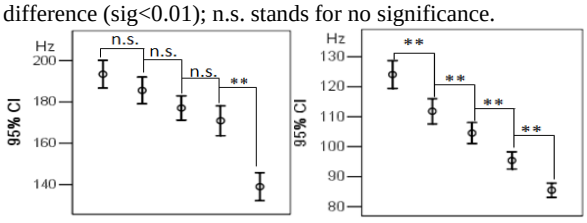
All the questions in the corpus can be divided into 6 types according to syntax structure and pragmatic function. There are 1405 wh- questions, 184 v-neg-v questions (a kind of particular Chinese question syntax), 101 alternative questions, 382 yes-no questions, 114 tag questions, and 2179 statements. Yes-no questions can be further divided into 41 unmarked yes-no questions and 341 particle yes-no questions (including interrogative particles "吧"/ba/ and "吗"/ma/). Since the contrast focus of alternative questions and the tag utterance of tag questions will make the situation much more complicated, they are not discussed in this paper.

3. Experiments and Results

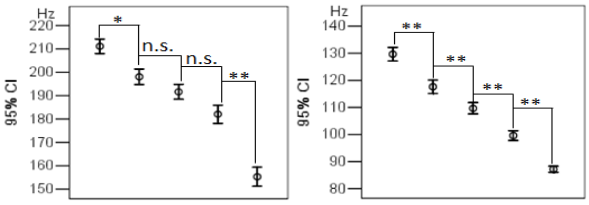
The present experiment was designed to study the F0 variations between prosodic words near the end of the sentences. Peaks and valleys of the last five prosodic words in each type of sentences were extracted. Sentences made of less than five prosodic words were removed from the samples. T5 in Chinese is a neutral tone, and the syllables of T5 are always

unstressed. Therefore, only sentences that end up with full lexical tones (T1-T4) were selected for wh- questions, v-neg-v questions, unmarked questions and statements.

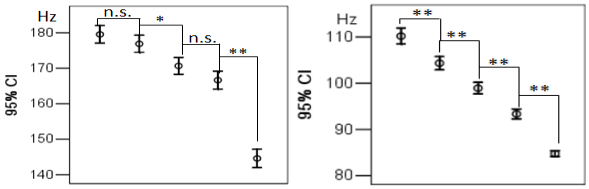
Error bars in Fig. 2 directly describe the pitch variations of the last five prosodic words in different types of sentences. Further ANOVA post-hoc test was done to compare pitch of adjacent prosodic words. Hereinafter, * stands for a significant difference (sig<.05); ** stands for an extremely significant difference (sig<0.01); n.s. stands for no significance.



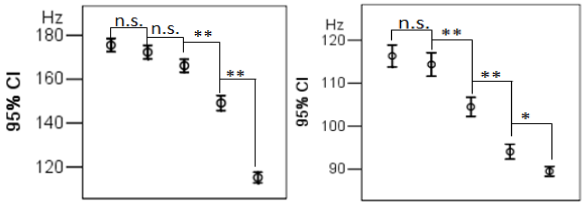
(a) The Topline (left) &Baseline (right) in V-neg-v Q



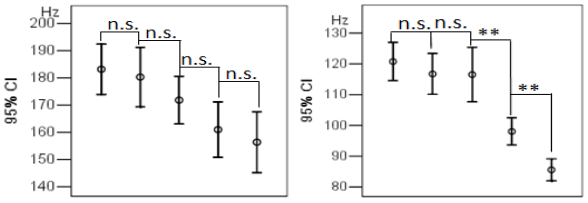
(b) The Topline (left) &Baseline (right) in Wh- Q



(c) The Topline (left) &Baseline (right) in Statement



(d) The Topline (left) &Baseline (right) in Particle Q



(e) The Topline (left) &Baseline (right) in Unmarked Q

Figure 2. *Pitch Variation of the Last Five Prosodic Words in Five Types of Sentences*

As shown in Fig. 2, pitch falls on top-lines are not evenly distributed over the whole sentence. An addition lowering effect appears at the end of all types of sentences except unmarked question, which is usually referred to as final lowering. Unlike top-lines, base-lines are encoded by a general pitch fall throughout the selected parts in most types of sentences. Therefore, the final lowering effect is supposed to be realized mainly by top-lines.

3.1. Top-lines: Presence of Final Lowering

Final lowering can be obviously detected in wh- questions, v-neg-v questions and statements. Pitch drops much more rapidly when it comes to the last prosodic word (around 30~40 Hz) than the former ones (around 10 Hz). Since sentences with neutral tone endings were removed from the sample, the above result was not influenced by the final unstressed syllables.

In particle questions, unstressed final particles were not removed and possibly made a contribution to the final pitch drop. However, a rapid fall also takes place between the last 2nd prosodic word and the last 3rd one. Since there is no evidence suggesting that neutral tone would affect its former syllables, the last second drop might be due to the effect of final lowering.

The presence of final lowering in v-neg-v questions and particle questions is supported by statistic results, for extremely significant differences are detected between the last (and last 2nd) pairs of prosodic words on top-lines. As for wh-questions and statements, there are also significant differences in other positions. Perhaps that is because pitch from natural speech varies more unstably due to the complication of tone. Although an extra pitch drop near the end of the sentence is observed in error bars of the two types of sentences, it has not yet been completely confirmed by statistical data. Thus, a supporting experiment is needed to eliminate tone differences and to narrow pitch gaps.

3.2. Base-lines: Evenly Distributed Pitch Falls

Fig. 2 shows two types of base-line encodings. One is a general decliantion throughout the selected part of sentences, which goes for wh-questions, v-neg-v questions and statements. The other is an additional final drop near the end of the sentence, which goes for yes-no questions. In unmarked yes-no questions, the drop takes place in the last two prosodic words. Coincidentally, in particle yes-no questions, if the last T5 particles were excluded, the extra drop also occurs on the last two prosodic words.

Statistical results on base-lines make a good fit with pitch variations in error bars. The difference between each pair of adjacent prosodic words is significant in wh- questions, v-neg-v questions and statements, suggesting a general smooth fall on base-lines. For unmarked questions and particle questions, the pitch differences stay insignificant except for the last two or three prosodic words. But in general, pitch falls on base-lines are distributed more evenly compared to top-lines.

3.3. Unmarked Q: Suppression of Final Lowering by Boundary Tone Effect

Final lowering is absent in unmarked questions, but the absence can be explained. Unlike other kinds of questions, unmarked questions do not depend on interrogative marks (such as wh- words, interrogative particles or syntactic means) to convey interrogative mood. Instead, boundary tone effect on the last syllable, which brings bring higher pitch as well as steeper pitch curse, is claimed to play an important part in the expression of interrogation [8]. According to our observations, final lowering in unmarked questions is partly set off by pitch rise caused by the boundary tone effect on the last syllable.

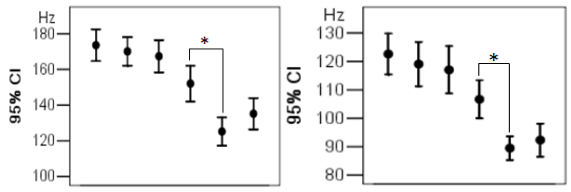


Figure 3: *Pitch Variation of the Last Six Syllables on Top-lines (left) and Base-lines (right) in Unmarked Q*

In Fig. 3, significant differences can be detected between the last 2nd &3rd syllables on both lines while in Fig. 2*(e)*, the differences becomes insignificant. This change is partly due to the pitch increase of the last syllable on top-lines. By contrast, the final pitch is not raised much on base-lines, so the significance is preserved. It is supposed that in unmarked questions, the pitch ascension of the last syllable on top-lines narrows the pitch gap between the last two prosodic words and suppresses the occurrence of final pitch drop to some extent.

3.4. The Basic Unit of Final Lowering: PW vs. SYL

In the light of Herman's data, the scope of final lowering is up to the last three syllables [5]. Also, we found that different syllables are influenced by different sentence types. According to Fig. 4, in wh- questions, pitch difference between the last 2nd&3rd syllables reaches its maximum; in v-neg-v questions, the biggest pitch falls take place between the last 1st&2nd and 3rd&4th syllables; in statements, the last three syllables are all influenced and share an even pitch fall. The conclusion contains much randomness and will cause extra troubles in the process of application.

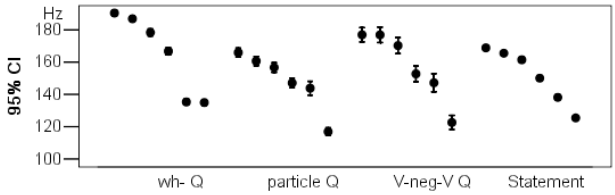

Figure 4. *Final Lowering Carried by Different Syllables on Top-lines of Different Sentences*

Once we changed the basic unit of final lowering from syllable into prosodic word, conclusions of higher consistency were obtained. As illustrated in Fig. 2, final lowering affects exclusively the last prosodic word in all sentences. This conclusion can reflect the prosody rules more precisely, and is more adaptable to intonation modeling and speech synthesis.

4. Supporting Experiment

The complication of tone combination in prosodic words brings about many troubles to our research. First, the pitch information of tone and intonation is hard to be decomposed. Second, many other tone-related effects will take place, such as downstep and neutral tone effect (also considered as a kind of downstep in some works) respectively triggered by low tone T3 and neutral tone T5. Besides, pitch difference between prosodic words could be enlarged. The above factors make the identification of final lowering more difficult.

To make up for such disadvantages, a supporting experiment was conducted to control tone effects. Pitch of the last six syllables was extracted and compared. Section 4.1 aims to discard tone difference by comparing syllables tone by tone. Section 4.2 is designed to evaluate whether our result is influenced by downstep and neutral tone effect. Since final lowering is mainly realized on top-lines according to Section 3, only maximal pitch of syllables is discussed in this section.

4.1. Elimination of Tone Difference

Tone-by-tone comparisons were done to neighboring syllables in order to rule out the differences of tone. Five pairs of syllables (last 1st&last 2nd~last 5th&last 6th) × 5 tones =25 times of comparison were done.

Table 1. *Syllable Pairs with Significant Pitch Difference*

Syllable Comparison	Last 6&5	Last 5&4	Last 4&3	Last 3&2	Last 2&1
Wh-	T2	T2	T1,T4	T1,T2 T4,T5	T1,T2 ,T4
Statement			T1,T4	T1,T2 T4, T5	T1,T3 T4,
V-neg-v				T2,T4	T3
Particle			T1,T3	T2	
Unmarked	n.s.				

According to Table 1, very few significant pitch falls are detected between the former syllables (last6&5, last5&4): only T2 syllables make a difference in wh- questions. Significant differences mainly occur between the last three pairs of syllables. Among them, the highest significance rate lies between the last second pairs, namely between the last 2nd&3rd syllables. To make things clearer, the rate of significant lowering between each pair of adjacent syllables is worked out.

$$Lowering\ Rate = \frac{Numbers\ of\ Significant\ Lowerings}{Five\ Times\ of\ Comparison} \quad (1)$$

Table 2. *Lowering Rate between Each Pair of Syllables*

Syllable Comparison	Last 6&5	Last 5&4	Last 4&3	Last 3&2	Last 2&1
Wh-	0.2	0.2	0.4	0.8	0.6
Statement	-	-	0.4	0.8	0.6
V-neg-v	-	-	-	0.4	0.2
Particle	-	-	0.4	0.2	-
Unmarked	-	-	-	-	-

According to Table 2, significant pitch lowering intensively occurs between the last three pairs of syllables, which approximately corresponds to the last prosodic words. In wh- quesitons, rapid pitch falls exist throught the whole sentence, but they are still most likely to appear between the last 2nd pairs of syllables, with a lowering rate of 0.8. The result proves that the occurrence of final lowering detected in this paper is independent of tone combinations.

4.2. Elimination of Downstep Effect

Since syllables of T3 and T5 mixed in the prosodic words may also result in pitch drops, in this section, sentences involving such syllables were excluded from the sample. Wh- questions and statements were chosen to be tested in this section because of their big quantity (1405 and 2179 respectively).

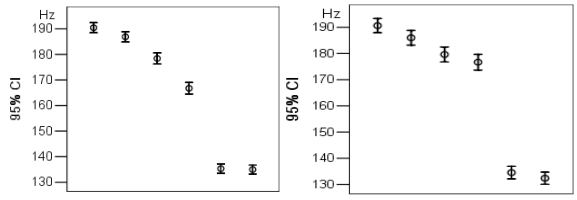

Figure 5. *Pitch Fall Original (left) and after the Exclusion of Sentences with T3 & T5 (right) in Wh- Q*

The left error bar in Fig. 5 shows that final lowering in wh-questions originally occurs between the last 2nd & 3rd syllables. Then, sentences with their last 3rd syllable carrying T3 or T5 are removed. Pitch variation of the qualified sentences was illustrated on the right. It turns out the only change is a pitch rise on the last third syllable, which is due to the delectation of low tones. Nothing happened to the following two syllables. In this case, the abrupt lowering of the last 2nd syllable is not caused by T3 or T5 of the last 3rd syllables in wh- questions.

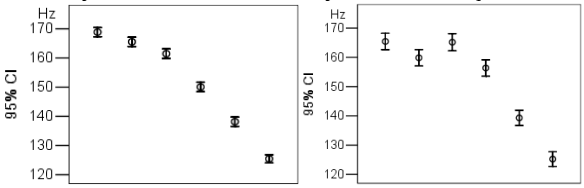

Figure 6. *Pitch Fall Original (left) and after the Exclusion of Sentences with T3 & T5 (right) in Statement*

In statements, significant pitch fall originally occurs at the last 3rd~1st syllables, instead of the last 2nd syllable in wh-questions. Accordingly, the exclusion of sentences was done with more syllables taken into account (the last 4th~2nd syllables). In consequence, a pitch rise appears on the last 4th~2nd syllables due to the exclusion of low tones. The extra pitch fall still occurs in the absence of T3 and T5. Based on the above analyses, we can deduce that our result is not affected by downstep effect triggered by low tones.

5. Discussion

The study brings about a disagreement on the presence vs. the absence of final lowering effect in Chinese Mandarin. Then, a more fundamental problem remaining to be solved is: what leaded to such a disputation? In previous research, designed sentences formed by syllables of the same high tone were used to get a direct observation of intonation, which indicated the absence of final lowering [12]. However, in our study of natural speech, when tone effects were controlled, an additional pitch lowering still appeared on the last prosodic words (or the last two to three syllables). By comparing the two methods, we noticed that the most obvious and substantial factor possibly leading to this disputation is the stimuli/corpus. In fact, the results suggested a potential difference between experimental speech vs. conversational speech, which is instructive to prosody research.

It is reasonable that different methods lead to different conclusions. Sometimes it is hard to label them as absolutely right or wrong, for both materials have their own pros and cons. On the one hand, it is true that designed stimuli can help us get minimal contrast pairs, and high-tone sentences do facilitate our observation of intonation. On the other hand, however, how likely are we to put together syllables of the same tone under natural conditions? Conversely, we tend to combine different tones in our speech intentionally or unintentionally to make it more melodious. That is why experiment stimuli are sometimes accused of being unnatural. Such problem can be fixed by natural corpora, for they contain a large quantity of sentences, extensive topics, diverse tones and flexible syntactic forms. Natural speech has its problems too. Since it involves the information of tone, intonation, stress, prosodic boundary, etc., extra efforts must be made to decompose all kinds of influents and to get what we want.

The experimental control has long been an indispensable part of phonetic research. It serves as an entry point in prosody research, owing to its convenience of simplifying complicated situations and developing new topics. However, we should not be complacent with the existing conclusions from experimental speech. In the next step, these conclusions should be extended into natural speech to get checked, revised or applied. Through this study, we propose a balanced consideration and a combination of the two methods. In our opinion, experimental speech is very essential for developing general topics into specific rules, and then the rules need an additional extension into natural speech for further check-up, revision and application. The combination of experimental control and natural corpus analysis will definitely bring new research topics, novel methods and promising conclusions

6. Conclusion

To support text-to-speech systems with plentiful prosodic details, we analyzed the pitch variation near the end of sentences in a Chinese natural dialogue corpus. A disagreement arises about the presence vs. the absence of final lowering in Chinese, and our results support the presence of final lowering in both questions and statements. Specifically, the effect occurs in wh- questions, v-neg-v questions, particle yes-no questions and statements, but is suppressed by boundary tone in unmarked yes-no questions. Besides, in the light of our data, final lowering is realized mainly on top-lines and affects exclusively the last prosodic word. At the end of the paper, we proposed a combination of experimental speech and natural speech in prosody research, with the former as an entry point of new topics and the latter as an extension of the existing prosodic rules.

In our future work, we will continue to explore the essence of final lowering in Chinese. More linguistic determinants such as accent, boundary tone, and position in the discourse are to be taken into account. Hopefully, the further research would bring out a full discussion on the physiological explication versus the phonological explanation.

Intonation Unit Size in Spontaneous Hebrew: Gender and Channel Differences

Vered Silber-Varod [1], *Tal Levy*[2]

Abstract

In this corpus-driven research, the question of whether there is a tempo at the Intonation Unit (IU) level, and whether defined IUs differ not only with regard to their pitch contour and boundary tones but also with respect to their phonological size. For this reason, the inventory of syllable size (in terms of segments (phonemes)) and word size (in terms of syllables) was examined, and then each IU category (mainly Terminal vs. Continuous) was measured with respect to the number of syllables and words it contains. Moreover, terminal IU size was also measured with regard to the amount of embedded continuous IUs. Results showed that terminal IUs in spontaneous Israeli Hebrew (IH) do not necessarily consist of embedded continuous IUs. This can be explained due to their massive use as short feedback units in spontaneous speech. Statistical measurements for gender and channel (Face-to-Face vs. telephone conversations) variables were carried with no significance for gender, but with statistically significance for several channel aspects. Last, estimated durational measurements of the IU size are presented.

Index Terms: prosodic unit size, Israeli Hebrew, gender, channel, duration

1. Introduction

When studying speech rate, or speech rhythm, the overall goal is to characterize speech in terms of how many speech units (syllables, prosodic words, etc.) are uttered within a certain time unit (milliseconds, seconds, minutes, etc.). This measure takes into account silent pauses and other types of disfluencies. For example, Syllables-per-second (SPS) is a well know measure for this purpose. For the same reason, analyzing speech unit size in terms of amount of syllables, words, and duration per a certain prosodic unit higher in the hierarchy, can reflects language, or speaker, characteristics. Indeed, since the duration of syllables varies according to their inner-structure [1, p. 55], speech rate is known to be language-dependent, or at least language-type dependent (syllable-timed vs. stress-timed; syllable-rhythm vs. word-rhythm [1, pp. 54-57]. Moreover, in order to characterize prosodic unit at all levels, from syllable to utterance, the prosodic representation "should take into account the heterogeneity and the variations in prosodic constructions encountered in ordinary speech" [2]. There are many applicative aspects of speech rate, such as diagnosing speech disorders, or developing natural speech synthesis. Thus "Obtaining normative data on speaking rate for various groups of speakers is required." [3, p. 131]. For Hebrew, [3] reported that "presently there are no published studies that have directly examined speaking rate among adult Hebrew speakers." [3, p. 131]. Indeed, [3] is a preliminary attempt to provide such data, by quantifying speaking rate within a specific subgroup of speakers – radio newscasters. Nevertheless, it is suggested that speech rate is affected by the communicational setup, specifically, the number of conversation partners was shown to influence rate, such that talking to a single interlocutor is typically performed at a relatively slower rate [4], [5]. Therefore, an examination of the channel aspect as a comparison between Face-to-Face dialogues and Telephone conversations serves this research end. As for gender differences, although there is no linguistic reasoning for such a difference, and indeed no gender differences were found before in Hebrew speech [6], albeit [6] examined the articulation rate and not the speech rate (the latter includes durations of pauses, disfluencies etc.), it was decided to look at this aspect as a baseline examination (and also to use it as a counter-evaluator for the prosodic annotation and segmentation). In the method section (section 2), the prosodic units under investigation are described. In section 3 the analyzed data is described, not only in terms of the corpus type, but also in terms of word and syllable structures. In section 4 the results of gender and channel comparisons are given, and section 5 examines the results and unfolds future research plans.

2. Method

2.1. The prosodic units under investigation

The present paper leans on the prosodic data documented in [7], where the main prosodic unit under investigation is the intonation unit ((IU). For IU definition, see [8, pp. 8-15]. The prosodic annotation process imposes two main types of IU boundary tones that can be defined according to the communicative value of intonation: Terminal (T-) boundary tones and Continuous (C-) boundary tones. A boundary tone was annotated as *T* when the surface intonation signaled that the speaker had "nothing more to say". A boundary tone was annotated as *C* whenever the final tone of the intonation unit signaled "more to come". The recordings were perceptually annotated with a set of prosodic boundaries. Additional validity was achieved using acoustic measurements (see details in [7, pp. 46-55]. This resulted in a back and forth annotation method between perceptual annotation and acoustic measurements, with priority given to major perceptual differences. However, it should be noted that prosodic boundaries were annotated independently of the syntactic structure. The label inventory of prosodic boundaries is as follows. Within the above two types (T- and C- boundary tones), there were two T-boundaries: Terminal Finality (T.), and Terminal Question or Appeal (T?), and five C-boundaries, which were determined according to their tone at the last syllable of the IU: Neutral (C→), Elongated (C:), Rise (C↑), Rise-Fall (C↑↓) and Fall (C↓). Fragmented, or truncated (TR), boundaries were also used in the annotation process.

2.2. The parameters under investigation

In the current research, the following data was extracted for each speaker:

1. No. of words per speaker
2. No. of syllables per speaker
3. No. of pauses (#) per speaker

4. No. of IUs per speaker
5. IU size (word): no. of words per IU
6. IU size (syllable): no. of syllables per IU
7. T- unit size: no. of C-units per T-unit

This will be demonstrated on (1):

heXlaft et ze **T? #** lo ani **C→** lo jodaat ma jihje **T.** (1)

changed-PAST.2SG.F Acc. this **T? #** no I **C→** no know.PARTICIPLE.F what be-FUT.3SG **T.**

'you have changed it**?** no I**,** don't know what is going to be**.**'

For the chunk presented in (1) the following data was extracted:

1. No. of words: 9
2. No. of syllables: 14
3. No. of pauses: 1
4. No. of IUs: 3 (T?, C→, T.)
5. IU size (word): 3/T?, 2/C→, 6/T.
6. IU size (syllable): 4/T?, 3/C→, 10/T.
7. T-unit size (by C-units): 0/T?, 1/T.

The first four parameters are general ones and reflect the speech activity of each speaker.

1. The word parameter counts how many words were transcribed per speaker. This included clitics (function words) that were transcribed separately of their host (the following NP). For example, [ha yeled] 'the boy' was calculated as *two* words and not as a single word, הילד, which is the way the Hebrew orthographic system does.
2. The syllable parameter counts the number of vowels per speaker, following the obligatory presence of a nucleus in the syllable and fact that in Hebrew the nucleus is only a vowel (vowel hiatus, such as in [Raa] see.PST3M 'he saw', was considered as two syllables, but not in cases of word-final diphthongs, where a vowel occurs before the sequence [aX], as in [RuaX] 'wind' (32 such diphthong cases in the corpus)).
3. The pause (marked #) parameter counts pauses above 100ms, per speaker.
4. The IU parameter counts how many IUs (Ts and Cs) were annotated per speaker.
5. IU size (word) parameter counts words per IU, as follows: T-unit size was defined as the number of words from one T-boundary to the next T-boundary. On the other hand, C-unit size was defined as number of words from *any* prosodic boundary to the given C-boundary.
6. IU size (syllable) parameter counts syllables per IU, as follows: T-unit size was defined as the number of syllables from one T-boundary to the next T-boundary. On the other hand, C-unit size was defined as number of syllables from *any* prosodic boundary tone to the given C-boundary.
7. T-unit size parameter refers to the number of minor C-units in major T-units. This parameter reflects rhythm at the intonational unit level.

3. Data

The corpus of this research consists of 19 spontaneous Israeli Hebrew dialogues extracted from The Corpus of Spoken Israeli Hebrew [9]. The recordings were made during 2001-2002. The total duration of analyzed speech is almost five hours. Total number of word types: 4,374; Total number of word tokens: 32,175. The 19 recordings consist of private spoken dialogues in two channels: direct, face-to-face (F2F), dialogues, and distance, telephone (TEL) conversations. Each recording consists of conversations between one core speaker (the "informant", who had the recording equipment on his body for 24 hours) and various interlocutors with whom the speaker interacted on that day. The TEL sub-corpus contains spontaneous phone conversations recorded by the same19 informants. These conversations were part of the 24 hours routine during which the participants recorded themselves. It should be noted that the TEL sub-corpus consists only of the informants' speech, and not their interlocutors'. The total duration of the F2F sub-corpus is 206 minutes; the total duration of the TEL sub-corpus is 83 minutes. Within these 19 recordings, a total of 62 speakers (28 men and 34 women) were transcribed and annotated. The women speech consists of 19,903 words, while the men speech encompasses 12, 272 words. The corpus is heterogeneous in terms of amount of speech per speaker, ranging from 3 to 2,074 words per speaker in the Women sub-corpus; and from 2 to 1,531 words in the Men sub-corpus. The channel groups are also varied. There are only 9 TEL conversations (4 men; 5 women; total of 7,230 words), with speech material ranging from 233 to 2,074 words per speaker; and 61 F2F dialogues (33 women, 28 men; total of 25,107 words), with speech material ranging from 2 to 1,531 words per speaker.

4. Results

The aim of this preliminary research was to investigate if there are: 1. Gender differences; or 2. Channel differences regarding IU size. The data was statistically measured by Mann-Whitney Test, which is a method which has more efficiency on data with non-normal distribution.

4.1. Syllable and word size

In order to measure IU size in terms of words and syllables, it is important to know what the *word* unit size is (in terms of syllables), and what the *syllable* unit size is (in terms of segmental (phoneme) content), in the corpus.

4.1.1. Word size

The statistics of the *word* lengths (in terms of the number of syllables) for the whole database is as follows: The minimum word length is 0 syllables (25 word types; 0.34% in the corpus). This includes cases of interjection such as [m:] 'mm' or truncated words (i.e., false starts). The maximum word length is of 6 syllables. This occurred only once in the loan word [otobijogRafja] 'autobiography'. The average syllables per word (SPW) is 2.3 (standard deviation 0.8). Figure 1 summarizes these statistics, which are close to other studies on word structure in Hebrew child directed speech [10]. Note that in Figure 1 it is demonstrated that monosyllabic words are mostly used in spontaneous IH speech (47.96% tokens), but disyllabic words are four times more varied than monosyllabic ones (black histograms reflects word types). This is an indication to the transcription method carried in the current research, where monosyllabic clitics (i.e., function words such as preposition, definite article, subordinate article) were transcribed as a single orthographic unit, and thus are the most frequent in quantity, but less varied in terms of word-types. Word length statistic was also carried with regard to phoneme per word (PPW). This can be an indication to types (and their relative frequency) of syllable structures in IH. The minimum word-length in terms of number of segments is 1 (18 word-types; 2.47% of corpus). These words include lexemes, such as [o] 'or', interjections and false starts which consist of consonants only. The maximum word length is 13, which

occurred only once in the loan word [otobijogRafja] 'autobiography'. The average word length is 5.6 PPW (standard deviation 1.7).

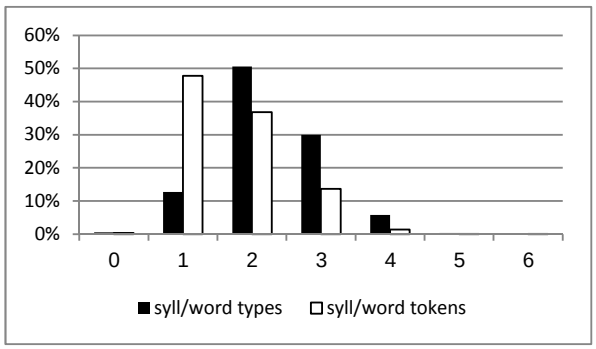

Figure 1: *Syllables per word (SPW) ratios (Types vs. Tokens).*

4.1.2. Syllable size

The average *syllable* length was also calculated using the following method: number of segments per word divided by the number of vowels (i.e., syllables) of that word. For example, in the word [otobijogRafja] 'autobiography' there are 6 syllables. According to the syllable length calculations the syllable length is 2.166 (phonemes per syllable). This is very close to the real average calculation, which is 2, as can be shown from the syllabic division [o.to.bi.jo.gRaf.ja]. There are 4 syllables with 2 phonemes; 1 syllable with 3 phonemes and 1 syllable with a single vowel. By excluding the 25 cases of consonant-based false-starts, the minimal syllable length is 1, meaning the syllable consists of a single vowel, and is related to five different vowel-only words (including [a] and [e] which are interjections). These vowel-only words constitute 2.2% of the corpus. The maximal syllable length (in terms of segments) is 6, and is referred to a single case of the word [dZoRdZ] 'George', which reflects the transcription method of 2 consonants to symbolize the affricate [dʒ]. The average syllable length is 2.6 (phonemes per syllable. standard deviation is 0.7). To sum up, IH speakers speak on average 2.3 syllables per word, an average of 5.6 phonemes per word.

4.2. IU size: gender and channel comparison

In this section, comparison between the two categories: gender and channel, will be analyzed as follows: a comparison with regard to the distribution of IU types; a comparison with regard to IU size in terms of word; Finally, an estimated durational measurements of IUs will be presented.

4.2.1. Gender

In the gender category, no statistically significant differences with regard to IU size were found. The distribution of prosodic boundary tones among females and males is shown in Figure 2. Both groups use the (T.) tone widely, and (T?) to a lesser extent. The T-units' sizes vary from 1-58 words (0-94 syllables). No significant gender differences were found with regard to number of words or syllables, but statistically significant results were found with regard to the gender use of T-boundaries (T and TQ) and C-boundaries ($x^2 = 31.8631; p < .0001$). Figure 2 demonstrates that men use more T(.) and T(?) units than women, who use relatively more C-units (32% of all units, compared to 26% in men's speech). This can imply more intonational variations in women's speech.

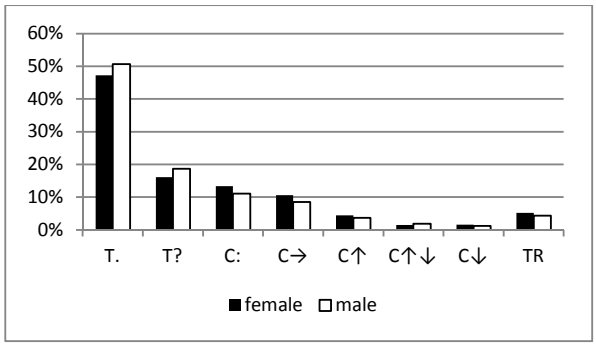

Figure 2: *Distribution of prosodic boundary tones among females and males.*

4.2.2. Channel

The distribution of the prosodic boundary tones in F2F and TEL are shown in Figure 3. The two variables, channel and boundary type (T- or C-) were tested in Chi-square statistics and the results are statistically significant ($\chi^2 = 98.116; p < .0001$), meaning that the two variables show contingency. Moreover, C:-units are relatively more common in TEL.

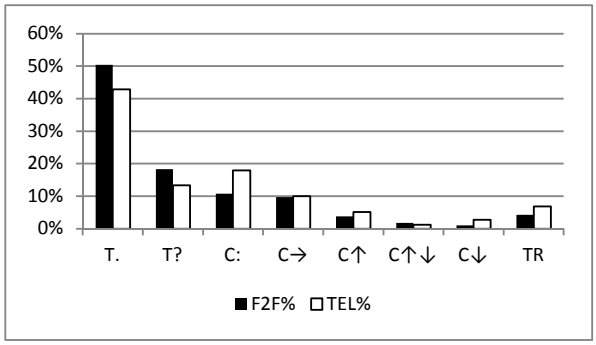

Figure 3: *Distribution of prosodic boundary tones in F2F and TEL.*

Statistically significance difference was found in the channel comparison, where the mean size values of several terminal units were found relatively much more frequent in TEL than in F2F. For example, 1-word T?-unit ($p=0.05$) and 3-words T?-unit ($p<0.01$) were found significant (among others); also 1-word T.-unit ($p<0.01$) and 2-words T.-unit ($p<0.05$). This can be explain as a discourse characteristic of TEL, where feedback are more frequent due to the lack of facial and other visual feedback. The question remains open for much larger units (8, 9, 10, 13 and 15 syllable units) that were found statistically significant. As to the T-size in terms of C-units, at the channel test this parameter was found significant in several cases. First, a difference was found in T-units with no C-units ($p<0.05$). Zero-C-units reflect mostly the short, feedback responses that were explained before as more common in TEL. It is interesting to see that also the T?-unit has some unique use in TEL: 1-C-boundary as well as 3, 8, and 9-C-boundaries were found significantly more frequent ($p<0.01$) in TEL. Perhaps this can be attributed to the opportunity to process longer stretches of speech in TEL, where the interlocutor is more attentive, with comparison to

more lively conversations in F2F dialogues. Significant was found also in the channel comparison of C-unit size. Each of the five C-units had at least one unit-size that demonstrated statistical significance. This correlates with the explanation of longer stretches of speech in TEL, which was mentioned before with regard to terminal units. Two more measurements were carried out on small sub-set of the corpus. First, since the 19 informants of each of the 19 recordings were the main speakers, a subset of Main speakers only was extracted. This subset consists of 8 men and 11 women. An Anova test with repeated measures was carried out, and no significant gender differences were found. For example, p=0.752 on T-unit size. This means that men and women use the same pattern of T-unit sizes (Large amount of 1-word T-units, much less 2-words T-units and declination in use till 15-words T-unit size). It seems that even when reducing the corpus to a less varied speech material, no gender differences are found. Another sub-corpus was extracted for channel pairs of the same speaker. The motivation behind this sub-corpus was to investigate if there is an intra-speaker channel difference. In this sub-corpus only eight speakers out of the 19 main speakers had both TEL and F2F speech material. A T-test was carried out and no significant channel difference was found (p>0.05). This means that speakers use the same patterns, with regard to IU size, in TEL and F2F conversations.

4.3. Syllable duration in various prosodic environments

In order to compare the durational parameter of the syllables in the five continuous boundaries, a pilot study of 22 minutes from TEL (female speaker) and 12 minutes from F2F (male speaker) were segmented manually into syllables. These two recordings were chosen since their acoustic quality meets basic acoustic measurement standards, such as a clear voice and an absence of background noises or speech overlaps. Moreover, in both recordings there is only one interlocutor (compared to other F2F recordings where normally consists of more than two interlocutors). Only the speech of the informant speaker was measured. In TEL, the number of IUs is 610; in F2F, 177. Figures 4 and 5 summarize the durational measurements taken. In this study, the duration of the entire syllable was measured. A threshold to the C: boundary tone was set on a minimum of 230ms. Therefore, the syllables that carry the C: tone were found in both recordings to have the highest mean values (rightmost B&W histograms in Figure 4), while the fluent syllables were found in both cases with the lowest mean values (leftmost B&W histograms in Figure 4).

4.4. Estimated IU size in IH

The estimated unit size was measured as a combination of two variables: 1. In order to avoid the "long tail" bias, we calculated the mean value (syllables) of the most frequent IU sizes; and 2. We used the durational measurements of syllables mentioned in subsection 4.3 above. The mean values of most frequent IU sizes are as follows (almost no difference between the two channels):

T. = 3 (TEL)-3.5 (F2F) syllables per IU
T? = 2.3 (TEL)-3 (F2F) syllables per IU
C→ = 5 syllables per IU
C: = 2.5 syllables per IU
C↑ = 4.5 syllables per IU
C↑↓ = 2 syllables per IU
C↓ = 6.6 syllables per IU

It is demonstrated in the above that the mean C-unit is *longer* than the average T-unit. This is exactly because the calculations took the frequency of use into consideration. Since above 75% of T-units are with no internal C-units, their mean size seems shorter. Second, it should be stressed here that due to the limited size of durational measurements, and to the mixed variables recordings, the results shown on Figures 4 and 5 are within the realm of estimation only. Again, the estimated duration of the two T-units does not include duration of C-units, since above 75% of T-units were without internal C-units.

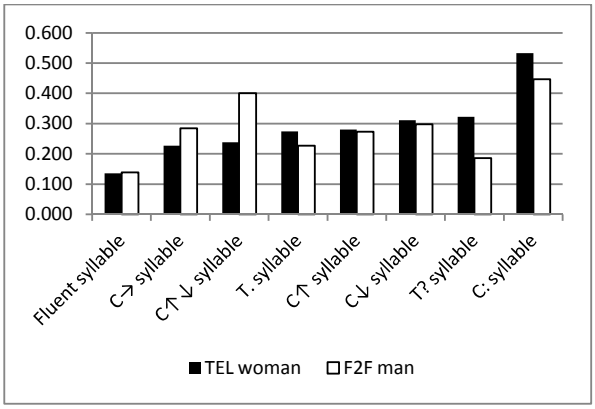

Figure 4: *Syllable duration (seconds) in TEL (woman) and in F2F (man).*

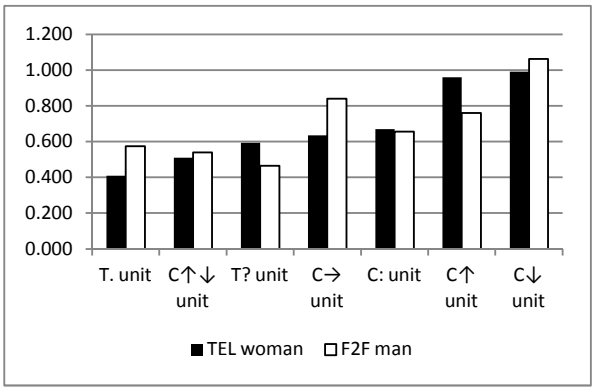

Figure 5: *Estimated IU size (seconds) in TEL (woman) and in F2F (man).*

5. Discussion

This preliminary study highlights the need to examine prosodic unit size in spontaneous IH. Prosodic unit size was examined with regard to syllable and word structures, and sub-units (C-units) in higher prosodic units in the hierarchy (T-units). TEL conversations are characterized by *single-word coherent contour* (T.)-units, while (T?)-units mostly consist of several IUs (with at least two C-units). The syllable durational measurements suggest that in IH, as in AE, "filled pauses differ dramatically from (…) other instances in duration" [11]. With regard to gender and channel differences, in both variables the use of T-boundaries versus C-boundaries was found to be statistically significant. Nevertheless, the duration measurements were carried out on a relatively small portion of the corpus, and syllable duration in spoken IH still needs to be investigated in future research.

Acoustic Cues to Tone and Register in Bai: Adult Baseline Data

Allison Benner, John H. Esling

Department of Linguistics, University of Victoria, Canada

abenner@uvic.ca, esling@uvic.ca

Abstract

This paper presents the results of a study of the acoustic cues associated with the tense/lax distinction in Bai, a Tibeto-Burman register tone language spoken in Yunnan, China. The purpose of the paper is to provide baseline adult data for comparison with infant speech in an acoustic study of infants' acquisition of Bai register tones in the second and third years of life. The results show that among adults, F0, F1, and spectral tilt combine to create the tense/lax contrast in Bai. While these three cues tend to be correlated, individual speakers differ in their use, particularly spectral tilt. The patterns in this study suggest that as Bai infants acquire tones in the second and third years of life, their utterances are likely to become structured around these three acoustic cues in previously unattested ways that exemplify the complex interaction between universal physiological and developmental tendencies and the ambient phonological tone system of Bai.

Index Terms: Bai, tone, acoustic cues, laryngeal constriction, first language acquisition

1. Introduction

Bai is a Tibeto-Burman language spoken by approximately 1.6 million speakers in the three dialect regions of Dali, Jianchuan, and Bijiang in Yunnan, China [1]. As shown in Table 1 below, Bai includes eight tones that are phonologically classified as lax or tense, based on pitch and/or phonation type. All these tones have contrastive nasal variants, with the exception of the rising tone. Tense tones are produced with more laryngeal constriction than lax tones, though tones in both registers may be produced with differing degrees of laryngeal constriction. For example, the tense register includes differing degrees of harshness. Tense tones 55+ and 33+ are often produced with tight or 'pressed' phonation, 31+ with harsh voice, and 21 with aryepiglottic trilling. Lax tones 55 and 33 are produced with modal voice, and lax tone 31 with breathy voice. Tone 35 varies between harsh and modal phases.

Table 1. *Bai register tone system.*

	Lax	Tense
high level	55	55+
mid level	33	33+
mid falling	31	31+
low falling		21
Rising		35

While the literature includes a description and classification of the Bai tone system [2] [3] [4], and while detailed studies of the laryngeal articulatory phonetic realization of these tones are available [1] [5], no acoustic studies on Bai tones exist. This study aims to find general trends in the acoustic cues to these tones. As such, the study contributes to the growing recent literature on acoustic cues to register tones [6] [7] [8] [9] and will be used for baseline comparison in our ongoing study of tone acquisition among infants acquiring Bai [10] [11] [12] [13].

2. Methodology

2.1. Data

To examine the acoustic cues to the tense/lax distinction, data were selected from two pre-existing sources: (1) the audio files that accompany the Phonetic Database article for Bai [14], which comprise recordings of a male native speaker of Bai; and (2) field recordings of six native speakers of Bai (5 female, 1 male) made in Yunnan in 2008. The latter recordings were made to find examples of vowels illustrating all eight tones in the paradigm on a single monosyllabic word, and to verify whether speakers made these contrasts in the same manner observed in the speaker in the Phonetic Database. There are some gaps in the data, because some speakers did not recognize words in the paradigm.

The 291 tokens included in this analysis are monosyllabic words containing the vowels /æ/, /a/, /i/, /e/, /u/, and /o/ spanning, where possible, all the non-nasalized tones in the register tone paradigm. In all, the data include 111 tokens of tones in the lax register, and 180 in the tense register. Table 2 shows the distribution of the data among the eight tones. Within the available data, it was not possible to balance the number of tokens by speaker or tone. Cells in Table 2 with at least 7 tokens include recordings of all 7 speakers in the study. In cells with large numbers of tokens, most utterances represent the single male speaker in the Phonetic Database, whose utterances comprise approximately one-third of the total data (102 tokens).

Table 2. *Data included in the analysis, by vowel and tone.*

Tone	/æ/	/a/	/i/	/e/	/u/	/o/	Total
55	7	8	11	3	7	7	43
55+	7	5	9	7	7	1	36
33	7	7	9	1	6	2	32
33+	7	23	10	9	7	8	64
31	7	7	9	1	7	5	36
31+	7	9	3	7	1	5	32
35	1	--	7	1	3	1	13
21	7	10	3	--	7	8	35
Total	50	69	61	29	45	37	291

2.2. Acoustic Analysis

Three acoustic cues were measured for each of the tokens: F0, F1, and spectral tilt. F0 was measured at the beginning, middle, and end of each token. F1 was measured in the middle of each token. Finally, spectral tilt measures, including H1-H2,

H1-A1*, H1-A2*, and H1-A3*, were taken from the middle of each token. All measurements were taken using Praat [15]. Average values for F0, F1, H1-H2, H1-A1*, H1-A2*, and H1-A3* were calculated for individual speakers and for the group as a whole for each of the eight tones, and for the lax and tense registers. Because of the uneven distribution of the data samples between individuals and tones, no statistical tests were performed.

3. Results

3.1. Fundamental Frequency

Tables 3 and 4 below show the average F0 at the beginning and end of each tone for male and female speakers, respectively. Figure 1 illustrates the average F0 values and direction of F0 movement for each tone across speakers. As shown, the eight contrasting tones in the paradigm are distinguished by pitch. Tense tones tend to be higher in pitch than their lax counterparts. For example, 55+, 33+, and 31+ are higher in pitch than 55, 33, and 31, respectively. The pitch range of the lax 31 tone and the tense 21 tone closely overlap (though they differ maximally in phonation type). All speakers follow this pattern. While lax level tones 33 and 55 are produced in different ways by individual speakers (as slightly rising, slightly falling, or small rise-falls), they are consistently produced with more level pitch than corresponding tense tones 33+ and 55+, which all speakers produce with noticeable falls.

Table 3. *Average F0 of tones (Hz), male speakers.*

	55	55+	33	33+	31	31+	35	21
Start	230	268	179	208	166	224	138	160
Mid	236	269	177	196	138	174	191	135
End	237	248	177	193	107	116	222	110

Table 4. *Average F0 of tones (Hz), female speakers.*

	55	55+	33	33+	31	31+	35	21
Start	270	291	249	272	237	288	245	228
Mid	275	276	248	260	205	247	260	206
End	267	227	231	249	160	179	296	169

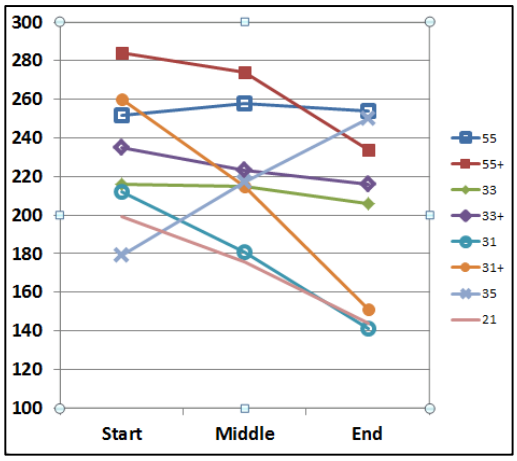

Figure 1: *Average F0 of tones, male and female speakers.*

3.2. F1 Frequencies

The F1 frequency is, on average, higher for tones produced in the tense register (55+, 33+, 31+, 35, and 21) than for tones produced in the lax register (55, 33, and 31) for all vowels studied, reflecting the greater laryngeal constriction in tense tones. Average F1 frequencies for vowels in the tense and lax registers are shown in Figure 2 below.

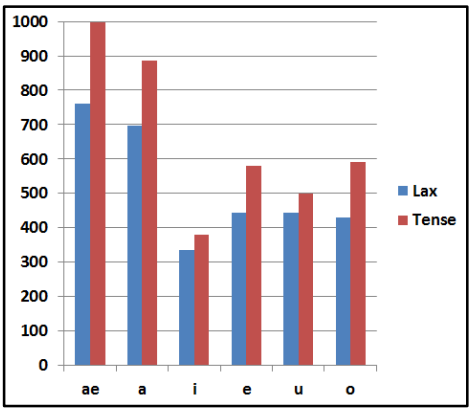

Figure 2: *Average F1 frequencies, all speakers.*

Within this pattern, F1 frequencies differ considerably across tones. Table 5 shows the average F1 for each vowel in the study for each tone. As shown, 55+, 33+, and 31+ have a higher average F1 than 55, 33, and 31, respectively, with the exception of the 33+/33 contrast for /i/. These contrasts in F1 help to preserve distinctions between pairs of tones that are phonologically contrastive and that are potentially confusable on the basis of pitch. Among the tones, across all vowels except /u/, the average F1 for 21 is the highest, and the average F1 for 31 is the lowest, in keeping with the fact that these tones differ maximally in laryngeal constriction: as noted earlier, 21 is produced with harsh voice and aryepiglottic trilling, while 31 is produced with breathy voice.

Table 5. *Average F1, by vowel and tone, all speakers.*

	/æ/	/a/	/i/	/e/	/u/	/o/
55	807	733	357	--	437	457
55+	958	824	405	616	569	593
33	782	681	337	399	400	402
33+	985	867	326	558	442	505
31	694	669	308	392	408	403
31+	1000	868	361	582	493	579
35	875	--	415	490	676	473
21	1056	964	422	--	474	700

F1 frequencies also differ between speakers. Figure 2 depicts the average F1 of /æ/ for speakers 1 to 7 for all tones, except 35 (there was only one recording of this tone in the data). This vowel is chosen as an illustration because the data are balanced across speakers, because tense/lax F1 values occur within a wider range for low vowels, and because the pattern depicted reflects the general trend found for most other vowels in the study. As shown, with the exception of speaker 6, all

speakers produce higher F1 values for tense tones than for their lax counterparts (55+, 33+ and 31+ have higher F1 frequencies than 55, 33, and 31, respectively). For 4 of the 7 speakers, 31 has the lowest F1, and 21 the highest. For some speakers, lax tones 33 or 55 have a lower F1 than lax 31, and/or tense 31+ has a higher F1 than tense 21. Across all speakers, with the exception of speaker 6, the F1 frequencies of tense tones 21 and 31+ are both higher than the F1 of lax (breathy) 31.

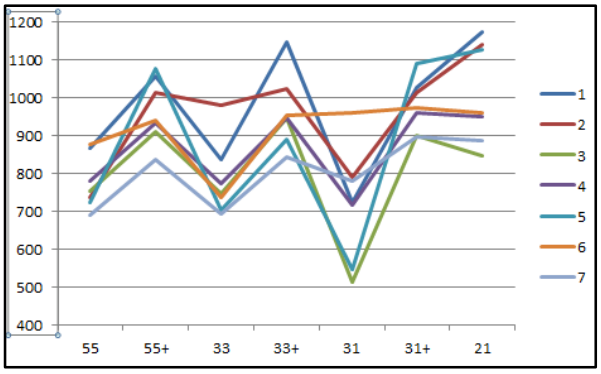

Figure 2: *Average F1 for /æ/, speakers 1-7.*

3.3. Spectral Tilt

As shown in Table 6, average spectral tilt values for the lax register are lower than for the tense register across all six vowels studied and across all four measures of spectral tilt employed (H1-H2, H1-A1*, H1-A2*, and H1-A3*), with the exception of H1-H2 for the vowels /a/ and /i/. These differences reflect the greater laryngeal constriction in the tense tones compared to the lax tones.

Table 6. *Spectral tilt by vowel, tense and lax registers.*

	H1-H2		H1-A1*		H1-A2*		H1-A3*	
	T	L	T	L	T	L	T	L
/æ/	2	7	-10	3	-8	5	4	19
/a/	4	3	-9	-2	-8	3	9	21
/i/	8	7	-1	0	12	18	12	18
/e/	-6	3	-8	3	1	13	6	18
/u/	-2	-1	-3	-2	8	9	27	29
/o/	-3	0	-7	-2	1	15	24	31

As with F1 values, spectral tilt measures varied among tones and among individual speakers. As an illustration of the general trend, Table 7 below shows the average H1-A3* values for each vowel and tone for the seven speakers. Across vowels, H1-A3* is higher for 55, 33, and 31 than for 55+, 33+, and 31+, respectively, with the exception of the 33/33+ contrast for /u/. Among the eight tones, H1-A3* is highest for lax tone 31 for most vowels (/æ/, /i/, /e/, and /u/) and lowest for tense tone 31+ for most vowels (/æ/, /i/, /e/, and /o/). The contrasts in H1-A3* values are most distinct between tense/lax pairs across the tonal paradigm for low vowels /a/ and /æ/, and less so for high vowels /i/ and /u/. These differences likely reflect the degrees of laryngeal constriction to which the production of each vowel is inherently susceptible. More specifically, there may be less latitude to produce tense/lax contrasts with high vowels, which are inherently produced with a more raised tongue and, consequently, a greater degree of pharyngeal expansion than low vowels, which are inherently more susceptible to tongue retraction, larynx raising, and laryngeal constriction [16] [5] [17].

Table 7. *H1-A3*, by vowel and tone, all speakers.*

	/æ/	/a/	/i/	/e/	/u/	/o/
55	16	17	16	17	29	28
55+	5	9	11	8	24	24
33	20	26	16	16	26	29
33+	6	11	15	5	27	28
31	22	22	22	22	33	36
31+	2	8	5	5	27	21
35	11	--	14	11	21	26
21	4	7	8	--	30	20

For all measures of spectral tilt, values range widely across individuals, likely reflecting the different envelope within which speakers produce phonatory contrasts. As an illustration of this point, Figure 3 below shows average H1-A3* values for speakers 1-7 for the vowel /æ/. As can be seen, with the exception of speaker 1, all speakers make a consistent contrast between tense and lax pairs of tones, though some speakers appear to make those contrasts within a more or less constricted setting, and within a narrower or wider range of constriction. Speaker 3, for example, consistently distinguishes between the tense/lax pairs, but does so within a vocal setting that is relatively unconstricted, compared to speakers 4 and 7, who produce these same contrasts within a relatively constricted setting. Of the seven speakers, speaker 5 produces the contrasts within a very wide range, while speaker 1 (with the exception of the 55/55+ contrast) produces most of the contrasts within a very narrow range.

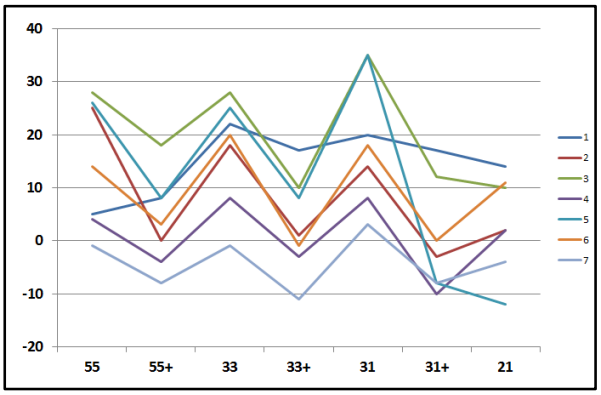

Figure 3: *H1-A3* for /æ/, speakers 1-7.*

On the whole, spectral tilt values are inversely correlated with F1 values, reflecting the relationship of these measures to laryngeal constriction (high spectral tilt values occur in less constricted sounds, which tend to have low F1 values; low spectral tilt values occur in more constricted sounds, which tend to have higher F1 values). In line with this tendency, for all seven speakers, the highest spectral tilt values correspond

to lax tones, and the lowest to tense. Similarly, for all speakers, the highest F1 values correspond to tense tones, and the lowest to lax tones. However, there are individual differences in the ways that spectral tilt and F1 values pattern with specific tones. For example, for speaker 5, the highest and lowest F1 values for /æ/ are for tones 21 and 31, respectively, and the lowest and highest spectral tilt values are for those same tones. However, for speaker 1, whose formant values pattern with speaker 5's (highest for 21, lowest for 31), the lowest and highest spectral tilt values are for tones 55+ and 33, respectively. Thus, speakers differ in the ways that they combine the different cues to the tense/lax contrast, though the relationships between the cues are far from arbitrary.

4. Discussion and Conclusion

In summary, this exploratory study found that Bai speakers distinguish between tense/lax tones on the basis of three acoustic cues: F0, F1, and spectral tilt. Speakers show the greatest homogeneity in their use of F0 as a cue to individual tones, and to tense/lax pairs of tones: across all seven speakers, tense tones have higher F0 than their lax counterparts. Speakers also systematically employ F1 to distinguish between tense and lax tones. In general, across speakers, tense tones have a higher F1 than lax tones. While there are individual differences, the most constricted tones (31+, 21) usually have the highest F1, and the least constricted (31) usually have the lowest. Similarly, for all spectral tilt measures employed (H1-H2, H1-A1*, H1-A2*, and H1-A3*), tense tones tend to have lower spectral tilt values than lax tones, and the most constricted tones (31+, 21) usually have the lowest values, and the least constricted (31) the highest. However, while all speakers use these three cues, individuals differ in the way they distribute these cues among the tones, and in the degree and range of laryngeal constriction they use in producing the tones. These findings suggest that while the phonological system strongly influences the use of acoustic cues, individual portrayals of that phonology differ.

It is possible that given the wide range of articulatory choices at a speaker's disposal in producing laryngeal constriction (i.e. the differing combinations of ventricular fold incursion, larynx raising, tongue and epiglottis retraction, aryepiglottic fold compression, and pharyngeal narrowing, and the differing qualities produced by such combinations, as described in [5]), there is greater scope for individual variation in the production of contrasts based on this feature compared to contrasts that are based exclusively on pitch or vowel formants. A Bai speaker could opt, for example, to produce tense tones with differing degrees of larynx raising, a choice that would tend to result in higher pitch for tense tones relative to their lax counterparts, as well as a more open jaw setting, which would raise F1. This strategy might be sufficient to produce the tense/lax contrast, while seldom resulting in audible harshness or, as a result, low spectral tilt measurements. Another speaker could adopt a more constricted setting across all tones, but employ a greater degree of laryngeal constriction on tense tones, resulting in audible harsh voice and/or aryepiglottic trilling on some tones. Such differences in articulatory strategies may account for the variability in individuals' spectral tilt measurements, while also accounting for the tendency for the F0 and F1 results to pattern similarly across speakers.

The primary intention of this study is to generate baseline adult data for comparison with infant utterances in a study of Bai infants' acquisition of the register tone system in the second and third years of life. This study has several implications for infants' acquisition of the relevant acoustic cues (F0, F1 and spectral tilt). Current research on first language acquisition suggests that in the first year of life (especially the first six months), infants can distinguish between all speech sounds that are employed in languages of the world. Towards the end of the first year, infants lose this sensitivity in favour of developing the ability to distinguish between the sounds used in their ambient language, a result that has been found for non-tonal [18] [19] and tonal [20] [21] [22] contrasts. Thus, like infants learning other tone languages, Bai-learning infants are likely to remain sensitive to pitch differences that are used to distinguish tones. However, in learning Bai, a register tone language, infants also need to remain sensitive to the relationship of these pitch differences to the inter-related cues of vowel quality and spectral tilt, which are used in varied ways by adult speakers of the language. Currently, no research exists on the acquisition of register tone languages, so how Bai infants achieve this perceptual organization remains an open question. Our auditory and acoustic studies of Bai infants' utterances in the first year of life [10] [11] [12] show that Bai-learning infants' babbling includes a higher incidence of, and greater variability in, laryngeal constriction than the babbling of English-learning infants. It remains to be seen, however, how this feature develops in the second and third years of life, and how it interacts with the infants' use of pitch and vowel quality.

Research on infants' and young children's tone production demonstrates that tone acquisition is a protracted developmental process. While infants begin to produce tones in the second and third years of life [23][24][25][26][27][28], their production is not fully adult-like [29][30][31][32], and shows little improvement in accuracy up to the age of five [33]. The latter studies are all based on infants' production of pitch. Our own study will focus on the previously unexplored relationships between pitch, vowel quality, and spectral tilt in the acquisition of register tones. It is likely that Bai infants, like learners of other tone languages, will not fully acquire the Bai tone system until at least the age of five. However, it will be of considerable interest to see which of the eight contrasting tones Bai infants begin to produce in the second and third years of life, and which of the relevant acoustic cues (F0, F1, and spectral tilt) they begin to correlate in their acquisition of the tense/lax contrast.

5. Acknowledgements

The authors would like to thank the Social Sciences and Humanities Research Council of Canada for their support of this research. We would also like to thank Dr. Jerold Edmondson for the use of field recordings of Bai made in Yunnan, China in 2008.

Abstract

We examine the realization of word accent contrasts in Standard Latvian and East Aukštaitian Lithuanian across intonational contexts. In our Latvian data the contrast is manifested as level vs. falling pitch in most contexts, in addition to a durational difference. In Aukštaitian Lithuanian, instead, differences in vowel quality and duration cue the lexical contrast in the nuclei that we examine. While Latvian retains a tonal contrast, in Aukštaitian Lithuanian it has been replaced with a combined segmental/quantitative contrast, where the so-called circumflex tone corresponds to relatively shorter duration and, in the case of diphthongs, centralized quality in the first half. We discuss the implications of these findings for further typological work.

Index Terms: Lithuanian, Latvian, word accent, prosody

1. Introduction

The Baltic languages, Latvian and Lithuanian, are traditionally described as possessing lexical tone in some syllables, although the nature of the lexical contrast, as being based on tone or other features remains controversial. We will use the more phonetically neutral term 'word accent'. Here we investigate the realization of word accent in Latvian and Lithuanian in different intonational contexts, going beyond previous work in this respect. To the extent that existing phonological analyses [1] [7] may be based on an incomplete understanding of the phonetic facts, they may be in need of revision.

Our data are based on utterances elicited from educated native speakers by means of a questionnaire and containing minimal or near minimal pairs. Given the controversies regarding the nature or even the existence of the contrasts that we are investigating, we decided that using a maximally explicit methodology for data elicitation was appropriate. Naturally, this methodology will tend to produce somewhat hyperarticulated realizations of any existing phonological contrasts. All participants were either faculty or students at Stockholm University at the time of the experiment.

2. Latvian

2.1. Status Quaestionis

In Latvian, stress generally falls on the initial syllable of the word. If the stressed syllable is heavy (that is, if it contains a long rhyme: long vowel, diphthong or a postvocalic consonant), in some dialects, a three-way contrast in accent type in syllables is said to obtain. The three accents have been described as level (also known as "even" or "circumflex"), falling (or "acute") and glottalized (or "broken"). In linguistic work the level accent is represented with a tilde, e.g. [ã], the falling accent with a grave accent mark, [à] and the glottalized accent with a circumflex accent mark, [â]. An acoustic characterization of these three accents in words obtained in medial position in a carrier phrase is found in [5] [6]. In this context, in terms of tonal contour, the level accent has a high level, slightly rising F0 throughout the stress syllable, whereas the other two accents, falling and broken, are characterized by an F0 peak towards the middle of the syllable, followed by a sharp drop in F0 in the second mora. The broken accent is distinguished from the falling accent in showing glottalization in the second mora. There are no accentual contrasts in light syllables.

In most dialects, however, there is only a two-way word-accent distinction. In particular, contemporary Standard Latvian, the variety that we examine here, distinguishes only "even" from "non-even" accent (the latter having resulted from the historical merger of the falling and broken accents, [7]).

2.2. Methods

We constructed a list of 15 mini-dialogues in order to elicit the same target word in different intonational contexts (e.g. Contrastive focus: Did Peter say apple? No, Peter say TARGET; Postfocus: So, Peter wrote TARGET? No Peter said TARGET; etc.). Target words were members of minimal pairs. Here we report on one of these pairs: *zāle* [zãle] (even, E) 'hall' vs. *zāle* [zâle] (non-even, N) 'grass'. Participants were asked to read the dialogues (both the context and the sentence containing the target word) naturally and at a comfortable speed. To avoid confusion between members of each minimal pair, all 15 mini-dialogues involving the same target word were presented together. Participants were three speakers of Standard Latvian, from the central dialectal area: one male from Riga and two females, from Seldus and Valmiera.

2.3. Results

Consistent with previous description, the even accent was realized as relatively flat high pitch over the heavy stressed syllable in contexts where the test word is under focus (Fig. 1, left). In postfocal and prefocal position, however, the even accent was realized as flat *low* pitch (Fig. 2). It thus appears that what characterizes the even accent across contexts is the absence of tonal differences between the beginning and the end of the syllable, with a relatively flat pitch throughout. The crucial aspect appears to be that both morae in the heavy stressed syllable receive the same tone, be it high or low.

In contrast, the non-even accent is produced in most contexts with a pitch fall from the first to the second mora (Fig. 1, right). This is except in final position in questions, where there may be a final rise.

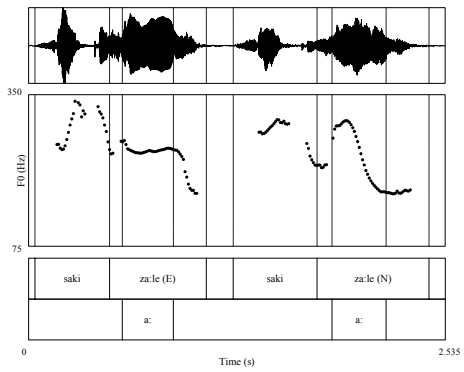

Fig. 1. *saki zāle* [zāle] (E) 'say hall' vs. *saki zâle* [zâle] (N) 'say grass'. Female speaker from Saldus.

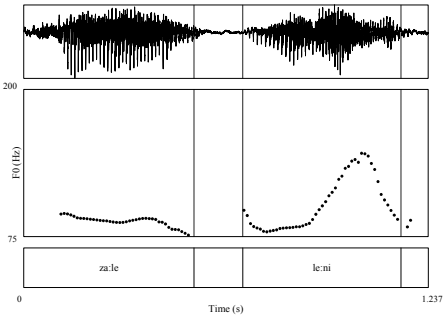

Fig. 2 (*Vai Peteris teica*) *zāle LENI*? '(Did Peter say) hall SLOWLY?' Even accent realized as low flat low pitch. Male speaker from Riga.

The contrast between the F0 contours can be captured numerically as the difference between F0 maximum and minimum during the stressed nucleus. For our two female speakers, average values including all contexts were 83 Hz under E accent and 123 Hz under N accent (t-test: t = –2.6895, df = 63.269, p = 0.009138). For our male speaker this value could not be accurately calculated for a large number of tokens because of the presence of glottalization during the second half of the stressed nucleus under non-even accent. Glottalization was realized either as a glottal stop (Fig. 3) or as irregular pulsation.

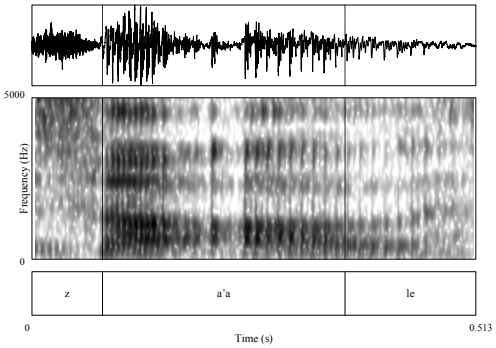

Fig. 3. *zâle* (N) 'grass'. Example of non-even accent accompanied by glottal stop. Male speaker from Riga.

For this speaker we have analyzed a second minimal pair, *loks* [luõks] 'spring onion' vs. *logs* [luôks] 'window'. A measure of the presence of glottalization can be obtained by calculating the percentage of the stressed nucleus with regular pulsation. This is shown in Fig. 4, with the results returned by the function VoicedFrames in PRAAT [2] for the stressed nucleus of E and N words. For both N words (*logs*-N, *zale*-N) glottalization is common, but not systematic. That is, for this speaker the neutralization of the falling and broken or glottalized accent in Standard Latvian (see [7]) appears to have resulted in an allophonic range that includes different degrees of glottal constriction. Our female speakers did not produce glottalization.

A significant difference in duration was also found for all speakers, with E words being realized with a longer vowel (means, *zãle* E = 335 ms, *zâle* N = 288 ms, t = 5.7486, df = 97.287, p = 1.035e-07)

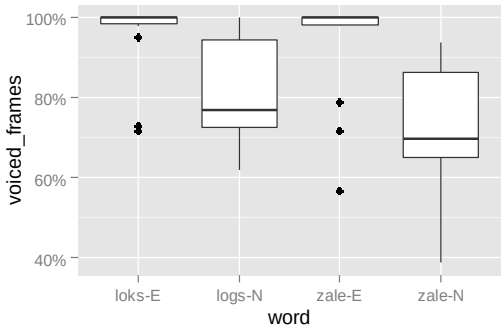

Fig. 4. 'Voiced Frames' in stressed nucleus for E and N words, male speaker from Riga.

2.4. Discussion

Kariņš [6] proposes a phonological lexical tone analysis of the Latvian accentual contrast, based on the F0 contours of words within a carrier phrase. In his analysis, the E accent is phonetically unspecified and receives a phrasal H tone that attaches to the second mora of the stressed syllable. In words with a falling, N, accent, on the other hand, there is a lexical L on the second mora and the phrasal H attaches to the first mora. (Kariņš assigns a more complex tonal specification, LH to words with a broken accent.) The contours that we have obtained in declarative sentences where the target word is under focus are similar to those described in [6], except that our speakers do not have a lexical contrast between non-even accents with and without glottalization ("falling" and "broken"). By expanding the elicitation to other phrasal and intonational contexts, we notice that there is no consistent tonal contour across all contexts. The E accent may be H or L. In final position in questions, this accent may show up without the fall, perhaps because a final H% boundary tone pushes the lexical L from the second mora to the first, under crowding. No phrasal H is then assigned to the accented syllable. Glottalization in the speech of our male speaker (from Riga), appears to be a secondary correlate of N accent.

3. Lithuanian

3.1. Status quaestionis

Lithuanian has a complex stress system, reminiscent of that of Russian, where some nouns have stress on the stem in some declensional cases and stress on the suffix in other cases, other nouns have stress on the suffix in all cases, etc.

A further complication with respect to Russian is that if the stressed syllable is heavy it may bear one of two lexical accents, traditionally known as "acute" (A) and "circumflex" (C). Although traditionally described as a contrast in lexical tone, the nature of this contrast in present-day Lithuanian has been disputed and may differ according to geographical variety. In the standard variety, the contrast is manifested not by pitch, but by differences in spectral structure and duration [3] [4] [9] [11]. Dogil & Möhler [3] report that, regarding pitch, in words pronounced in carrier phrases, A has a clear rise-fall pattern within the stressed syllable, whereas C has a very variable realization and its F0 shape cannot be defined.

3.2. Methods

We selected three near-minimal pairs, stressed on the same syllable and contrasting in word accent: *láužą* A 'bonfire' vs. *laũmę* C 'pixie', *láimę* A 'happiness' vs. *laĩvą* C 'ship' and *výrą* A 'man' vs. *vỹną* C 'wine'). Two of our minimal pairs illustrate the falling diphtongs /ai/ and /au/ and the third one is used to test the contrast with a long vowel, /i:/ (orthographical <y>). To elicit the data we used a questionnaire that included the same 15 pragmatic contexts as for Latvian: broad focus, all new, contrastive, prefocal, narrow focus final, narrow focus non-final, obviousness, postfocus, yes-no question, confirmation question, surprise, suggestion, command, vocative and continuation. Our two subjects are both college-educated female speakers of Lithuanian, from the Highland Lithuanian or Aukštaitian area: one of them is from Utena and the other one is from Panevėžys. They were asked to read both the context and the target sentence with natural intonation.

3.3. Results

Regarding pitch contours, we find no consistent difference between words with A and C accent in the same sentential and intonational context. Both speakers produced very similar F0 contours in each of the contexts tested. Under focus, words of both accent classes show a rise in pitch throughout the stressed syllable with a peak towards the middle or end of this syllable, see Fig. 5 (although, the alignment within the syllable nucleus is different given the longer duration of the first element of the diphthong in A words, see below).

For both classes of words, quite different contours were obtained under other contextual conditions, including a later rise with a peak after the stressed syllable in prenuclear position (Fig. 6) and a low flat contour in phrase-final position under broad focus (Fig. 7).

For words with the diphthongs orthographically represented as <au> and <ai>, we find, however, considerable spectral and durational differences according to etymological class. In particular, in C words, the first element in the diphthong is considerably reduced in duration and centralized in quality, cf. [9]. For all three pairs of words, the stressed nucleus is significantly longer in A than in C words: *láimę* A 'happiness' vs. *laĩvą* C 'ship', t=2.2, df=57.8, p=0.028 ; *láužą* A 'bonfire' vs. *laũmę* C 'pixie', t=4.2 , df =57.57, p <0.0001; *výrą* A 'man' vs. *vỹną* C 'wine', t= 2.9153, df = 57.668, p=0.005.

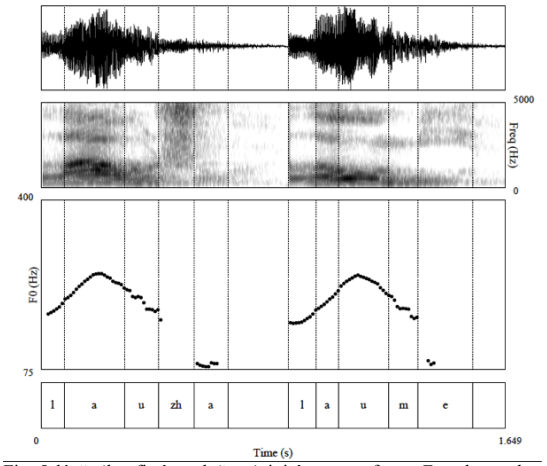

Fig. 5 *láužą* 'bonfire' vs. *laũmę* 'pixie', narrow focus. Female speaker from Utena.

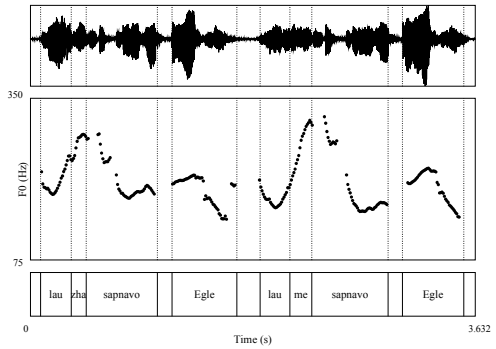

Fig. 6. Late rise on *láužą* vs. *laũmę* in prefocal position: *láužą*/*laũmę sapnãvo Ẽglė*, lit. 'about bonfire/about a pixie dreamt Eglė'. Female speaker from Panevėžys.

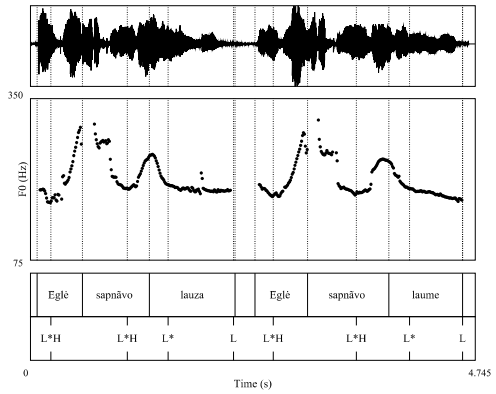

Fig. 7. Flat low pitch on *láužą* and *laũmę* in phrase-final position, broad focus: *Eglė sapnãvo láužą*/*laũmę* 'Eglė dreamt about a bonfire/a pixie'. Female speaker from Panevėžys.

For words with the diphthongs orthographically represented as <au> and <ai>, we find, however, considerable spectral and durational differences according to etymological class. In particular, in C words, the first element in the diphthong is considerably reduced in duration and centralized in quality, cf. [9]. For all three pairs of words, the stressed nucleus is significantly longer in A than in C words: *láimę* A 'happiness' vs. *laĩvą* C'ship', t=2.2, df=57.8, p=0.02856; *láužą* A 'bonfire' vs. *laũmę* C 'pixie', t =4.2 , df=57.5 , p<0.0001; *výrą* A 'man' vs. *vỹną* C 'wine', t =2.9, df=57.6, p=0.005.

In Fig. 8, F1 maxima in stressed nuclei are compared. It is apparent that the A diphthong words *láimę* and *láužą* have a much higher F1 maximum than their C counterparts *laĩvą* and *laũmę*, indicating a considerably lower first element. (t-tests: *láimę* vs. *laĩvą,* t=21.6, df = 40.5, p < 0.0001; *láužą* vs. *laũmę,* t =28.5, df =50.9, p<0.0001). There is no significant difference between the two items containing a long monophthong /i:/.

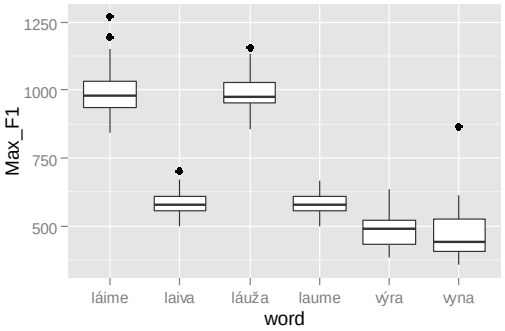

Fig 8. F1 maximum in Hz. The C words, *laĩvą*, *laũmę* have a significantly lower maximum F1 than their A counterparts.

In Fig. 9 we plot the means of formant values at F1 maximum and minimum for <ai> and <au> diphthongs. The graph shows that the A words *láimę* and *láužą* have a low vowel as first element of the diphthong, whereas in the circumflex words, *laĩvą* and *laũmę* this element is a mid vowel. On the other hand, the glide has more extreme values for the C words: higher for <ai> and higher and more posterior for <au>.

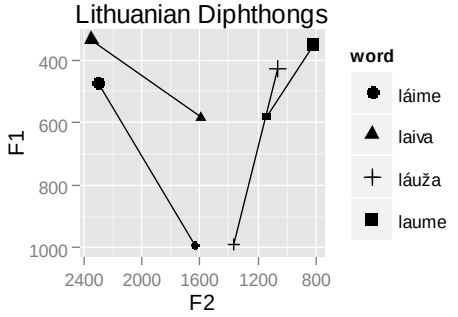

Fig. 9. Plot of F1 maxima and minima and F2 values at those two points for each of the four diphthong items: *láimę*, *laĩvą*, *láužą* and *laũmę*. (Diacritics are missing in the figure for typographical reasons.)

3.4. Discussion

In our East Aukštaitian Lithuanian data, vowel quality and relative duration cue the A vs. C contrast. In particular, the diphthongs <ai>, <au> have a shorter, raised nucleus and a more extreme glide in circumflex words. The long vowel <y> is also slightly shorter in circumflex words. Other heavy syllables, including those closed by a sonorant consonant remain to be investigated. As in other recent acoustic work, we have not found a difference in tonal contours between the two lexical classes.

4. General discussion

The two systems that we have examined are at some typological distance from each other. The stress systems are different, Latvian having developed fixed initial stress, and Lithuanian retaining mobile stress. Whereas for Latvian we find a consistent tonal contrasts in stressed syllables (enhanced by duration), in Lithuanian the etymological accentual contrast is cued by durational and vowel quality differences. For both languages an analysis of the word accent contrast in terms of domain of prominence (syllable vs. mora, [3]) seems possible. However, such an analysis has implications for phonology (e.g. metrical theory), as well as for typology, where intermediate varieties (e.g. mobile stress combined with a tonal contrast) would need to be examined, before an adequate phonological analysis could be determined.

From a diachronic perspective an important question that arises is how a contrast in lexical tonal accent develops into a vowel-quality/durational contrast.

We end with a cautionary note. Given the small number of speakers and test items, the results of this paper must be taken as provisional and awaiting further confirmation.

5. Acknowledgements

We are thankful to our Latvian and Lithuanian speakers for their participation, to Peteris Vanags and Kristina Bukelskytė-Čepele for their help with the experimental materials and to Daniel Scarpace for help with the PRAAT and R scripts. We also gratefully acknowledge the support of the Illinois-Sweden Program for Education and Research (INSPIRE).

Abstract

A deep neural network (DNN) classifier based only on 40 mel-frequency cepstral coefficients (MFCCs) achieved 29.99% frame error rate (FER) and 16.86% segment error rate (SER) in recognizing five tonal categories in Mandarin Chinese broadcast news. With the addition of subband autocorrelation change detection (SACD) pitch-class features [1], the classifier scored 27.58% FER and 15.56% SER. These results are substantially better than the best previously reported results on broadcast news tone classification [2] and are also better than a human listener achieved in categorizing test stimuli created by amplitude- and frequency-modulating complex tones to match the extracted F_0 and amplitude parameters [3]. The same DNN architecture scored substantially worse when trained and tested with SACD pitch-class parameters alone: 39.22% FER and 24.89% SER. RAPT F_0 estimates are worse yet: 44.37% FER and 27.28% SER. The 40 MFCC parameters do not encode F_0 in any obvious way and attempts to predict SACD or other pitch features from them work badly. These surprising results raise difficult questions for theories of Chinese tone.

Index Terms: speech recognition, Mandarin, tone modeling, deep neural networks

1. Introduction

Typically, Chinese speech-recognition systems have included tonal features in order to improve performance in the integrated task of recognizing tonally-specified segments [4, 5, 6, 7]. More recently, there has been increased interest in the more specific problem of automated recognition of tonal categories alone in continuous speech [8, 2, 9, 10]. For instance, Pui-Fung [8] uses decision trees and a segmental representation based on the fitting of polynomials to the F_0 contour to achieve 27.8% segment error rate (SER). Lei [2] achieves 23.8% SER using MLPs and contextual information. Most recently, Kalinli [10] achieved 21% SER, albeit for command-and-control utterances, with the incorporation of biologically inspired auditory features.

Of the above papers, all save Kalinli perform explicit pitch tracking (though even Kalinli includes parameters that are probably an excellent proxy for F_0 slope). However, pitch is notoriously hard to accurately estimate even in cases where it is not inherently ambiguous [11]. Moreover, for the task of interest, tone classification, absolute pitch is not itself even particularly relevant but, rather, changes in pitch over an interval of time. Such being the case, it has been suggested that it is more appropriate to estimate pitch changes directly [1]. Using subband autocorrelation change detection (SACD) features, Slaney achieves superior performance for 4-way tone classification on a corpus of Mandarin phone speech with the SACD features providing relative reductions in error ranging from 10% for clean materials to 17% for speech corrupted by white noise.

Yet more recent work demonstrated successful Mandarin tone classification for broadcast news materials in the absence of any explicit pitch-related information whatsoever [3]. Using a deep neural network (DNN) based classifier and an input representation consisting of 21 consecutive frames of 40 mel frequency cepstral coefficients, our previous work achieves an SER of 16.62%, a 7.04% absolute reduction relative to a baseline system incorporating explicit, but perhaps errorful, F_0 information.

Jointly the findings of Slaney and Ryant suggest that at least for some tone languages, highly accurate tone classification is possible in the absence of explicit pitch tracking; indeed, that tone is not "just" about F_0. In this paper we extend this work and directly compare the efficacy of these features for Mandarin tone classification using the same training/test sets and machine learning infrastructure. We also consider possible explanations for why the MFCC frontend is so successful.

2. Data and evaluation

Testing and training sets were constructed using the 1997 Mandarin Broadcast News Speech corpus [12][1]. We extracted all "utterances" (the between-pause units that are time-stamped in the transcripts) from the corpus and manually excluded those containing background noise or music. Utterances from speakers whose names were not tagged in the corpus or from speakers with accented speech were also excluded. In total 7,849 utterances from 20 speakers were selected. From these we randomly selected 50 utterances from each of six speakers to compose a test set, with the remaining 7,549 utterances reserved for training. The 300 test utterances were manually labeled and segmented into initials and finals by a native Mandarin speaker. Tones were marked on the finals, including Tone1 through Tone4, and Tone0 for the neutral tone. The total number of utterances, segments, and hours of speech are detailed in Table 1.

	Hours	Utterances	Segments	TBUs
Train	6.05	7,549	196,330	96,697
Test	0.22	300	7,189	3,464

Table 1: Train/test set composition. TBU = tone-bearing unit, defined as the syllable final.

System performance is measured in two ways. As an initial evaluation of the quality of the representation learned by the network, we consider its frame error rate (FER), defined as the percentage of frames incorrectly classified by the DNN. Our primary metric, however, is segment error rate (SER), defined as the percentage of TBUs incorrectly classified.

3. System description

We propose attacking the problem of explicit tone classification as follows:

1) Train a DNN to classify each frame of speech into one of six tone classes: Tone0, Tone1, Tone2, Tone3, Tone4, No-tone.

2) Compute "tonal features" for each segment, defined as the mean of the outputs of the DNN over all frames contained within that segment. These are similar to Chao's articulatory features [9].

3) Use these "tonal features", along with segment duration and contextual features, to classify the tone-bearing units (TBUs).

3.1. Features

We train four separate tone-classification systems using different feature frontends:

1. *RAPT F_0 estimate*
   Our first feature consists of F_0 as estimated by peaks in the normalized cross-correlation function using RAPT [13] as implemented in ESPS's *get_f0* with the following parameters: wind_dur=0.01, min_f0=60, max_f0=650.

2. *SAaC F_0 estimate*
   A second F_0 estimate is computed using the SAaC system [14]. A correlogram is constructed by running the signal through an auditory filterbank and calculating the autocorrelation for each channel. The size of this representation is reduced using PCA and the retained principal components serve as input to an MLP that classifies frames into one of 70 pitch classes (67 classes spanning 60-400 Hz on a logarithmic axis plus additional classes corresponding to unvoiced, out of range low, and out of range high). Viterbi decoding of the MLP outputs produces a smoothed pitch track.

3. *SACD*
   We also consider SACD features [1]. As with SAaC, an MLP is trained to classify frames into one of 70 pitch classes on the basis of the principal components of a correlogram. The MLP-derived pitch class probabilities are smoothed across frames using a 5-frame moving average window and cross-correlation between adjacent frames calculated for a range of lags. The final SACD features consist of the cross-correlation values corresponding to lags from -2 to 2.

4. *MFCC*
   Forty mel frequency cepstral coefficients (MFCCs) were extracted using the following analysis parameters: i) 0.97 pre-emphasis factor; ii) 25 ms Hamming window; iii) 1024-point DFT; iv) 40 filter mel-scale filterbank[2].

In addition to systems trained using the RAPT, SAaC, SACD, and MFCC features individually, we also consider each combination of the MFCC features and the pitch-related featuress. All features, including the F_0 estimates, were computed every 10 ms and normalized to have 0 mean and unit variance on a per-utterance basis[3].

3.2. Network training

For each feature combination a DNN was trained [16] to classify frames of the signal as one of the six targets.

[1] The specific dataset used in these experiments will be published by the LDC and meanwhile is available from the authors by request.

[2] Our MFCCs may be reproduced using *melfcc* [15] with the following parameter values: wintime=0.025, hoptime=0.010, nbands=40, numcep=40, lifterexp=-22, sumpower=0, minfreq=0, maxfreq=8000, dcttype=3.

[3] We examined other normalization schemes, including one in which F_0 normalization was restricted to voiced segments, but this choice had negligible impact on the final accuracy.

Input to the DNN consisted of a high-dimensional feature vector derived by concatenating the extracted features for all frames in a 21-frame context window (10-1-10). Training targets were derived by forced alignment of the HUB-4 training utterances using an HMM-based forced aligner built on the training utterances with the CALLHOME Mandarin Chinese Lexicon [17] and HTK. The aligner employed explicit phone boundary models [18] and achieved 93.1% agreement within 20 ms compared to manual segmentation on the test set. Additionally, we checked 100 training utterances on the tone labels automatically generated by the aligner. Among the 1,252 syllables in the 100 utterances, 15 syllables had a wrong tone, an error rate of 1.2%[4].

The full network topology consisted of: i) the input layer; ii) 4 hidden layers, each consisting of 2000 rectified linear units (ReLUs) [19]; iii) an output layer consisting of 6 softmax units. The network was trained for 60 epochs (each epoch consisting of 250,000 examples) using stochastic gradient descent with a minibatch size of 128, 20% dropout [20] in the input layer, 30% dropout in the hidden layers, and a cross-entropy objective. Learning rate was kept constant within epochs and followed the schedule $\eta(n) = \eta(0)\frac{500}{n+500}$, where $\eta(0) = 0.5$, while momentum was kept constant at 0.5 throughout training. No L_2 weight decay was used, but the incoming weight vector at each hidden unit was constrained to have a maximum L_2-norm of 3.

3.3. Segment-level classification

Segment-level classification decisions were made using a single-layer neural network trained to assign tone classes to the TBUs. Input features consisted of the tonal features of the segment, duration (in seconds) of the segment (as determined by the forced alignment boundaries), and tonal features and durations of the two immediately preceding and two immediately following segments. The neural network contained a single hidden layer of 128 ReLUs and was trained for 1,000 epochs (epoch=100,000 instances) using stochastic gradient descent with minibatch size of 512, 30% hidden layer dropout, a decaying learning rate beginning at 1, and a constant momentum of 0.9. The incoming weight vector at each hidden unit was constrained to have a maximum L_2-norm of 1.

4. Results

FERs and SERs for the trained systems are shown in Table 2. Because silences and other unvoiced regions are relatively easy to recognize in material of this kind and, therefore, a FER that includes such regions will depend on the amount of silence that is included in the test set, we depict not only overall FER, but also FER excluding frames that do not correspond to a tone bearing unit in the gold standard segmentation. Three results are immediately apparent. One, in accord with earlier findings [1], the SACD features are more informative than either RAPT or SAaC-derived F_0 estimates. Indeed, FER on TBUs for the the system trained on SACD features is 39.22% and SER 24.89%, which represents relative error reductions of 11.61% and 8.76% respectively from the figures achieved by the system using RAPT F_0 estimates. Two, replicating our earlier findings [3], the system trained only using the MFCC frontend trounces the systems trained using only pitch related features, reducing TBU FER by 23.53% and SER by 32.36% relative to the system trained using SACD. Three, while inclusion of F_0 alongside MFCCs fails to improve (hurts actually) performance, adding SACD features does appear to help, resulting in relative reductions of 8.04% for FER on TBUs and 8.35% for SER. This result suggests that, whatever information is contained in the MFCCs, it is complementary to that contained in the SACD features.

	Frame Error Rate (FER)			
	Overall	TBUs	Tones 1−4	SER
RAPT	29.09	44.37	42.05	27.28
SAaC	32.39	49.64	47.55	28.67
SACD	25.25	39.22	37.05	24.89
MFCC	18.88	29.99	29.35	16.86
MFCC+RAPT	18.70	29.98	29.43	17.47
MFCC+SAaC	18.79	29.38	28.75	17.52
MFCC+SACD	17.57	27.58	27.00	15.56

Table 2: Frame error rates and segment error rates (%) on test set for DNNs trained using various combinations of the feature frontends.

5. General discussion

The success of MFCCs with a context window of many frames of MFCCs is, at first glance, perplexing: how does a representation in which information about pitch should be eradicated, or at least substantially blurred, do so well at predicting tones on segments, a task that is supposedly entirely about pitch? One possible explanation for our performance is that the DNN system is actually somehow implicitly learning to do overall phone recognition with the tone recognition merely a byproduct. While perfect (toneless) phone recognition is implausible[5], we do put the idea to the test by comparing FER and SER of the MFCC-trained system with the FER and SER of an oracle

[4]These errors are primarily due to application of third tone sandhi across word boundaries.

[5]When we trained a DNN with the same topology and hyperparameters used for the tone classification experiments to predict the (toneless) phone categories using the MFCC features as input, final frame error rate on the test set came to 21.2%, suggesting that, in the absence of a language-model or other higher-level information, we would be unlikely to do better than 80% accuracy at predicting phones, much less 100%.

with perfect knowledge of the pinyin of each initial/final, but no other information about tone at all (Table 3). An oracle making maximum-likelihood guesses given perfect phone knowledge produces 51.96% SER compared to 16.86% for the MFCC only system.

Perhaps more context helps? Just in case, we also consider the performance of a second oracle, which predicts the tone class of each segment using perfect (toneless) knowledge of the phone class of the preceding, current, and following segments and a neural network with a single hidden layer of 128 rectified linear units (depicted as Oracle (tri) in the table). Inclusion of this additional context does improve performance markedly, bringing TBU FER down to 21.27% and SER to 20.76%, suggesting that in the unlikely event of perfect recognition of a span of three pinyin initials or finals, reasonably good tone recognition is possible, even in the absence of a language model. However, these error rates remain substantially higher than what the DNN is achieving, suggesting some other mechanism is at work.

	Frame Error Rate (FER)			
	Overall	TBUs	Tones 1−4	SER
Oracle (mono)	28.28	52.14	53.79	51.96
Oracle (tri)	11.54	21.27	21.84	20.76

Table 3: Frame error rates and segment error rates (%) on test set for two oracle systems.

Alternately, it may be the case that the DNN is making use of a multitude of other, non-pitch, phonetic dimensions, which jointly are predictive of tone class. Acoustic analysis of Mandarin syllables suggests that duration [21, 22], temporal envelope [22], and formant structure [23] differ for different lexical tones of the same syllable. Moreover, it is well established that, though impaired relative to clean speech, native speakers are able to identify tone in both real [24, 25] and synthetic [26, 22] whispered speech at well above chance levels. In light of these findings the thesis tying the DNN's performance to efficient use of non-pitch information represented in the MFCCs is plausible.

Finally, it should be considered that the DNN may be recovering F_0 information from the MFCC parameters, either in terms of the actual pitch track or some other form. Conventional wisdom suggests that MFCC and its ilk are good for speech recognition because they represent the rough shape of the spectrum, but without the pitch information[6]. Nevertheless, as a test of the hypothesis that F_0 is being extracted, we trained a DNN to predict the SAaC/SACD pitch classes using the MFCC features as input. While this network was able to achieve a frame error rate of 29.48% on the test set for pitch-class prediction, error analysis reveals that this is principally because the network is very good at making voicing distinctions as opposed to actually successfully determining pitch in voiced segments (unvoiced frame error: 1.83%; voiced frame error: 45.3%).

However, this does not rule out the other possibility: that the network is pulling out some other, pitch-related information from the MFCC representation that has predictive power. To explore this idea, we performed a simple comparison experiment by synthesizing a large number of static vowels with random pitches centered at 120 Hz (male) and 200 Hz (female) using Praat [29]. Figure 1 shows the relative contrast between three different vowels (/a/, /ɪ/, /u/), and the same vowel at two pitches separated by 2 semitones. As we vary the number of cepstral coefficients between 1 and 40, the MFCC representation does a better job of capturing their differences, as reflected in the Euclidean distance. For these highly stylized vowels (fixed pitch, no noise, no coarticulation) the female pitch change leads to longer distances, suggesting that the pitch change is reflected in the MFCC coefficients at least for widely spaced harmonics. Interestingly, this difference only shows up when the number of cepstral coefficients is more than 20. This difference might allow a classifier to more easily notice the two classes. Yet, we were not able to see any significant difference in the performance of the DNN network when we looked at male vs. female speakers.

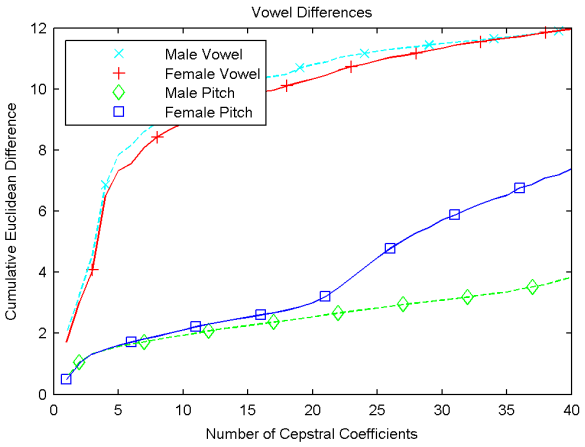

Figure 1: The average distance between two vowels, as a function of the size of the cepstral vector. The top two curves are for two different vowels at the same pitch. The bottom two curves are for the *same* vowel at two pitches that differ by 2 semitones. The synthetic vowels have an average pitch of 120 Hz for the male examples, and 200 Hz for the female examples, in line with the Mandarin database used in this paper.

Most probably, all three hypotheses are true to an extent and the DNN is using all three sources of information jointly to make its final predictions.

[6]Though see also [27, 28], who report success in predicting F0 in English read speech using a standard 23 channel, 13 cepstral coefficient MFCC representation.

Abstract

This paper examines acoustic correlates of intonation in Polish whispered, semi-whispered and normal speech modes. In particular, it investigates correlates of utterance-final rising intonation in polar questions and falling intonation in statements. The paper examines not only properties of vowels but also properties of the following voiceless consonant clusters.

The study is based on measurements of 4608 sibilants (fricatives and affricates) produced by 16 native speakers of Polish. The results point to differences in spectral properties of both utterance-final vowels and consonants where falling intonation in statements contrasts with rising intonation in polar questions. Regarding the consonants, both fricatives and affricates are produced with higher spectral peaks, higher intensity and higher COG and STD values in questions than in statements. Skewness and kurtosis values are lower in questions than in statements. Some spectral differences of sibilants, including spectral slopes, are more distinguishable for questions versus statements in the whispered speech mode than in other speech modes. The more pronounced role of these cues in whispered speech suggests their compensatory function for the fundamental frequency, which is the main correlate of intonation in phonated speech but is completely absent in whispered speech.

In summary, the study shows that speakers produce intended intonation patterns by varying the choice of cues as well as their magnitude in dependence on both (i) speech modes and (ii) intonation patterns.

Index Terms: whispered speech, intonation, voiceless clusters, Polish

1. Introduction

Interaction between segments and prosody, in general, and between segments and intonation in particular, still belongs to an understudied area of phonetic and phonological research. Relatively little is known about this interaction in whispered speech, and less so in semi-whispered speech; cf. [1] for studies of this interaction in the normal speech mode.

The overall goal of this paper is two-fold. First, it is aimed at providing an insight into the realisation of intended intonation in whispered speech where F0, the main correlate of intonation is completely absent and semi-whispered speech, where F0 is partially absent. Second, the study is intended to contribute to a better understanding of the role of voiceless segments in conveying different intonation patterns in various speech modes.

In particular, the paper addresses two questions:

(1) How are different patterns of intonation produced in whispered speech in comparison to semi-whispered and normal speech modes?

(2) How do voiceless consonant clusters contribute to intended intonation patterns in all three speech modes?

In order to answer these questions we conducted an acoustic speech production experiment on Polish, a language which provides suitable test material due to its abundance of complex consonant clusters.

2. Methods

We recorded eight different items ending in clusters consisting of voiceless retroflex fricatives followed by retroflex affricates. Each item was presented in a polar question ('Widzi ten blu[ʂt͡ʂ]?' '*Does he see the ivy*?') and a statement ('Widzi ten blu[ʂt͡ʂ]' '*He sees the ivy*'). All words were monosyllabic. The polar question was expected to be produced with a rising intonation and the statement with a falling intonation. In order to compare the realisation of intonation in whispered speech with other speech modes we recorded the questions and statements described above in three different speech modes: normal, whispered and semi-whispered.

Sixteen native speakers of Polish (eigth male), aged 20 to 52 years, took part in the experiment. All speakers were monolingual and spoke Standard Polish. They were asked to read the sentences in all three speech modes, as described above. All recordings were conducted in the sound-proof room at the Electrical Engineering Department of the West Pomeranian University of Technology in Szczecin using a TLM103 Neumann microphone (20cm distance from lips) connected to a ProTools system with a Digi 003 interface (sample rate 44100 Hz). The items were analysed with Praat (version 5.3.57 [2]) and MATLAB (version R2007b [3]). In total, measurements of 4608 sibilants were taken (8 items × 2 sentence types (question, statement) × 3 speech modes (normal, semi-whispered, whispered) × 2 sibilant types (fricative, affricate) × 3 repetitions × 16 speakers).

We investigated the following acoustic parameters, see [4] for all parameter details. Note that the parameters displayed in (f), (g) and (h) were calculated at the onset, midpoint and offset of the frication of both sibilants.

(a) duration of the vowel, fricative and affricate;

(b) maximum and mean of F0 of the preceding vowel;

(c) F0 difference between the vowel offset and onset;

(d) formants F1, F2, F3 (using the formant extraction of PRAAT [2]) at the (i) vowel onset, (ii) midpoint and (iii) vowel offset;

(e) mean intensity over the complete duration of the vowel, the fricative and the affricate;

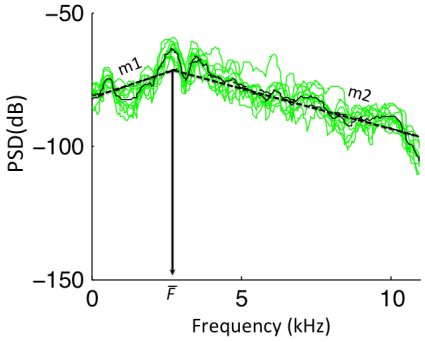
(f) frequency of the highest spectral peak of the frication noise in the range from 20Hz to11kHz;

(g) spectral Centre of Gravity (COG), its standard deviation (STD), skewness, and kurtosis;

(h) the spectral regression slopes, as described in [5]: m1 is the slope of the spectral regression line for the frequency range between 500 Hz and 3000 Hz, and m2 is the slope of the spectral regression line for the range between 3000 Hz and 11025 kHz (see Figure 1).

We computed multitaper spectra with a 12 ms window for the frication noise midpoint (512 point Hamming window). The power spectral density (PSD) was estimated via the Thomson multitaper method (linear combination with unity weights of individual spectral estimates and the default FFT length) available in the MathWorks Signal Processing Toolbox Version 6 [3].

Figure 1 shows an example of 10 different multitaper spectra, from one individual speaker, the overlaid mean spectrum and the computation of the regression lines m1 and m2, with the endpoint/startpoint $\bar{F}$.



(i)

Figure 1: *Multitaper spectra (light colour) with mean spectrum (black solid) and regression lines (dashed black) used to calculate the low-frequency slope (m1) and high-frequency slope (m2), with the end/starting point at the mean frequency* $\bar{F}$.

Regarding statistical analysis, linear mixed effect models were employed for the investigated variables, which were studied as effects of INTONATION (rising vs. falling) and SPEECH MODE (normal, semi-whispered and whispered), as well as their interaction (INTONATION*SPEECHMODE). GENDER (male, female) was included as fixed effect as well. In addition, speaker-specific random slopes for INTONATION TYPE and SPEECH MODE were included into the model. ITEM and SPEAKER were taken as random effects.

All analyses were conducted in the R environment software (version 3.0.2) [6].

3. Results

Our results show that different acoustic cues are used to a different extent when producing questions versus statements in various speech modes. In the following we report only those results which – due to their significance – are important for answering the main questions of this study, cf. (1) and (2).

Regarding duration of the vowel, whispered vowels were generally longer than vowels produced in semi-whispered (t=7.304, p<.0001) and normal speech mode (t=5.799, p<.0001). No significant differences were found between statements and questions in all three speech modes.

As was expected, the F0 maximum and the F0 mean of the vowel preceding the sibilant cluster were significantly higher in questions than in statements (F0 max: t=11.21, p <.0001, F0 mean: t=13.41, p <.0001). In addition, we calculated the F0 difference between the vowel offset and onset which in fact points to raising F0 in questions (female:142 Hz, male:81 Hz) and falling F0 in statements (female:-15 Hz, male:-17 Hz) confirming our initial assumption about F0 differences in intonation patterns (t=10.726, p<.0001); cf. also [7], [8]. Due to the complete absence of the F0 in whispered speech and the partial absence of the F0 in semi-whispered speech, (where the F0 cannot be reliably extracted) we did not analyse this parameter in those two modes.

The absence of F0 in whispered speech leads us to a key question for the present study, namely: How can a distinction in intonation be realized in questions and statements in whispered speech if the F0, the most important correlate of intonation, does not play a distinguishing role?

First, our results point to the importance of formants. The first formant frequency is significantly higher in questions than in statements in whispered (t= 6.23, p<.0001) and normal speech (t=5.174 p<.0001) but lower in semi-whispered speech (t=-3.726 p<.0001). Furthermore, the second formant frequency of the vowel is significantly higher in questions than in statements only in whispered speech (t=2.812, p<.01) but lower in semi-whispered speech (t=-6.485 p<.0001). In normal speech mode the formants do not show any significant difference when questions and statements are performed. Finally, the third formant frequency is higher in questions than in statements in whispered (t=4.15, p<.0001) and normal speech (t=1.76, p<.05).

Regarding the mean intensity of the vowel, the results show that it is significantly higher in questions than in statements across all speech modes: whispered (t=16.76, p<.0001), normal (t=20.67, p<.0001) and semi-whispered (t=14.91, p<.0001).

Besides clear differences in the realisation of whispered vowels in questions and statements, our results point to significant differences in sibilant clusters depending on the intonation type.

Regarding duration, fricatives were longer in whispered speech than normal speech mode (t=2.941, p.<01). Similarly, duration of affricates was longer in whispered speech than semi-whispered (t=1.774, p<.05) and normal speech modes (t=2.493 p<.001). No differences in duration of both fricatives and affricates were found regarding question vs. statement distinction across all three speech modes.

Furthermore, considerable differences were found in spectra of the consonants.

Figure 2 presents multitaper spectra of all recorded items of 8 male speakers obtained at the acoustic midpoint of frication for all three speech modes, where the black lines show statement conditions and the grey lines question conditions.

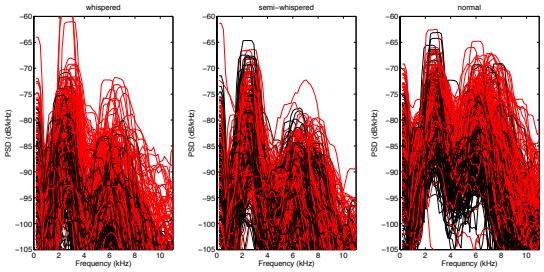


Figure 2: Multitaper spectra of 1145 affricate spectra from 8 male speakers obtained at the acoustic frication midpoint for all three speech modes in separate panels.

With regard to the spectral regression lines slopes of the fricative (m1, m2, cf. Figure 1), m1 exhibits significantly lower values in whispered than in normal speech (t=-2.288, p<.05) and semi-whispered speech (t=-1.997, p<.05). The m2 value is significantly higher in whispered than in normal speech (t=4.01, p<.0001) and semi-whispered speech (t=4.35, p<.0001). Only in whispered fricatives, a distinction in m1 is significant when comparing questions vs. answers, i.e. whispered fricatives display higher m1 values in questions than in statements (t=3.349, p<.001). Regarding m2, questions are produced with a lower m2 in comparison to statements in whispered (t=-8.581, p<.0001) and semi-whispered fricatives (t=-2.19, p<.05).

The spectral slope m1 at the midpoint of the following affricate shows significantly lower values in whispered than in normal speech mode (t=-3.757, p<.0001). Similar to fricatives, a distinction between questions and statements was only found in whispered speech mode (t=3.290, p<.001). Furthermore, with respect to m2, the results show significantly higher m2 values in whispered than in semi-whispered (t=3.915, p<.0001) and normal speech mode (t=-4.67, p<.0001). Again, questions are produced with lower m2 values than statements across all three speech modes differing in t-values: whispered speech mode (t=-12.60, p<.0001), normal speech mode (t=-4.67, p<.0001) and semi-whispered speech mode (t=-4.194, p<.0001). Both slopes are shown in Figure 3; cf. also Figure 1.

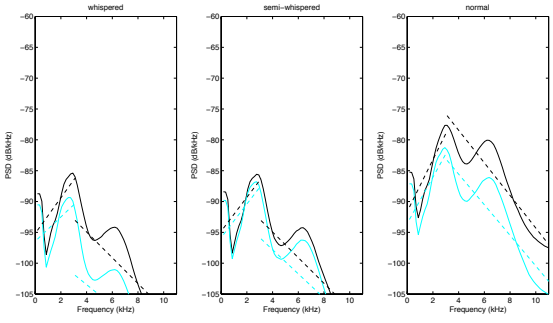

Figure 3: *Multitaper spectra (mean plots over all items and speakers) for the frication midpoint of affricates in whispered, semi-whispered and normal speech mode. Black solid lines correspond to the question and lighter colour to the statement condition. Dotted lines are the spectral regression lines m1 and m2.*

The mean intensity of both fricatives and affricates differs significantly for questions compared to statements: the fricative displays a higher intensity mean for questions than for statements (whispered: t=17.01, p<.0001, normal: t=15.76, p<.0001, semi-whispered: t=5.29, p<.0001). A similar pattern applies for affricates (whispered: t=12.99, p<.0001, normal: t=16.63, p<.0001, semi-whispered: t=4.11, p<.0001).

The frequency of the highest peak of the fricative at its midpoint is higher in questions as opposed to statements for all three speech modes: whispered (t=2.737, p<.01), semi-whispered (t=3.259 p<.001) and normal (t=4.886, p<.0001). Similar observations apply to the affricate midpoint, but exclusively to whispered (t=3.149, p<.001) and normal speech (t=8.726, p<.0001).

Significant differences are also found for the four spectral moments (COG, STD, skewness and kurtosis) at the sibilants' midpoint. The COG values are significantly higher for questions than for statements across all speech modes. This conclusion holds true for both fricatives and affricates whereby the t-values are higher for whispered and normal speech in comparison to the semi-whispered speech mode. The results are presented in Table 1 together with the COG's standard deviation (SD) at the midpoints of both sibilants.

Table 1: Comparison of COG and SD values for the difference between questions and statements across three different speech modes.

	whispered	semi-whisp.	normal
Fricative (COG)	t=5.316 p<.0001	t=2.977 p<.01	t=4.99 p<.0001
Affricate (COG)	t=6.101 p<.0001	t=1.574 n.s.	t=7.88 p<.0001
Fricative (STD)	t=5.923 p<.0001	t=1.786 p<.05	t=0.82 n.s.
Affricate (STD)	t=3.375 p<.001	t=1.153 n.s	t=2.43 p<.01

Regarding skewness, the third spectral moment, our results indicate significant differences between all three speech modes. For fricatives, skewness is significantly higher in whispered speech compared to normal (t=4.418, p<.0001) and semi-whispered speech (t=3.297, p<.0001). In the same vein, frication in affricates displays higher skewness values in whispered than in normal (t=7.096, p<.0001) or semi-whispered speech mode (t=4.343, p<.0001). If we compare the production of questions in comparison statements, the results indicate lower skewness values for questions as compared to statements for fricatives in whispered speech mode only (t=-3.949, p<.0001). In affricates, the skewness is lower in questions than in statements for both whispered (t=-6.636, p<.0001) and normal speech (t= -1.975, p<.05).

The fourth spectral moment, kurtosis, is significantly higher for fricatives in whispered than in semi-whispered (t=3.290, p<.001) and normal speech mode (t=3.842, p<.0001). However, when comparing questions to statements, kurtosis values are significantly smaller in whispered speech (t=-5.656 p<.0001). Regarding affricates, the results show that kurtosis was significantly higher in whispered than in semi-whispered (t=3.968, p<.0001) and normal speech mode (t= 6.066, p<.0001). However, a significant difference in the production of statements vs. questions is found only in whispered speech, where kurtosis is lower in questions (t=-8.163, p<.0001).

4. Discussion

The results show that, in Polish, different intonation patterns between questions and statements are produced by means of various acoustic cues which are, in turn, dependent on the speech mode. In whispered speech, where the F0 is entirely absent, intended rising intonation in questions is produced by both vocalic and consonantal cues. Regarding the former, the results point to a higher F1 and F2 in the utterance-final vowel, a higher amplitude in questions only and no difference in vowel duration between questions and statements.

These results are in accordance with findings reported for the Dutch language where it was shown that in whispered speech F1 and F2 are higher in questions than statements for /ə/ [9]. However, a higher F1 was not found when other Dutch vowels were investigated [10]. Similarly to the results of the present study, the amplitude of the vowel was higher in questions as opposed to statements [9], [10]. In addition, no difference in vowel duration was found between whispered questions and statements [9].

Whereas the majority of previous studies have focused on the properties of vowels when investigating intonation/pitch [11], [12], [13], the results of the present study also point to spectral differences of utterance-final consonants [14], [15]. Significant differences in virtually all spectral parameters are found when comparing questions to statements. The former are produced with higher spectral COG values. This finding is in line with [14], where higher COG values of voiceless fricatives were reported for questions in German phonated speech mode. In the present study, higher COG values are also found for both fricatives and affricates in whispered and semi-whispered questions as compared to statements. The higher COG values are accompanied by higher SD values (with the exception of affricates in semi-whispered speech mode).

The third and the fourth spectral moments are of special importance as they differ considerably between questions and statements across all speech modes. The significantly higher skewness in whispered speech indicates that the mass of the spectral distribution is towards lower frequency values in whispered speech in contrast to the other speech modes. However, for whispered questions, the mass of the spectral distribution moves towards higher frequencies as compared to whispered statements. In affricates, the latter difference applies to normal speech as well, but it is considerably less pronounced in normal speech than in whispered speech.

The higher kurtosis (peakedness; width of peak) in whispered speech indicates a narrower spectral peak for fricatives and affricates in comparison to their semi-whispered and normal speech counterparts. The width of peak in frication of both fricatives and affricates is wider in questions than in statements in whispered speech. In affricates, the width of peak is wider in questions than in statements in both speech modes. Thus, the question vs. statement differences with regard to the third and fourth spectral moment are found exclusively in whispered speech.

Furthermore, intensity is higher in questions than in statements in both sibilants across all three speech modes. Similarly, the highest spectral peak is found at higher frequencies in questions than statements (with the exceptions of affricates in semi-whispered speech).

Finally, regarding the spectral regression line slope m1, the spectra of semi-whispered and normal speech rise more steeply in the frequency range of 500-3000Hz than the spectra of whispered speech. However, a significant m1 difference between questions and statements is found in whispered fricatives and affricates where questions are produced with steeper m1 slopes in comparison to statements. Regarding the spectral regression line slope m2 (from 3kHz to 11 kHz), the spectra for questions in whispered and semi-whispered fricatives fall more steeply above 3kHz compared to the spectra of statements. For affricates, the spectra of questions also fall more steeply above 3kHz than statements but the difference in steepness was largest in whispered followed by normal and then semi-whispered speech modes.

5. Conclusions

In summary, our results point to differences in spectral properties of not only vowels but also consonants when statements and polar questions are produced. These differences, especially with regard to consonants, are intensified when speakers switch from normal speech to whispered speech. In particular, questions are not only realized with a higher F1 and F2 of the vowel but also with a higher intensity, higher spectral peak frequency, higher COG, and SD as well as lower kurtosis and skewness of the consonant. Further differences are found in the spectral regression line slopes.

Some spectral differences between the production of questions and statements are found exclusively, or to the greatest extent, in whispered speech, emphasising a relevance of these cues for this particular speech mode. Moreover, the more pronounced role of these cues in whispered speech suggests a compensation for the distinguishing role of F0 in phonated speech mode. The perceptual relevance of this finding requires further investigation.

This study also sheds further light on the interaction of segments and intonation. It shows, in fact, that taking intonation patterns into consideration seems to be indispensable if spectral properties of segments - in this case sibilants - are to be investigated. Differences in intonation patterns significantly change consonantal properties. This conclusion applies to all speech modes: whispered, semi-whispered and normal.

Finally, due to the investigation of different speech modes, the study provides new aspects for a discussion of the phonological concept of intonation. It shows that speakers produce the intended intonation patterns, encoded at the underlying level, by varying a choice of acoustic cues, i.e., cues-trading as well as their magnitude in dependence on both (i) speech modes and (ii) intonation patterns.

Abstract

This paper sheds new light on the intonation of imperatives in Mexican Spanish. Results from a production experiment based on scripted speech show that imperative sentences have two different nuclear configurations depending on the position of the imperative verb (V_I): (i) (L+)H* L% with V_I in sentence-final position, and (ii) L* L% with V_I in non-final position. The pitch accent on V_I in non-final position is characterized by a late peak (L+>H*). However, if the sentence is uttered with some sort of emphasis, the nuclear configuration in the non-final context can also be rising. While these results partly confirm claims made concerning the nuclear configuration in [1], they contradict the findings in [2], who attested strong pitch accent variation on V_I.

Index Terms: Intonation, Imperatives, Mexican Spanish, Spanish ToBI, Pitch Accent, Nuclear Configuration

1. Introduction

While intonational aspects of imperatives in Peninsular Spanish have attracted considerable attention (e.g. [3], [4], [5], [6]), there are only few studies on Mexican Spanish which also follow different goals. Work [2], for example, examines the pitch accent realization on V_I in sentence-initial position (as in *Abre* in *¡Abre la puerta!* 'Open the door!'). He does not consider the nuclear configuration (i.e. the nuclear pitch accent plus the following boundary tone), which is located on the sentence final DP *la puerta* 'the door'. His results show a three-way variation in the pitch accent on V_I (a predominant *late H peak*, but also an *early H peak* and *a peak with no distinct rise*; [2], p. 355). [1], in turn, concentrates solely on the nuclear configuration, thereby neglecting the pitch accent on V_I, since V_I is non-final. They transcribe the nuclear configuration as L+H* L%. Despite the thorough study, the results in [1] are typically based on imperatives which include final elements such as *ahorita mismo* in *¡Ven aquí, ahorita mismo!* 'Come here, right now' (see [1], p. 340). In this example, a prosodic boundary (H-) occurs between *ven aquí* and *ahorita mismo* (with another between the V_I *ven* and the adverb *aquí*). For this reason, it is not clear whether the elements after V_I are actually part of the imperative or whether they should be understood as added, extra-sentential elements. Thus, the question arises as to whether [1] really transcribe the imperative intonation or merely the intonation of some added, facultative material. Both studies ([1] and [2]) share the common characteristic of failing to consider V_I in sentence-final position, and as such it is unclear whether their claims also hold for V_I in final position. In a pilot study based on semi-spontaneous speech (and not on scripted speech, as is done here), [7] show that the nuclear configuration of imperatives actually differs depending on the position of V_I (final V_I: L+H* L% vs. non-final V_I: L* L%). However, their study is based on a very small set of data in which only thirteen instances of final V_I occur (such as *¡Cállate!* 'Be quiet!'). While the utterances with non-final, here sentence-initial V_I, have the form of the sentences used in [2], all utterances with final V_I contain only one metrically strong position. The pilot study thus seems to confirm the assumption that long declaratives (consisting of at least two metrically strong positions) in Spanish and Catalan are realized by a rising prenuclear accent and a low or falling nuclear configuration, while short declaratives (with only one metrically strong position) are realized by a rising nuclear accent and a low boundary tone (see [8]). The question arises as to whether V_I in sentence-final position also shows a rising accent when preceded by other material. We are not aware of any previous study addressing this issue in Mexican Spanish.

This paper unifies different perspectives and examines both (a) the nuclear configuration of imperative utterances in Mexican Spanish with V_I in sentence-final and sentence-initial position and (b) the pitch accent on the imperative verb. Three hypotheses H1-3 are established:

- *Hypothesis 1:* short imperatives, i.e. declaratives consisting of only an imperative verb (such as *¡Dámelo!* 'Give it to me!'), are realized with a rising nuclear accent (in accordance with [8]) and as such they don't show any pitch accent variation (as opposed to [2]).
- *Hypothesis 2:* Long imperatives (such as *¡Dame la mermelada!* 'Give me the marmalade!') should be realized with a low or falling nuclear configuration and a rising accent on V_I (in accordance with [8], but contradicting [1]); consequently, we do not expect any pitch accent variation either (in contrast to [2]).
- *Hypothesis 3:* Utterances with sentence-final V_I preceded by additional material are expected to be realized by a low or falling nuclear contour as in the case of long imperatives. There are several studies which question whether an imperative intonation really exists in Spanish ([3], [9], [2], [6]). If these authors are on the right track, long utterances with V_I in final position should not behave differently than long declaratives.

2. Methodology

A production experiment based on scripted speech was conducted in which three monolingual, native speakers of Mexican Spanish (one female from Torreón aged 23 [TF], one female and one male from México DF aged 25 and 33 [MF, MM]) uttered a total of 180 sentences (3 subjects x 30 target sentences x 2 repetitions). The material consisted of three conditions, C1-3 (which correspond to hypotheses 1-3):

- *Condition 1:* short imperatives consisting of one prosodic word, as shown in (1);
- *Condition 2:* long imperatives, with V_I in sentence-initial position, as shown in (2); and
- *Condition 3:* long imperatives with V_I in sentence-final position, as shown in (3). Since imperatives are typically

characterized by omitting the preverbal subject, the preceding material in (C3) is a conditional clause.

The imperative verb V_I is marked by bold letters. The metrically strong position of V_I is underlined, while the position of the nuclear accent is indicated by capitals.

¡**MÍrala**! (1)
'Look at her!'

¡**Mira** a BÁRbara! (2)
'Look at Barbara!'

Si estás interesada, ¡**MÍrala**! (3)
'If you are interested, look at her!'

As can be seen in (1) and (3), the metrically strong position of V_I overlaps with the nuclear position when V_I is in final position. Only in (2), in which V_I is sentence-initial, can the two positions be distinguished from one another. By using sentences like that in (2), in which V_I is followed by an argument, we make sure that the prompts do not evoke additional, facultative material.

There were a total of 30 target sentences (i.e. 10 sentences per condition). These target sentences were accompanied by 15 filler clauses (consisting of simple DPs such as *Las manzanas* 'the apples' or constructions with clitic left-dislocations such as *El águila, la vendió mi hermano* 'The eagle, my brother sold it.'; (for details on the intonation of left-dislocations in Spanish see [10])). The stimuli were presented in a pseudo-randomized order on sheets of paper with approximately 6 sentences per sheet. The subjects were recorded in a quiet room and were told to read the stimuli out loud at a normal rate of speech only after having silently read and understood the sentence. The subjects read the entire set of stimuli two times. The recording sessions started with a small practice session. The data were recorded in a quiet room in Frankfurt (Germany) and Paris (France) using an audio interface (44 KHz sample frequency, 24-bits precision) and a condenser headset microphone. All recordings were stored as digitized as wav-audio files. The F0 tracks were analyzed using *praat* [11]; the pitch tracks and spectrograms were used to guide the segmentation and the text-to-tune alignment. The tonal analysis is based on the ToBI annotation system for Spanish (Sp_ToBI, [12], [13], [1]).

3. Results

3.1. Results between speakers

The results for the nuclear configuration are given in Table 1. In Condition 1 (C1, short imperatives), the metrically strong syllable of V_I is tonally realized by either a high (H*) or a rising (L+H*) nuclear pitch accent (55% and 45%, respectively). A chi-square test shows that the difference in frequency between H* and L+H* is not significant ($\chi^2 = 0.6$, df = 1, p = 0.44; [14] was used for the calculations). The IP edge tone is always low (L%). In Condition 2 (C2, long imperatives with initial V_I), the predominant nuclear accent is a low tone (L*; 36 instances, 60%), followed by rising or high accents (25% and 10%, respectively) and a few instances of falling accents (H+L*, 3 times, 5%). The difference between L* and L+H* / H* is significant ($\chi^2 = 3.947$, df = 1, p = 0.047). Again, there were only low IP edge tones (100%). In Condition 3 (C3, long imperatives with final V_I), the metrically strong position of V_I is predominantly realized by a high (H*) or a rising nuclear accent (L+H*), 46 times, 77%. There are some instances of low nuclear accents (9 times, 15%) and few cases of a falling accent (5 times, 8%). A chi-square test shows that the difference in frequency between H* / L+H* and L* / H+L* is significant ($\chi^2 = 17.067$, df = 1, $p < 0.01$), i.e. the number of high or rising accents is significantly higher than the number of low or falling accents. All intonational phrase boundaries were realized by a low edge tone (L%).

While the metrically strong syllable of V_I in C1 and C3 is simultaneously the nuclear accent in the utterance, V_I in C2 is not part of the nuclear configuration, but belongs to the prenuclear area. This is not shown in Table 1. V_I in C2 is predominantly realized by a delayed peak L+>H* (92%, 55 times) and sometimes can also be realized by a rising accent L+H* (5%, 3 times) and a high tone H* (3%, 2 times).

Table 1, *Nuclear configurations for each condition for all subjects (given in % and absolute numbers)*

C1	H* L% (55%, 33)	L+H* L% (45%, 27)		
C2	L* L% (60%, 36)	L+H* L% (25%, 15)	H* L% (10%, 6)	H+L* L% (5%, 3)
C3	H* L% (47%, 28)	L+H* L% (30%, 18)	L* L% (15%, 9)	H+L* L% (8%, 5)

Typical pitch contours for the three conditions are given in Figure 1 to 4. A typical contour for the short imperatives (C1) is given in Figure 1. The nuclear pitch accent on V_I is realized with a high plateau (H*), followed by a low IP edge tone (L%). Pitch contours for long imperatives (C2) are given in Figure 2 and Figure 3. Both contours share a pre-nuclear accent located on V_I, which is realized by a rising tone with a delayed peak (L+>H*). Additionally, the IP edge is realized by a low tone (L%). The two contours differ in the shape of the nuclear accent. While it is low in Figure 2, it is rising (L+H*) in Figure 3. As a consequence, the contours differ with respect to their nuclear configuration (L* L% vs. L+H* L%).

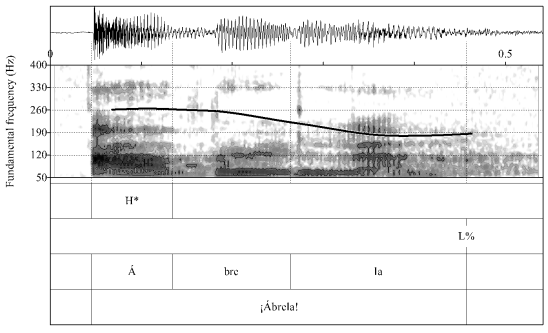

Figure 1: *Waveform, spectrogram, and F0 trace for the short imperative (C1)* ¡Ábrela! *'Open it!' of speaker TF (sentence 2_17), produced with a high nuclear pitch accent (H*) and a low edge tone (L%).*

A pitch contour for long imperatives with final V_I (C3) is given in Figure 4. The conditional clause is composed of rising accents (L+>H*, L+H*) and a high edge tone (H-). A pause (of 132ms) separates the following V_I from the conditional clause. The nuclear configuration on V_I is composed of a high

tone (H*) and a low IP edge tone (L%). As can be seen in Table 1, the typical nuclear configurations are no different from those in conditions 1 and 2 (cf. the contours on V_I in Figure 1 and in Figure 4). C3 differs from C1 and C2, however, through the presence of a sentence-internal break: While all sentences within conditions C1 and C2 show no sentence internal break, there is always a break in the sentences in C3. This break is located between the conditional clause and the imperative main clause, and is characterized phonetically by a rising contour at the end of the conditional clause, followed by a pause. The mean duration of the pause for all speakers is 236ms (not normalized).

Finally, we comment on some additional differences observed between the three conditions. The difference in frequency between H* / L+H* in C1 and H* / L+H* in C2 is significant ($\chi^2 = 57.778$, df = 1, p = 0), as is the difference between H* / L+H* in C1 and H* / L+H* in C3 ($\chi^2 = 15.849$, df = 1, p < 0.01). This means that the frequency of high and rising accents is significantly higher in C1 than in C2 or C3.

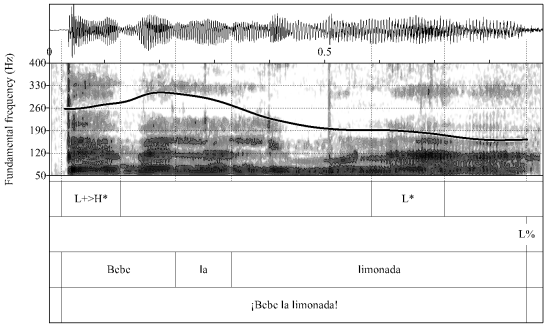

Figure 2: *Waveform, spectrogram, and F0 trace for the long imperative (C2)* ¡Bebe la limonada! *'Drink the lemonade!' of speaker TF (sentence 2_25), produced with a delayed peak (L+>H*) on V_I and a low nuclear configuration (L* L%).*

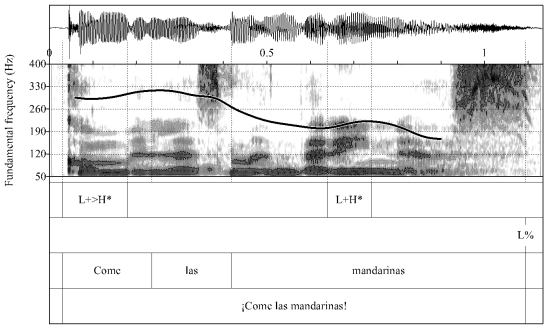

Figure 3: *Waveform, spectrogram, and F0 trace for the long imperative (C2)* ¡Come las mandarinas! *'Eat the tangerines!' of speaker TF (sentence 2_21), produced with a delayed peak (L+>H*) on V_I and a rising/falling nuclear configuration (L+H* L%).*

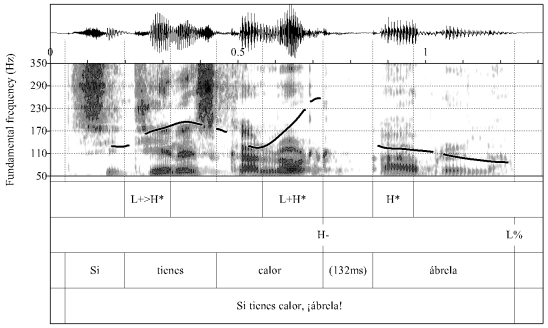

Figure 4: *Waveform, spectrogram, and F0 trace for the long imperatives with final V_I (C3)* Si tienes calor, ¡ábrela! *'If you are warm, open it!' of speaker MM (sentence 2_7), produced with a high nuclear pitch accent (H*) and a low IP edge tone (L%), preceded by a pause (of 132ms).*

3.2. Individual results

As for the nuclear configurations attested in C1, each speaker realizes the two configurations H* L% and L+H* L%, see Table 2. There are some differences, however, with respect to the frequency of the realizations. While the two speakers from México DF prefer H* L% over L+H* L% (MF: 70% vs. 30%; MM: 55% vs. 45%), the speaker from Torreón realizes H* L% less often than L+H* L% (40% vs. 60%). For the nuclear configurations attested in C2, each speaker has a repertoire of three configurations, see Table 2. Only two configurations, L* L% and L+H* L%, were realized by each speaker. The speakers from México DF additionally use H* L%, while TF uses H+L* L%. The low nuclear configuration L* L% is the prevailing choice for each speaker (MF: 60%; MM: 45%; TF: 75%). The rising-falling or circumflex contour L+H* L% is the second most common choice for the speakers from México DF, while H+L* L% is the second most common for TF.

Table 2, *Nuclear configurations for each condition and each individual speaker (given in % and absolute numbers)*

C1	MF	H* L% (70%, 14)		L+H* L% (30%, 6)	
	MM	H* L% (55%, 11)		L+H* L% (45%, 9)	
	TF	L+H* L% (60%, 12)		H* L% (40%, 8)	
C2	MF	L* L% (60%, 12)	L+H* L% (25%, 5)	H* L% (15%, 3)	
	MM	L* L% (45%, 9)	L+H* L% (40%, 8)	H* L% (15%, 3)	
	TF	L* L% (75%, 15)	H+L* L% (15%, 3)	L+H* L% (10%, 2)	
C3	MF	L+H* L% (55%, 11)	H* L% (45%, 9)		
	MM	L* L% (45%, 9)	H* L% (25%, 5)	H+L* L% (15%, 3)	L+H* L% (15%, 3)
	TF	H* L% (70%, 14)	L+H* L% (20%, 4)	H+L* L% (10%, 2)	

As for C3, there is not only clear variation between the speakers with respect to the number of different contours used (MF: 2, MM: 4; TF: 3), but also with respect to the most popular choice of the speakers. While MF and TF prefer high or rising nuclear accents, MM prefers a low nuclear accent. Furthermore, he is the only speaker to use a low nuclear configuration in C3.

Finally, in terms of the realization of the prenuclear accent located on V_I in C2, all three speakers strongly prefer the delayed peak L+>H* (MF: 90%; MM: 95%; TF 90%). As a consequence, the frequency of the other realizations (which are H* and L+H*) is very low. The delayed peak is realized significantly more often than the other tones across the speakers ($\chi^2 = 41.667$, df = 1, p = 0).

4. Discussion

Hypothesis 1 (short imperatives are realized with a rising nuclear accent and do not show variation) can be taken as fulfilled, since the nuclear accent is either high or rising. This supports the claims by [8] for short declaratives and contradicts [2], in which considerable tonal variation is attested on V_I. In defense of [2], however, it is important to note that short imperatives were not investigated in this work. We return to [2] in greater detail when discussing the results in the light of the second hypothesis.

Hypothesis 2 (long imperatives have a low or falling nuclear configuration and a rising accent on V_I in sentence-initial position) cannot be taken to be completely fulfilled, as the data give a rather mixed picture. Even though 65% of the data is realized by L* L% (60%) and H+L* L% (5%), 35% of the nuclear accents are either high or rising. Thus, the low or falling contours support the claims made in [8], while the high and circumflex contours show that the authors of [1] appear to be on the right track. In contrast to [1], though, no optional emphatic upstep of H was attested in our data. Additionally, our data show that long imperatives with V_I in sentence-initial position can indeed be realized with a low or falling nuclear configuration. This is in line with studies on neutral, broad focus declaratives in Mexican Spanish, which show that both contours, L* L% and L+H* L%, are typical nuclear configurations ([15], [16], and also [1]). As such, our work confirms the studies on Mexican declaratives, leading us to conclude that hypothesis 2 is simply too strict for Mexican Spanish. In terms of pitch accent variation, variation of pitch accents on V_I is possible in C2, but in contrast to the results of [2], the delayed peak is chosen by nearly all of the speakers (92%), with instances of non-delayed peaks being very rare (totaling 8%). A considerably larger number of instances of non-delayed peaks were attested in [2] (see p.359). Furthermore, [2] reports on a variation between three different pitch accents in 3 out of his 4 speakers, while in our data two speakers (MM and TF) use only two different pitch accents. In addition, the third pitch accent used by speaker MF occurs only once. Thus, as for C2, there is considerably less pitch accent variation in our data than in [2].

Hypothesis 3 (long imperatives with final V_I are realized by a low or falling nuclear configuration) was shown not to be fulfilled. The nuclear contour is typically either high or rising (77%), while the rest is low or falling (23%). In addition, the low or falling instances were mainly uttered by a single speaker (MM), while the other two speakers either did not realize any falling nuclear accent (MF) or did so to only a small extent (TF).

Due to the fact that the material preceding V_I is a conditional clause whose edge is obligatorily marked by a high edge tone accompanied by a pause, we wonder whether the entire sentence can really be considered to be a typical declarative utterance. The main clause, consisting of only V_I, behaves as the short imperative of C1. [17], [18], [19] have already noted that adjunct clauses have a considerable impact on the intonation of a sentence. This might explain the great variation in pitch accent observed between our speakers. While speaker MM varies between the low contour of typical declaratives and rising accents of short imperatives, MF and TF (almost) always choose the short imperative pattern. Interestingly, it was the male speaker who showed the greatest variation. The male speakers in [2] also use a greater number of different pitch movements.

Finally, our data confirm the results of [7], in which final V_I is shown to have a rising intonation for semi-spontaneous speech. The comparison of our study and that in [7] indicates that some differences exist with respect to the tonal realization of non-final V_I in semi-spontaneous and scripted speech with scripted speech showing less variation (see [20], [21], and [22] for studies on spontaneous speech in Spanish and a discussion of differences between laboratory and spontaneous speech).

5. Conclusions

The contribution of this paper consists in presenting a unified perspective on (a) the pitch accent located on the imperative verb and (b) the nuclear configuration of imperative sentences - a view that has not taken been before. Coming from this perspective, we show that imperative sentences in Mexican Spanish have two different nuclear configurations depending on the position of the imperative verb: (i) (L+)H* L% with V_I in sentence-final position (as in short imperatives and imperatives preceded by a conditional clause), and (ii) L* L%, with V_I in non-final position (as in long imperatives). Long imperatives can also have a rising accent, which is in line with [1]. However, in contrast to [1], the circumflex nuclear configuration is not the prevailing choice of the speakers for (long) imperatives. In contrast to [2], we could not attest strong variation in pitch accent on V_I across the conditions. Our speakers strongly preferred the delayed peak L+>H* in long imperatives and hardly realized the other pitch accents. High/rising accents such as H* or L+H* are either the most popular or sole choice in short imperatives (C1) and in long imperatives with final V_I (C3).

In this study, we hoped to answer the question of whether V_I in sentence-final position also shows a rising accent when preceded by other material. Our data were able to confirm this. Nevertheless, it would be interesting to see whether high or rising accents also occur when V_I is preceded by material other than a conditional clause. If so, this might shed further light on the ongoing discussion on whether differences exist on the tonal level between declarative and imperative intonation.

6. Acknowledgements

We would like to thank Pilar Prieto and the two anonymous reviewers for supportive comments. We also thank Fabián Santiago Vargas, Ellenit Hernández Mendoza, and our subjects for their help during the recording session. Moreover, our gratitude goes to Audrey MacDougall for her assistance with editing.

The Acquisition of English Lexical Stress by Cantonese-English Bilingual Children at 2;06 and 3;0

Jingwen Li, Peggy Pik Ki Mok

Department of Linguistics and Modern Languages, The Chinese University of Hong Kong
joanneljw@gmail.com, peggymok@cuhk.edu.hk

Abstract

This study investigates the acquisition of English lexical stress by simultaneous Cantonese-English bilingual children at the age of 2;06 and 3;0 respectively, comparing them with the English monolingual peers. Research on early bilingual phonological acquisition often focuses on segmental level. Few studies are available when it concerns prosodic features, especially in children speaking non-Indo-European languages. This study examines an important prosodic feature, lexical stress, in Cantonese-English bilingual children. The results showed that there is delayed acquisition of English lexical stress among the bilingual children, as reflected in less contrastive syllable duration and peak F0, possibly due to a lack of lexical stress in Cantonese, a typical syllable-timed language. This study helps to understand the bilingual interaction of two distinctive prosodic systems, and broaden our knowledge about early bilingual prosodic development.

Index Terms: lexical stress, Cantonese, English, bilingual acquisition

1. Introduction

Lexical stress (word stress) is the stress placed on a given syllable, and the assignment of lexical stress in words is language-specific. For example, in languages like Czech and Finnish, stress is always assigned on the first syllable of a word; while in some other languages like English and Russian, the position of stress in a word is less predictable. In English, there are two main types of stress patterns in English: trochaic and iambic [1]. Trochaic word refers to a disyllabic word with stressed-unstressed pattern (e.g. baby); iambic word refers to an unstressed-stressed pattern (e.g. behind). The acoustic correlates of lexical stress in English have been examined extensively ([4][7][11][12]). Most of these studies focused on minimal pairs, in which the placement of stress determines whether the word is a noun or a verb. The results consistently indicate that within a lexical word, the stressed syllable has higher fundamental frequency (F0), longer syllable duration, and greater intensity than the unstressed syllable. Besides, vowel quality has also been considered as an important acoustic correlate of English lexical stress, and failure in reducing vowels in unstressed syllable contributes to non-native accent ([10][14][24]).

Previous studies suggested that English-speaking children's early acquisition of lexical stress involves enlarging the stress-unstressed ratios in all acoustic correlates (F0, syllable duration and intensity), especially by reducing the unstressed syllable duration but maintaining the stressed syllable duration ([1][8][19][21]). An equally important question is how bilingual children at a young age acquire lexical stress. However, there is a dearth of empirical data in this line of research. Most previous studies focused on preference of word truncation by bilingual children ([18][20][22]). For example, [18] conducted a nonsense-word repetition task in French-English bilingual children. English and French contrast in that the majority of English words have a trochaic rhythm while French words have an iambic rhythm. [18] found that the English-dominant bilinguals tend to preserve trochaic pattern and the French-dominant bilinguals tend to preserve iambic pattern, indicating cross-linguistic effects and the prominent influence of language dominance on the directionality of the effects. In contrast, based on an English-French bilingual child's speech, [20] found no evidence for trochaic bias in the data. By far, few studies have used an acoustic approach to investigate prosodic development in young bilingual children, especially before the age of three. Mok ([16] [17]) investigated the acquisition of speech rhythm in Cantonese-English bilingual children at the age of 2;06 and 3;0. She found that the bilinguals displayed less variable syllable duration and less vowel reduction in unstressed syllables, compared with their English monolingual peers. Contrastive syllable duration and vowel reduction are important indicators for lexical stress, too. Therefore, Mok's studies ([16][17]) provide insights into the present study that cross linguistic effects in the acquisition of lexical stress in Cantonese-English bilingual children can also be found.

Unlike English, Cantonese does not make use of lexical stress, and neither has it phonological vowel reduction. As a tone language, F0 in Cantonese is primarily used to differentiate lexical meaning. Additionally, Cantonese is a typical syllable-timed language ([15]). It is thus worth investigating whether the different experience with F0, syllable duration and vowel quality in Cantonese would influence the acquisition of English lexical stress in simultaneous Cantonese-English bilingual children. Given that the period between age 2;0 and 3;0 is an important stage for children's prosodic and lexical development, the present study examines the acoustic correlates (F0 and syllable duration) of lexical stress in Cantonese-English bilingual children and in English monolingual children at 2;06 and 3;0 respectively.

2. Method

2.1. Subjects

Based on the age of the children, there are two groups of data: 2;06 and 3;0. In the 2;06 group, there are seven simultaneous Cantonese-English bilingual children and five English monolingual children; in the 3;0 group, there are eight bilingual children and six monolingual children. The bilingual children all came from the YipMathews corpus in CHILDES (http://childes.psy.cmu.edu/media/Biling/YipMatthews/). Yip and Matthews [23] gave detailed introduction to the background of the children. The data of monolingual children came from various sources, which will be introduced in the following sections.

Table 1. *Background information of the bilingual children.*

Child	Input languages	Sex	Language dominance	Age range for data used	
				2;06	3;0
B1	BrE/Cantonese	M	Cantonese	2;5.12-2;7.07	2;11.12-3;1.13
B2	BrE/Cantonese	F	Cantonese	2;5.16-2;7.01	2;11.05-3;0.09
B3	BrE/Cantonese	F	Cantonese	2;6.02-2;7.28	2;11.19-3;0.24
B4	BrE/Cantonese	F	Cantonese	---------	2;11.27-3;0.18
B5	BrE/Cantonese	F	English	2;5.19-2;6.16	2;10.29-3;0.03
B6	BrE/Cantonese	M	Cantonese	2;6.20-2;7.04	2;11.29-3;0.27
B7	HKE/Cantonese	M	Cantonese	2;5.05-2;7.00	2;11.05-3;0.03
B8	HKE/Cantonese	M	Cantonese	2;4.29-2;7.24	2;10.03-3;2.03

2.1.1. Bilingual children

Table 1 shows the background information of the bilingual children. Six of them, B1, B2, B3, B4, B5 and B6, were exposed to Cantonese and English from birth and grew up in a 'one parent one language' environment, with one parent being a native speaker of British English and the other a native speaker of Cantonese. The other two children, B7 and B8, grew up in Hong Kong families and were exposed to Hong Kong English and Cantonese from birth. Except for B5, all the other children were Cantonese dominant.

2.1.2. Monolingual children

Table 2 shows the background information of the monolingual children. Their parents are all British English native speaker.

Table 2. *Background information of the monolingual children.*

Child	Input Languages	Sex	Age of recordings	
			2;06	3;0
M1	British English	F	2;5-2;7	2;11
M2	British English	F	---	3;1
M3	British English	F	2;7.01	3;1
M4	British English	M	2;7.01	3;0
M5	British English	M	---	3;0
M6	British English	F	2;5-2;6	---
M7	British English	M	2;6.00-2;6.22	3;0

Data of M1 and M7 came from the Forrester corpus ([6]) and the Thomas corpus ([13]) in CHILDES respectively. M1's natural conversations were recorded and all participants involved in the dialogues were British, white, and middle class. M7 was born in a middle class family and he was primarily cared for by his mother. The frequency of data between 2;00,12 and 3;00,12 is very intensive, and during this period, M7 was recorded for one hour each time, five times a week, every week for the entire period. Two of the English speaking children M2 and M5 were recruited in an English-medium kindergarten in Hong Kong for children from expatriate families. The other two English children M3 and M4 were twins from an expatriate family living in Hong Kong.

2.2. Materials

Disyllabic words of both trochaic (strong-weak) and iambic (weak-strong) patterns were used. We have gone through every video/audio recording, extracted the target words, and saved them as .wav files for acoustic analyses. The quality of some recordings was not very good, so we only used interpretable utterances that have clear formant structure in the spectrogram. To exclude excessive initial F0 raising and duration shortening, as well as final lengthening and lowering, we only chose disyllabic words in sentence-medial position, which means the target word together with the preceding word and the following word all come from the same intonational phrase. We also excluded words with excessive stress on one of the syllables. For example, in many cases, the child was shouting, singing, crying or arguing with his/her siblings. Utterances produced under such occasions were not used. Since corpus data were used, there may be segmental and sentential context effects that affect the acoustic properties of the targets words, but this is unavoidable.

The number of the extracted utterances varies from child to child, but it does not affect the overall results because the F0 ratios and duration ratios were averaged across all the tokens from the same child. We use stressed/unstressed ratios for cross group comparison because ratios can demonstrate how contrastive the stress pattern is, and more importantly, they normalize the data for individual variation. We obtained many more trochaic words than iambic words. The imbalance of the two types of disyllabic words can be explained by the fact that there are many more trochaic words than iambic words in English ([9]).

2.3. Measurements

Each disyllabic word was labeled, and the syllable duration and peak F0 of the vowel of each syllable were measured with Praat ([3]).

When measuring syllable duration, if the word begins or ends with a stop, then the closure phase of the stop would be excluded because there is no reliable cue for marking it ([14][16]). Each disyllabic word was segmented into two syllables, and word-medial consonants were segmented based on the maximal onset principle. For example, the /p/ in 'paper' was treated as the onset of the second syllable. Peak F0, which is the highest point on the F0 contour of the vowel, was automatically tracked by Praat. After the values of syllable duration and syllable peak F0 of all the disyllabic words had been measured, stressed-/unstressed-syllable ratios were calculated, and then they were averaged across tokens for each child.

3. Results

3.1. Children at 2;06

The stressed/unstressed ratios of syllable duration in trochaic words for the 2;06 years old bilingual and monolingual children are shown in Table 3. Calculating ratio means the value of the stressed syllable duration is divided by the value of the unstressed syllable duration. Therefore, a value >1 means that the stressed syllable duration is longer than the unstressed syllable duration (as expected), and vice versa.

It can be seen that for trochaic words, the stressed and unstressed syllable duration ratios are comparable across the bilingual children, hovering around 1. In contrary, the stressed syllable durations are consistently higher than the unstressed syllable durations within the same disyllabic words for monolingual children. An independent-samples t-test was conducted to compare the ratios in the bilinguals and the monolinguals. There was a significant difference in stressed and unstressed syllable duration ratios between the bilinguals and the monolinguals [$t(10) = -5.50$, $p<0.01$]. The results showed that the difference between stressed and unstressed syllable duration is larger in monolingual than bilingual children.

Table 3. *Syllable duration ratios (s.d.) for bilingual children: 2;06.*

Bilinguals	Duration ratio	Monolinguals	Duration ratio
B1	1.12(0.42)	M1	1.35(0.24)
B2	1.19(0.36)	M3	1.64(0.35)
B3	0.94(0.32)	M4	1.57(0.48)
B5	0.93(0.21)	M6	1.65(0.57)
B6	1.08(0.28)	M7	1.25(0.31)
B7	1.01(0.30)	---	---
B8	1.09(0.23)	---	---
Mean	1.05(0.10)	Mean	1.49(0.18)

Table 4. *Peak F0 ratios (s.d.) for bilingual children: 2;06.*

Bilinguals	Peak F0 ratio	Monolinguals	Peak F0 ratio
B1	1.03(0.10)	M1	1.75(0.18)
B2	1.00(0.04)	M3	1.04(0.05)
B3	1.24(0.69)	M4	1.17(0.42)
B5	1.15(0.19)	M6	1.15(0.25)
B6	1.04(0.06)	M7	1.04(0.19)
B7	1.08(0.44)	---	---
B8	1.02(0.03)	---	---
Mean	1.08(0.09)	Mean	1.23(0.30)

The stressed/unstressed ratios of peak F0 in trochaic words for all the children are listed in Table 4 and the data show more individual variation. Among the bilingual children, B3 (1.24) had a larger difference in peak F0 between stressed and unstressed syllables, while the others had comparable stressed and unstressed peak F0, hovering around 1. The monolinguals did not show as distinct a stress pattern in peak F0 as they did in syllable duration, e.g., M1 having very contrastive peak F0 (1.75) while M7 showing similar F0 peaks (1.04). Overall, in terms of peak F0, the monolingual children did not show more distinct pattern than the bilingual children. Independent t-test confirmed that the difference between the bilinguals and the monolinguals was not significant [$t(10) = -1.28$, $p>0.05$].

In the 2;06 age group, iambic words were not analysed because of the lack of data. For example, in all the monolingual speech, only two iambic words were found in M6's utterances.

3.2. Children at 3;0

3.2.1. Trochaic words

The stressed/unstressed ratios of syllable duration of trochaic words for the bilingual and monolingual children at the age of 3;0 are shown in Table 5.

Table 5. *Syllable duration ratios (s.d.) for bilingual children: 3;0.*

Bilinguals	Duration ratio	Monolinguals	Duration ratio
B1	1.02(0.26)	M1	1.71(0.30)
B2	1.15(0.28)	M2	1.60(0.52)
B3	1.15(0.31)	M3	1.98(0.71)
B4	1.02(0.23)	M4	1.67(0.52)
B5	1.06(0.40)	M5	1.63(0.38)
B6	0.99(0.46)	M7	1.69(0.63)
B7	1.32(0.51)	---	---
B8	0.99(0.30)	---	---
Mean	1.09(0.11)	Mean	1.71(0.14)

Table 6. *Peak F0 ratios (s.d.) for bilingual children: 3;0.*

Bilinguals	Peak F0 ratio	Monolinguals	Peak F0 ratio
B1	0.99(0.12)	M1	1.17(0.24)
B2	0.99(0.15)	M2	1.26(0.66)
B3	1.14(0.40)	M3	0.97(0.19)
B4	1.08(0.13)	M4	1.10(0.24)
B5	1.09(0.23)	M5	1.23(0.37)
B6	1.01(0.12)	M7	1.15(0.40)
B7	1.07(0.36)	---	---
B8	1.13(0.24)	---	---
Mean	1.06(0.06)	Mean	1.15(0.10)

It can be seen that the stressed-unstressed syllable duration ratios are comparable among bilingual children. Although B7 (1.32) appears to have more distinct stress pattern than the other bilingual children, his duration ratio is still lower than the lowest value for monolingual children (M2: 1.60). On the other hand, the stressed/unstressed ratios of syllable duration in monolingual children are consistently higher than those in the bilingual children, suggesting that the monolinguals have more contrastive stressed/unstressed syllable durations than the bilinguals. An independent-samples t-test confirms the significant difference in stressed and unstressed syllable duration ratios between the bilinguals and

the monolinguals [t(12) = -9.48, p<0.01]. The results showed that the difference between stressed and unstressed syllable duration is larger in monolingual than bilingual children at the age of 3;0.

The stressed/unstressed ratios of peak F0 in trochaic words for all the bilingual and monolingual children are listed in Table 6. The values are comparable across the bilingual children, and the condition is similar for the monolingual children, except that M2 (1.26) and M5 (1.23) seem to have more contrastive stressed/unstressed peak F0. Independent t-test indicated no significant difference between the bilingual group and the monolingual group in terms of ratios of peak F0 [t(12) = -1.93, p>0.05].

3.2.2. Iambic words

The number of iambic words in the 3;0 group is also very limited. All the iambic words are listed in Table 7, and the value in bracket is the number of tokens obtained from all the utterances of all the children.

Table 7. *Iambic words: 3;0.*

Bilingual		Monolingual
about (3)	*behind* (1)	*about* (6)
alright (1)	*cannot* (1)	*again* (1)
around (1)	*forgot* (2)	*around* (2)
away (2)	*Michelle* (3)	*because* (1)
because (6)	*upstairs* (1)	*behind* (1)

It can be seen in Table 7 that the majority of the iambic words are function words. Given the small number of them, no statistics can be used to compare the stressed/unstressed ratios in terms of peak F0 and syllable duration between the two groups of children. Nevertheless, the average stressed/unstressed syllable duration ratio is much larger in the monolinguals (2.72) than that in the bilinguals (1.55); while the average ratios in peak F0 are comparable across the two groups (monolingual: 1.18; bilingual: 1.13). The observed patterns of iambic words confirm the findings in trochaic words very well that monolingual children displayed more distinct stress pattern than the bilingual children did, demonstrated by more contrastive syllable duration. It is interesting to note that, the bilinguals seem to perform better in contrasting stressed syllable duration from unstressed syllable duration in iambic words than in trochaic words. It is possible that because the iambic function words are more frequently heard in the input language, and so acquired better by the bilingual children.

3.3. Cross-age comparison

Besides cross language comparisons, cross age comparisons were also carried out within each group of children. For instance, paired sample t-test were conducted to compare the stressed and unstressed syllable duration ratios in the monolingual children at 2;06 and that in the same children at 3;0. The results show that the stressed and unstressed syllable durations are more contrastive in the monolinguals at 3;0 (M = 1.76, SD = 0.14) than at 2;06 (M = 1.45, SD = 0.18), with a significant difference [t(3) = -4.2, p<0.01]. Interestingly, this was the only significant result in all the cross age comparisons. It suggested that English monolingual children were enlarging the contrast between the stressed and unstressed syllable durations between 2;06 and 3;0, but the development of syllable durational contrast is much slower in Cantonese-English bilingual children.

4. Discussion

This study aims to investigate whether the linguistic experience of Cantonese would affect the acquisition of English lexical stress in simultaneous Cantonese-English bilingual children. Data of eight Cantonese-English bilingual children and six English monolingual children were used, including two ages: 2;06 and 3;0.

In both age groups, monolingual children displayed more contrastive syllable duration than the bilingual children did in disyllabic words, and the difference is significant. Both monolingual and bilingual children have comparable stressed and unstressed syllable peak F0. It was expected that Cantonese-English bilingual children would use F0 to contrast stressed/unstressed syllable better than the monolinguals, since they have more experience with F0 variation in Cantonese. However, the finding that even English monolingual children did not contrast stressed/unstressed peak F0 suggests that, syllable duration, rather than peak F0, is the primary cue to distinguish stressed syllable from unstressed syllable by children, at least before the age of 3;0. Unlike the monolingual children, the Cantonese-English bilingual children do not show clear stress pattern in either of the acoustic correlates, and they have less reduction in unstressed syllable duration. Besides, cross age group comparison indicated the development of English lexical stress pattern is much slower in the Cantonese-English bilingual children between the age of 2;06 and 3;0, when they are compared with the English monolingual children.

The results confirm our prediction, and the delayed development of lexical stress is possibly due to the fact that Cantonese lacks lexical stress and phonological reduction. Lack of durational variation in Cantonese has affected the acquisition of durational contrast in English. But the finding that both bilinguals and monolinguals have comparable stressed and unstressed peak F0 suggests that, first, F0 is not the primary cue for lexical stress contrast in children by the age of 3;0; second, though the bilingual children have more intricate use of F0 in Cantonese tones, they had not applied it in contrasting English lexical stress.

Further investigation is still required to examine whether and when the bilingual children can catch up with the English monolingual children and acquire adult-like lexical stress pattern.

5. Conclusions

The results of the current study have broadened our knowledge about early bilingual acquisition of lexical stress from several aspects. Firstly, for English monolingual children before the age of three, syllable duration, rather than F0, is the primary cue for lexical stress contrast. Secondly, Cantonese-English bilingual children have a delay in developing syllable durational contrast for clear lexical stress pattern. The delayed development is possibly due to the fact that Cantonese, as a typical syllable-timed language, lacks lexical stress, and the experience with less variable syllable duration causes negative cross-linguistic effects.

Abstract

Speech rhythm is highly variable. Previous studies reported variability between languages, dialects, speakers, and labelers. Research further revealed an effect of *sentence* in the rhythmic characteristics of speakers of the same language. In the present study we tested whether the effect of sentence material is constant across varieties of the same language. We addressed this question by an example of analyzing rhythmic variability between eight dialects of Swiss German in three different sentences. Results showed a significant interaction for *dialect*sentence* for most of the tested rhythm metrics. We take this as evidence that differences between dialects are contingent upon the sentences used in the experiment. We further investigated which sources in the sentence material caused between-dialect differences in rhythm scores to vary. We found exemplary evidence that dialect-specific phonological and morphological phenomena contained in the individual sentences are the prime suspects. Implications for future speech rhythm research are discussed.

Index Terms: Speech rhythm; dialectology; Swiss German, rhythm metrics

1. Introduction

Acoustic measures of speech rhythm that are based on temporal features of speech have been reported to vary significantly between and within languages. Yet, relatively little is known about the actual sources behind this variability. [1] suggested that metrics such as the percentage over which speech is vocalic (%V) reflect the degree of vowel reduction, and metrics such as the standard deviation of consonantal intervals (ΔC) capture syllable complexity. [2], however, provided evidence that differences in rhythm metrics of typologically different languages emerge even when syllable structure complexity is controlled for. They reported that the durational marking of prosodic heads or pre-final heads accounted for more rhythmic variability for the language set investigated. [3, 4] examined the degree to which sentence material affected rhythm scores. Both studies reported effects of *sentence*, implying that rhythm scores strongly differ depending on the sentence material being analyzed.

While these studies have shown an effect of *sentence* in the rhythm scores of speakers of the same language, it is unclear whether such effects are constant across varieties of the same language. In this preliminary study we address this question by an example of analyzing rhythmic variability between dialects of Swiss German (SwG) in different sentences. Our paper addresses the following research questions:

(1) Does sentence material have an influence on rhythmic differences between dialects?
(2) Which parameters exactly in the sentence material cause between-dialect differences in rhythm scores to vary?

To test these hypotheses, we applied rhythm metrics on the following 8 SwG dialects, see Table 1.

	West	East
Midland	**BS:** Basel	**TG:** Thurgau
	BE: Bern	**ZH:** Zurich
Alpine	**SB:** Sensebezirk	**SZ:** Schwyz
	VS: Valais	**GR:** Grisons

Table 1: Selected dialects and their abbreviations.

The sentences used in the present study are a subset of those used in [5], where the declarative intonation patterns of the dialects mentioned were examined based on 7 read sentences per speaker. Since the current study is preliminary in nature, we analyzed only 3 of [5]'s 7 sentences per speaker. The other 4 out of 7 sentences used in [5] were the basis of between-dialect rhythmic analyses in [6]. [6] reported significant differences for these 8 SwG dialects particularly in the variability of vocalic intervals, while consonantal variability was less discriminant. The current study is thus a follow-up of [6].

We hypothesize that dialect-specific phonological processes present in some but not all sentences are possible reasons as to why rhythm scores vary according to *sentence*. Consider, for instance, the following example: a typical feature of Basel SwG is extensive vowel lengthening before [r]; often the [r] is elided completely. In *stark* 'strong', for example, Basel speakers articulate [ˈʃtɑːx], while most other SwG dialect spekaers realize [r] before the [x] without vowel lengthening, resulting in [ˈʃtɑrx]. If some sentences in the data set contain words that allow for this phonological process to take place, it is conceivable that this has an effect particularly on %V and vocalic variability measures such as VarcoV, ΔV, and nPVI_V. To test this hypothesis, we selected three sentences that vary in the proportions of vowels and consonants as well as in syllabic make-up. Given these examples, we expect to find significant interaction of *dialect*sentence*.

2. Data and methods

2.1. Subjects

6 speakers were recorded for each of the 8 dialects, adding up to a total of 48 speakers (33 females, 15 males). The subjects aged between 17 and 69 confirmed to be using the dialects in question on a daily basis. None of the speakers reported speaking or hearing problems.

2.2. Material

Each speaker was asked to read in their respective dialects three sentences that were written in Standard German:

(1) *Warum verfolgt der Hund die Katze?*
'Why does the dog chase the cat?'

(2) *Der Bildschirm leuchtet stark*
'The monitor glows brightly'

(3) *Die Union von den Nonnen hat einen neuen Namen*
'The union of the nuns has a new name'

Sentence 1 on average consisted of 12 consonants and 6 vowels, sentence 2 of 14 consonants and 6 vowels, and sentence 3 of 12 consonants and 13 vowels. With respect to the syllabic make-up of the sentence material, the three sentences demonstrated the following distributions of syllable structures averaged over all dialects, see Figure 1.

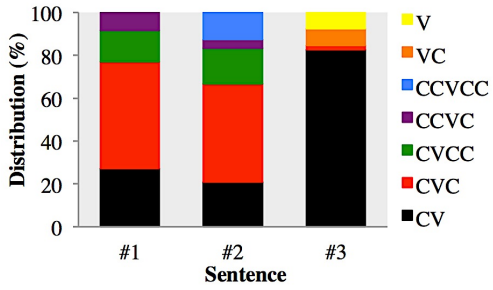

Figure 1: Syllabic make-up of sentences 1, 2, and 3.

Figure 1 reveals that sentences 1 and 2 were very different from sentence 3. Averaged over all dialects, the latter contained 83% CV syllables (black) while sentences 1 and 2 featured only 27% and 21% CV syllables. Sentences 1 and 2 contain much more CVC syllables (red) (sentence 1: 50%, sentence 2: 49%, sentence 3: 2%), however. Syllabic make-up of the sentences was further different between the dialects examined. Figure 2 shows the syllabic make-up of sentence 1 by dialect, for example.

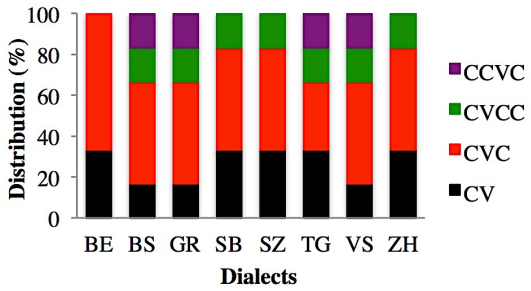

Figure 2: Syllabic make-up of sentence 1 by dialect.

Figure 2 reveals that dialects differed with regard to the relative proportions of syllable types in sentence 1. The BE speakers only exhibited CV (33%) and CVC (67%) syllables, for instance.

2.3. Procedure

Subjects were recorded in their respective locations with a Marantz PMD-671 solid-state recorder (sampling rate of 44.1 kHz and 16 bit quantization) and a Sennheiser clip-on ME2 omni lavalier microphone. Sentences were transcribed in SAMPA and labeled on the segmental level in *Praat* [7]. Consecutive vowels or consonants were merged into vocalic and consonantal intervals respectively, which provided the preferred labeling format for a subsequent application of rhythm metrics and statistical analyses. The following metrics were calculated using the *Praat* plugin 'Duration analyzer' (http://www.pholab.uzh.ch/leute/dellwo/software.html).

C:V ratio measure
The percentage over which speech is vocalic: %V [1]

Vocalic variability measures
a). The rate-normalized standard deviation of vocalic intervals: VarcoV [8]
b). The rate-non-normalized average differences between consecutive vocalic intervals: rPVI_V [9]
c). The rate-normalized average differences between consecutive vocalic intervals: nPVI_V [9]
d). The rate-non-normalized standard deviation of vocalic intervals: ΔV [1]

Consonantal variability measures:
a). The rate-normalized standard deviation of consonantal intervals: VarcoC [10]
b). The rate-non-normalized average differences between consecutive consonantal intervals: rPVI_C [9]
c). The rate-normalized average differences between consecutive consonantal intervals: nPVI_C [9]
d). The rate-non-normalized standard deviation of consonantal intervals: ΔC [1]

3. Results

3.1. Statistical analyses

All data were analyzed using R [11] and the R packages *lme4* [12] and *languageR* [13, 14]. If not indicated otherwise, we analyzed data using linear mixed effect models (LMEs). Normality was checked by visual inspection of quantile plots. *Dialect* was treated as a fixed effect, *speaker* and *sentence* as random effects. Effects were tested by model comparison between a full model, in which the factor in question was entered as either a fixed or a random effect, and a reduced model without this effect. p-Values were obtained by comparing the results from the two models using ANOVAs. For the assessment of the relative goodness of fit, we report *AIC* (Akaike Information Criterion) values that decrease with goodness of fit. Only p-values that are considered significant at the $\alpha = 0.05$ level are reported.

3.2. Interaction of *sentence* and *dialect*

Table 2 summarizes the statistics for the effects of *dialect*, *sentence*, and *dialect*sentence* by rhythm measure.

Rhythm measure	Factor	Result	Rhythm measure	Factor	Result
ΔV	dialect	AIC=-748, p<.0004*	ΔC	dialect	AIC=-502, p<.007*
	sentence	AIC=-748, p<.0001*		sentence	AIC=-502, p<.0001*
	dialect*sentence	AIC=-519, p<.003*		dialect*sentence	AIC=-519, p<.003*
VarcoV	dialect	AIC=-180, p<.0001*	VarcoC	dialect	ns.
	sentence	AIC=-180, p<.0001*		sentence	AIC=-110, p<.0001*
	dialect*sentence	AIC=-194, p<.006*		dialect*sentence	AIC=-124, p<.004*
rPVI_V	dialect	AIC=603, p<.0005*	rPVI_C	dialect	AIC=719, p<.0008*
	sentence	AIC=603, p<.0001*		sentence	AIC=719, p<.0001*
	dialect*sentence	AIC=572, p<.0001*		dialect*sentence	AIC=705, p<.01*
nPVI_V	dialect	AIC=1195, p<.0001*	nPVI_C	dialect	ns.
	sentence	AIC=1195, p<.0001*		sentence	AIC=1147, p<.0001*
	dialect*sentence	AIC=1173, p<.0002*		dialect*sentence	AIC=1132, p<.008*
%V	dialect	AIC=846, p=.024*			
	sentence	AIC=846, p<.0001*			
	dialect*sentence	ns.			

Table 2: Summary of mixed model comparisons for *dialect* and *sentence* by rhythm measure.

The comparison between the full and reduced models showed a significant difference in all rhythm metrics for *dialect* and *sentence* (except for VarcoC (cf. [6]) and nPVI_C for *dialect*), with the full model exhibiting an increased goodness of fit. Moreover, for all metrics except for %V we obtained a significant interaction of *dialect*sentence*. We take this as evidence that between-dialect variability strongly depends on the sentence used. To study simple effects of *dialect*, we conducted individual model comparisons for each of the three sentences for those rhythm metrics that showed significant interaction. 16 of the 24 model comparisons (3 sentences*8 rhythm metrics that showed interaction) revealed significant effects of *dialect* (Bonferroni adjusted for sentence, α=.017).

To visually illustrate that rhythmic differences between the dialects are contingent upon *sentence*, Figures 3 and 4 show boxplots of the dialects' VarcoV and nPVI_V by *sentence*.

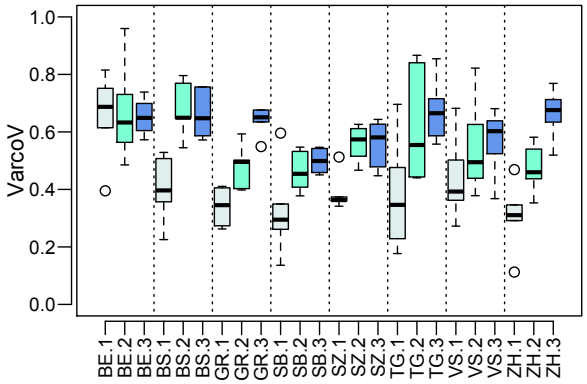

Figure 3: Boxplots of the dialects' VarcoV by sentence.

For VarcoV (see Figure 3), simple effect tests showed significant effects for *dialect* in all three sentences (Bonferroni adjusted for *sentence*, α= .017; sentence 1: *AIC*=-50, *p*<.0001, sentence 2: *AIC*=-51, *p*<.005, sentence 3: *AIC*=-90, *p*<.002). Post-hoc tests (also model comparisons, Bonferroni adjusted for *dialect* and *sentence*, α=.002) revealed, however, that dialectal differences in many cases were contingent upon the sentence being examined. In sentence 1 (grey), for example, BE speakers revealed significantly more vocalic variability (M=.66, SD=.15), than ZH speakers (M=.31, SD=.11). In sentences 2 (turquois) and 3 (blue), however, differences between these two dialects were no longer present.

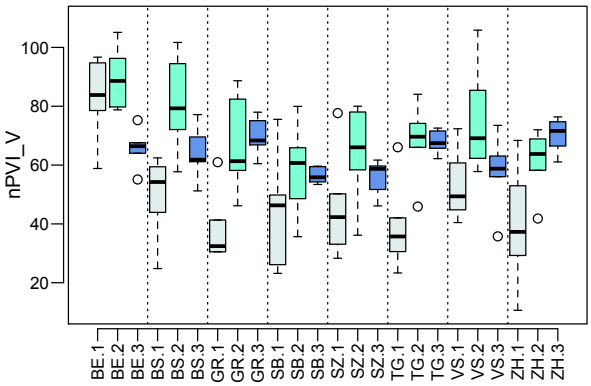

Figure 4: Boxplots of the dialects' nPVI_V by sentence.

For nPVI_V (see Figure 4), simple effect tests revealed significant effects of *dialect* in all three sentences (Bonferroni adjusted for *sentence*, α=.017; sentence 1: *AIC*=413, *p*<.0001, sentence 2: *AIC*=408, *p*<.005, sentence 3: *AIC*=339, *p*<.0005). Post-hoc tests also showed, however, that dialectal differences often depended on the sentence being examined. In sentence 1 (grey), for instance, BE speakers had significantly more vocalic variability (M=.83, SD=14), than BS speakers (M=50, SD=14). In sentences 2 (turquois) and 3 (blue), however, these differences were no longer present.

It is interesting to see that in both Figures, Figure 3 and 4, sentence 1 exhibits the lowest VarcoV and nPVI_V values for nearly all dialects, even though sentence 1 and sentence 2 demonstrate a nearly identical distribution of syllable structures (cf. Figure 1). It is conceivable that this has to do with the rhythm metrics at work in these examples: measures such as VarcoV and nPVI_V capture vowel duration variability and not syllable duration variability.

3.3. Searching for potential triggers in the material

In this section we examine possible sources in the material that cause rhythm scores between dialects to vary. The data provided are exemplary evidence and described impressionistically, largely based on visual inspection. Only VarcoV and nPVI_V are considered because these measures are controlled for speech rate, they revealed significant interaction for *dialect*sentence* (see Table 2), and they have proven to be highly discriminative for the 8 SwG dialects examined [6].

VarcoV: SB and TG

Figure 3 revealed that VarcoV differentiates SB (M=.49, SD=.04) from TG speakers (M=.67, SD=.10) in sentence 3. Post-hoc tests showed that the difference between the dialects was only significant for this sentence. In the other two sentences the dialects do not differ. If we look at a typical SB and TG realization of sentence 3, we detect two phenomena that may contribute to a lower VarcoV in the SB dialect, see Figure 5.

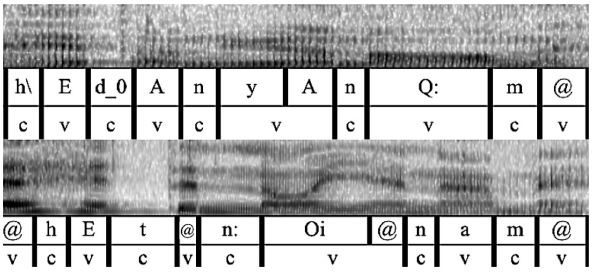

Figure 5: Typical articulation of the constituent *hat einen neuen Namen* (sentence 3) by an SB speaker (top panel) and a TG speaker (bottom panel).

Firstly, the indefinite article in 'a new name' in Figure 5 (top panel) is realized as a full vowel [ɑ] by the SB speaker, with a duration of 59 ms. The TG speaker, on the other hand, articulates a short schwa with a duration of 42 ms. Alpine dialects such as SB SwG have a tendency of realizing unstressed light syllables as full vowels. Secondly, Figure 5 reveals that the SB speaker lengthens the [ɑ] in *Name*, 'name'. SB speakers have a tendency of lengthening Middle High German short vowels [15]. This [ɑ] in the SB SwG is 155 ms long, while the TG speaker's [a] is only 112 ms long. If a sentence contains tokens that allow for full vocalic articulation and lengthening of short vowels, it is plausible that this leads to less vocalic variability and thus smaller VarcoV values for SB SwG.

nPVI_V: BE and TG

Figure 4 revealed that BE (M=83, SD=14) and TG (M=39, SD=15) differed significantly in nPVI-V in sentence 1. Post-hoc tests showed that the two dialects differ in this sentence, not, however, in sentences 2 and 3. If we look at a typical BE and TG realization of sentence 1, we find one phenomenon which may contribute to the higher nPVI_V values in the BE dialect, see Figure 6.

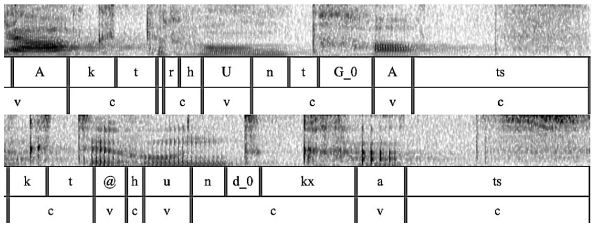

Figure 6: Typical realization of the constituent *jagt der Hund die Katze?* (sentence 1) by a BE speaker (top panel) and a TG speaker (bottom panel).

One of the triggers for a higher nPVI_V value in the BE dialect in this sentence may be the realization of an [r] in the masculine NOM. definite article *der*, as in *der Hund*, for which most other SwG dialects use the form [d̥ə]. Because of this [r], the [ə] is strongly reduced (15 ms). The TG speaker realizes *der* as [d̥ə], where the schwa is articulated more fully (76 ms). This morphological property is particularly typical of BE SwG and may have contributed to the higher proportions of CVC syllables for the BE speaker group in sentence 1 (cf. Figure 2). If a sentence contains such dialect-specific morphological properties, it is possible that this leads to different distributions in syllable structures between the dialects, and possibly more vowel reduction, which in turn may cause an increase in nPVI_V.

4. Discussion and conclusions

Results of the current study support an answer to question (1) *Does sentence material have an influence on rhythmic differences between dialects?* as a *yes*. Effects of *sentence* are not only found within one and the same language, as shown by [3, 4], but also across varieties of the same language: in the majority of the studied rhythm metrics we found significant effect of *sentence* as well as a significant interaction of *dialect*sentence*. That is, cross-dialectal rhythmical differences heavily depend on the sentence material being examined. To complicate matters, the *dialect*sentence* interaction was manifested differently depending on the applied rhythm metric (see Figures 3 and 4). For VarcoV, for example, we found that in VS and ZH SwG sentence 3 has a higher VarcoV than sentence 2. In nPVI_V, however, VS SwG sentence 3 has a lower value than sentence 2, while in ZH SwG, sentence 3 still has a higher value than sentence 2. Rhythmic variability between dialects is more complex than hitherto predicted.

These results provide further support that the selection of sentences in speech rhythm research must be given extra attention, cf. [3, 4, 16]. One can choose to work with a small data set and a special consideration for issues of dialect- or language-specific phonotactic and prosodic representativeness [3, 4], or one can work with a data set large and manifold enough to level out sentence effects. While the applied rhythm metrics have shown an interaction of *dialect*sentence*, it remains unclear to what degree these metrics reflect audible rhythmic aspects of speech [2, 3, 4, 8, 17]. It would be interesting to conduct further experiments to test whether between-sentence variability in different SwG dialects is perceptually salient.

In answer of research question (2), this study reported a number of potential triggers in the sentences material that may cause variation in the rhythm scores. By merely looking at two exemplary instances, the following dialect-specific phonological and morphological phenomena were suspected to contribute to variation in rhythm scores: SB SwG: Full vocalic articulation of unstressed light syllables, cf. [15], lengthening of short vowels [15]. BE SwG: NOM. definite article *der* is realized as [d̥ər], which increases the number of CVC syllables in this dialect (cf. Figure 2) and quite possibly results in reduced realizations of [ə].

If, hypothetically, a study uses only a small set of sentences where some sentences contain words that allow for these processes to apply and other sentences do not feature such words and consequently no such processes, dialects are likely to differ in rhythm scores in one sentence yet behave similarly in another sentence. While our preliminary findings clearly showed sentence-dependencies for between-dialect differences, these dependencies are in fact a result of dialect-specific phonological processes present in the sentence material. It is conceivable that the mentioned dialect-specific phonological processes in fact strongly contribute to between-dialect differences in rhythm scores. Such insights call for further microanalyses of the kind presented in Figures 5 & 6. In a follow-up study, one could control for features such full vocalic articulation of unstressed syllables. This would reveal the significance of such a dialect-specific phonological process for cross-dialectal comparisons in speech rhythm.

Dialectal variation at the Prosody-Syntax interface: Evidence from Catalan and Spanish interrogatives

Maria del Mar Vanrell[1], *Olga Fernández Soriano*[2]

Abstract

In this study we investigate how prosody interacts with word order in the expression of interrogativity in different varieties of two Ibero-Romance languages, Catalan and Spanish. We analyze a corpus obtained by means of the Discourse Completion Task Methodology. The collected data were prosodically and syntactically annotated and show that the absence of syntactic marking (wh-word, subject-verb inversion or subject dislocation) for questions tends to correspond to a more salient intonational marking. Thus, wh-questions favor general falling intonational patterns. By contrast, yes-no questions can be classified depending on the nuclear tone (with preference for low tones in Catalan and high tones in Spanish) and final tone (low for language varieties with subject inversion or dislocation, but optionally high for those that do not present syntactic marking in a mandatory way).

Index Terms: prosody, word order, interrogativity, Catalan, Spanish, dialectal variation.

1. Introduction

The interface between prosody and word order in Ibero-Romance has not been consistently studied. A considerable amount of research has been devoted to languages like Spanish, but other languages such as Catalan are much less known. In addition, most of the work concentrates on declarative modality, particularly on the expression of focus ([1], [2], [3]), as well as on the location of the main prominence (nuclear accent) and the theoretical implications of the location of this prominence. However, somewhat less attention has been devoted to how focus structure can influence pitch accent choice.

Regarding previous studies on Catalan and Spanish questions, although we find exceptions such as the work in [4] and [5] for Catalan and Spanish respectively, there is often a stark division between those studies that emphasize the syntactic perspective (word order in the marking of interrogativity: [6] for Catalan) and those that focus on the prosodic perspective (pitch accent choice in different question types: [7], [8] for Catalan; [9], [10] for Spanish). Moreover, syntactic studies tend to disregard dialectal variation, dealing instead primarily with standard varieties or specific characteristics of particular varieties (e.g., the absence of subject inversion in Caribbean Spanish). It is also necessary to note that, as pointed out by [2], syntactic works and phonological studies tend to use different methodological approaches. Whereas syntactic works make use of introspection and grammaticality judgments, phonological studies have a tendency to use experimental methods. This makes the results from the two linguistic fields very difficult to compare.

This paper makes an attempt to encompass all those aspects and reconcile the two perspectives (prosodic and syntactic), while dealing with dialectal variation and applying a uniform, controlled methodology. We investigate the interaction between nuclear configuration types and word order in the marking of interrogativity in different varieties of Catalan and Spanish.

2. Methodology

2.1. Participants

The participants in our production experiment were 4 men and 10 women aged between 22 and 45 from the following locales of the two languages under study: a) Central Catalan (CCat): 2 female speakers, province of Barcelona; Balearic Catalan (BCat): 1 female speaker and 1 male speaker, island of Majorca; Valencian Catalan (VCat): 1 female speaker and 1 male speaker, province of Alacant and Valencia respectively; and b) Castilian Spanish (CasSpa): 2 female speakers, Madrid; Spanish as spoken in the Basque Country: two female L1-Spanish speakers, province of Biscay (BCSpaL1Spa) and 2 female L1-Basque speakers (BCSpaL1Bas), province of Biscay too; Canarian Spanish (CanSpa): 2 male speakers, island of Gran Canaria.

2.2. Materials

The corpus analyzed in this paper was obtained by means of the Discourse Completion Task methodology or DCT ([11], [12], [13]). It is an inductive method in which the researcher presents the subject with a series of situations and then asks him or her to respond accordingly. The full survey is made up of 130 situations that allowed us to obtain a wide range of interrogative contours controlling for the type of verb, the type of subject and the degree of certainty about the likelihood that the speaker will get a "yes" answer to his/her utterance. We elicited in this fashion a total of 1820 contours (130 contours x 14 speakers). In this paper we will present the results for 779 contours (224 Catalan y/n questions, 118 Catalan wh-questions; 292 Spanish y/n questions, 145 Spanish wh-questions). Indirect questions and y/n questions other than information-seeking y/n questions were not analyzed in this paper.

2.3. Procedure

The descriptions of the prompt situations provided in the DCT were read aloud to the participants. After each description, the participant was asked to respond appropriately to the situations as spontaneously as possible. Speakers were recorded on a Zoom H4n digital audio recorder using an AKG C520 condenser microphone. The following example illustrates a situation used to elicit a y/n question in Spanish with nominal subject: 'You have no idea whether Juan bought the car or not.

Ask your friend about this.' Intended target response: 'Did Juan buy the car?'.

2.4. Analysis

Data were annotated in Praat ([14]) for the following fields: (i) orthographic transcription, (ii) position of the subject (postverbal or preverbal, right or left dislocated, dropped), (iii) additional lexical markers such as *que* or *oi?* for Catalan and (iv) prosodic transcription using the latest version of the Cat_ToBI and Spa_ToBI systems ([8] for Catalan and [10] for Spanish). The annotations were compiled automatically in .txt format through a Praat script and then transferred to a SPSS file for purposes of subsequent statistical exploration.

3. Results

3.1. Word order results

Table 1 reports the frequency of observation (e.g., number of occurrences) of the variable SUBJECT EXPRESSION AND POSITION (dropped, preverbal, postverbal and dislocated) for nominal and pronominal subjects in y/n questions and different language varieties. A clear-cut division emerges between language varieties that can present postverbal subjects and those that cannot. Thus, VCat and Spanish in general can have a postverbal subject, see (1), whereas Eastern Catalan (BCat and CCat) tend to dislocate the subject, as in (2). Interestingly, there are two varieties, VCat and CanSpa,[1] which—although they can resort to subject inversion as a question marker—prefer to have the verb in preverbal position, as in (3). Our data show that the probability of a subject appearing in preverbal position increase in the case of 1st and 2nd person pronominal subjects. That is, sentences like (4) are possible, whereas sentences like (5) are more marginal though still possible. Our results also show that in Spanish the 2nd person formal form *usted*, which agrees in 3rd person with the verb, appears more frequently in postverbal position, as in (6), than 1st and non-formal 2nd personal pronominal subjects, which tend to be dropped, due to the fact that they usually cannot be distinctive in these contexts (hence the contrast with full NPs). The analogous Catalan form *vostè* tends to be dislocated but can also appear in preverbal position.

(1) *¿Nació el hijo de la vecina en Madrid?* (CasSpa)
be born.PAST.3SG the son of the neighbor in Madrid

(2) *Treballa fins tard, el fill de la veïna?* (CCat)
work.PRES.3SG until late the son of the neighbor

(3) *¿La mujer de Juan es francesa?* (CanSpa)
the wife of Juan is French

(4) *Tu vares comprar un cotxe?* (BCat)
you buy.PAST.3SG a car

(5) *Ets francès, tu?* (CCat)
be.2sg French, you

(6) *¿Nació usted en Madrid?* (BCSpaL1Spa)
be born.PAST2SG2SG.FORMAL in Madrid

Table 1. *Frequency of observation of the variable SUBJECT EXPRESSION AND POSITION for nominal and pronominal subjects in y/n questions across different language varieties. The highest numbers or (in some cases) the second highest numbers after subject drop in pronominal subjects are indicated in bold.*

Language varieties	Nominal subject			Pronominal subject			
	Pr	Po	Di	Dr	Pr	Po	Di
BCat	1	0	**17**	5	7	0	**14**
CCat	0	0	**18**	5	0	0	**14**
VCat	**14**	3	0	12	**7**	1	0
CanSpa	**16**	0	0	7	2	**7**	0
CasSpa	6	**13**	0	11	2	**5**	0
BCSpaL1Spa	**14**	6	0	8	**6**	4	0
BCSpaL1Bas	3	**17**	0	9	3	**5**	0

Table 2 shows the frequency of observation of the variable SUBJECT EXPRESSION AND POSITION (dropped, preverbal, postverbal and dislocated) for nominal and pronominal subjects in wh-questions and different language varieties. Again BCat and CCat tend to dislocate the subject, as in (7), whereas VCat and Spanish clearly do not, as in (8). Like in y/n questions, pronominal subjects tend to be more commonly produced in preverbal position than nominal subjects. Again, it is of interest to single out the behavior of the form *usted*. As was seen for y/n questions, this pronominal form does not behave like other Spanish personal pronouns, nor does it behave like a full DP (see [15]).

(7) *I quan fa feina, n'Aina?*(BCat)
and when make.PRES.3SG work, PERS.ART-Aina

(8) *Què volia el fill de la veïna?* (VCat)
what want.past.3sg the son of the neighbor
¿Dónde nació Ana? (CSpa)
where be.born.PAST.3SG Ana

The results of a two-way ANOVA test with SUBJECT EXPRESSION AND POSITION as the dependent variable and SUBJECT TYPE, LANGUAGE VARIETY and QUESTION TYPE as independent variables revealed statistically significant effects of SUBJECT TYPE ($F(1,751)=103.320$, $p<.001$), LANGUAGE VARIETY ($F(6,751)=18.581$, $p<.001$) and QUESTION TYPE ($F(1,751)=4.492$, $p<.05$). Post-hoc analyses confirmed that Eastern Catalan (BCat and CCat) differed significantly from the other language varieties (Tukey $p<.001$).

Table 2. *Frequency of observation of the variable SUBJECT EXPRESSION AND POSITION for nominal and pronominal subjects in wh-questions across different language varieties. The highest numbers or (in some cases) the second highest numbers after subject drop in pronominal subjects are indicated in bold.*

Language varieties	Nominal subject			Pronominal subject			
	Pr	Po	Di	Dr	Pr	Po	Di
BCat	3	4	**34**	18	10	0	**11**
CCat	0	0	**42**	2	2	0	**25**
VCat	6	**36**	0	18	4	**5**	0
CanSpa	6	**37**	1	13	7	**8**	1

BCSpaL1Spa	0	**43**	1	15	**7**	**7**	1
BCSpaL1Bas	0	**42**	0	9	0	**22**	0

3.2. Intonation results

Table 3 shows the frequency of occurrence (as counts) of the variable NUCLEAR PATTERN for two question types (y/n questions and wh-questions) and the different language

[1] Preverbal nominal subjects are also common in BCSpaL1Spa. However, due to space limitations, this issue cannot be discussed in any greater depth.

varieties under study. In Table 3 only the most common patterns are reported. Regarding question intonation, first we would first like to highlight the crucial role of prosody in marking whether the subject is dislocated or not. Each dislocated element constitutes a tonal unit which is independent of the core sentence. Hence, an intonational contour made of a core sentence and two dislocated elements (e.g., *Vindrà, la Maria, demà?* Will come, Maria, tomorrow) is produced with three different tonal units. Most instances of dislocated subjects in our data are right dislocations. Right dislocated elements reproduce the intonation pattern of the core sentence but with some variation depending on whether the intonational contour is rising or falling (see [16]).

Table 3.*Frequency of observation of the variable* NUCLEAR PATTERN *for y/n and wh-questions across different language varieties.*

Language varieties	Y/n questions		Wh-questions	
	NC	Freq	NC	Freq
BCat	¡H+L* L%	35/43	H+L* H%	37/80
CCat	L* H%	29/37	H* L%	68/71
VCat	L* H%	37/38	H+L* L%	73/73
CanSpa	L+¡H* L%	14/32	H* L%	33/73
	L* H%	14/32		
CasSpa	L+¡H* L%[2]	17/38	L* H%	22/71
			H* L%	18/71
BCSpaL1Spa	L+¡H* HL%	18/37	L* L%	48/74
BCSpaL1Bas	L+¡H* HL%	17/38	L* L%	65/74

The intonation of yes-no questions in our data can be grouped into two different patterns according to the pitch tonal event associated with the nuclear syllable: falling/low or high. Whereas Catalan follows the first pattern, nuclear accents in Spanish yes-no questions tend to be high. As for the boundary tones, they can also be low (BCat and Spanish) or high (CCat, VCat and CanSpa). These are not absolute tendencies, since for instance CanSpa can also present a rising pattern, that is, a low nuclear accent followed by a high boundary tone (as can be seen in Table 3). These general tendencies regarding the intonational patterns are consistent with the data presented in [7], [8] and [9], [10] for Catalan and Spanish respectively. When putting the results together, one could hypothesize that the tonal variation found in the nuclear syllable reflects language-specific differences (Catalan vs. Spanish), whereas the tonal variation located at the final stretch of the contour is related to the syntactic marking of the interrogative modality. In other words, language varieties that use syntactic means such as subject inversion or dislocation to mark interrogativity tend to use low tones,[3] but language varieties which do not resort to syntactic markers in a compulsory way (such as VCat or CanSpa) have high final boundary tones available in their intonational grammars. Figure 1 shows an instance of the y/n question *És francesa, la dona del Joan?* (Is French, the wife of.PERS.ART. Joan) produced by a CCat speaker. The utterance presents a L* nuclear accent associated with the accented syllable of *Joan* followed by a H%. Figure 2 illustrates the y/n question *¿Trabaja Juan hasta tarde?* (work.pres.3SG Juan until late) produced by a speaker of CanSpa. The intonational pattern is characterized by a nuclear L+¡H* accent associated with the accented syllable of *tarde* and a low boundary tone (L%).

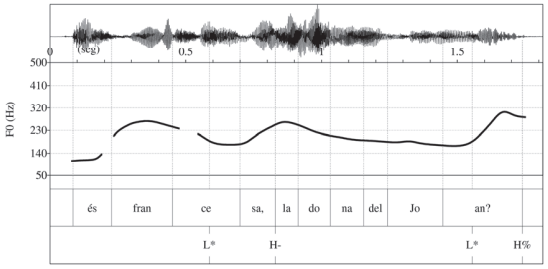

Figure 1: *Waveform and F0 contour of the y/n question with right dislocation of the subject És francesa, la dona del Joan? 'Is she French, Joan's wife?' produced by a speaker of CCat.*

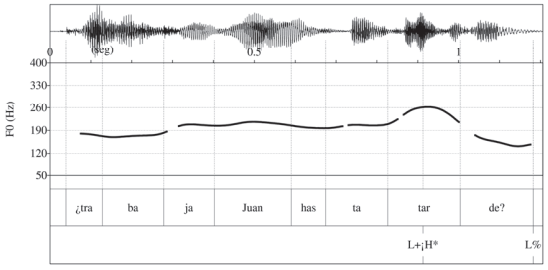

Figure 2: *Waveform and F0 contour of the y/n question ¿Trabaja Juan hasta tarde? 'Does Juan work until late?' produced by a speaker of CasSpa.*

As in the case of y/n questions, wh-questions can be grouped into two categories depending on the tone associated with the nuclear syllable: falling/low or high. Falling/low patterns are common in all the varieties except CCat, CanSpa and CasSpa, which produce high nuclear pitch accents. The final boundary tones tend to be low, although BCat and CasSpa can also present a final rising boundary tone (H%). This H+L* H% pattern in wh-questions has often been regarded as more polite compared to the falling pattern (H+L* L%) (see [17], [5], [7]). The more frequent presence of falling nuclear configurations in wh-questions could be explained by the fact that these questions are formally marked by a preposed wh-word and therefore they do not need to be marked intonationally. Figure 3 displays an example of the wh-question *Quan treballa el fill de la veïna?* 'When does the son of the neighbor work?' produced by a speaker of VCat and characterized by the H+L* L% nuclear configuration. Figure 4 shows the wh-question *¿Dónde nació Ana?* '¿Where was Ana born?' produced by a CanS speaker. The intonational contour includes a H* nuclear accent aligned with the accented syllable of *Ana* and a low final boundary tone.

An inter-transcriber reliability test of the ToBI transcription was conducted with a 10% sample of the data. The subset of data was selected on the basis that all the language varieties and question types were uniformly represented. Four transcribers labeled the subset using the Cat_ToBI and Sp_ToBI systems. Since there were more than two transcribers, the Fleiss' kappa statistic was used. We obtained a moderate agreement for the choice of pitch accents

[2] It should be noted that this result does not conform to the predictions made by traditional studies such as [17], [18]. However, our results agree with those of [19] in which y/n questions uttered in spontaneous speech are analyzed. A possible explanation for this inconsistency could be that L* H% contours are more restricted to formal speech situations ([20], [19]).

[3] As pointed out by a reviewer, CCat would not follow our generalization, since although y/n questions tend to be marked by subject inversion, 78% of the contours were pronounced by a H% boundary tone. The case of CCat deserves a more fine grained study since the alternation between rising and falling patterns could be related to subdialectal variation (see [7], Map 8.7.).

(0.62) and an almost perfect agreement for boundary tones (0.85) ([21]).

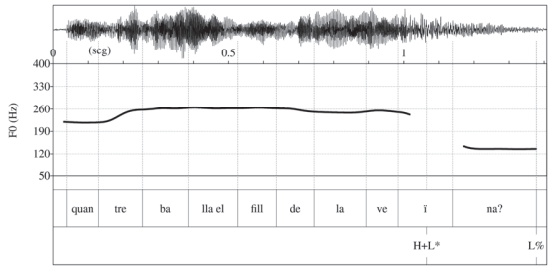

Figure 3: *Waveform and F0 contour of the wh-question Quan treballa el fill de la veïna? 'When does the son of the neighbor work?' produced by a speaker of VCat.*

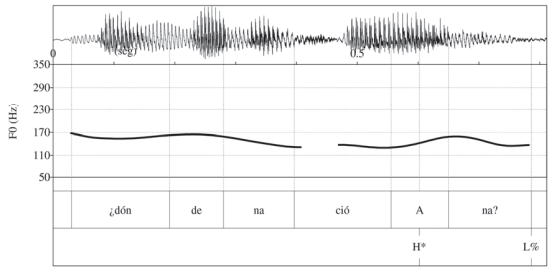

Figure 4: *Waveform and F0 contour of the wh-question ¿Dónde nació Ana? 'Where was Ana born?' produced by a speaker of CanSpa.*

4. Discussion and conclusions

This study represents a first step in exploring how prosody interacts with word order in the expression of interrogativity in Ibero-Romance. To this end, a production study was designed using the DCT methodology to elicit different question types. In addition, we controlled for verb and subject type, and degree of certainty about the response—here only subject type was included in the analysis. The data were annotated prosodically and syntactically with Praat ([14]). After performing a quantitative analysis using the dependent variable SUBJECT EXPRESSION AND POSITION, we conclude that there are three factors that play an important role in the expression of interrogativity by means of word order: question type (y/n question and wh-question), language variety and subject type (nominal, pronominal or *usted*). One of the most crucial differences obtained is between languages that can invert the subject to mark questions (VCat and Spanish) and language varieties that cannot (Eastern Catalan, i.e., BCat and CCat). The latter resorts to subject right/left dislocation. The exception to this general behavior concerns pronominal subjects (1st and 2nd person singular), which tend to occur in preverbal position. The formal pronoun *usted* behaves like a nominal subject in this respect. Our explanation for this particular behavior is based on the lack of a match between the features of the form *usted* (a second person, formal) and the features in INFL, inflection (third person). Our data advocates for the existence of a particular position for this form inside IP (inflectional phrase). VCat and CanSpa show a preference for preverbal subjects in yes-no questions including nominal subjects. These results for VCat and CanSpa should be related to the results obtained in a recent study we carried out (see [16]) which focused on the role of word order and prosody in the expression of not solely interrogativity but also different focus structures. The results revealed that especially CanSpa but also VCat, compared to other Catalan varieties such as BCat and CCat, are [+ plastic] (see [22], [23]) language varieties in the marking of focus, that is, the interaction between focus and prominence is achieved by means of prominence shift rather than changes in word order. This comes as no surprise since Caribbean varieties have been reported to have many commonalities with CanSpa (e.g., the use of the circumflex intonational pattern, possibility of lacking subject inversion in wh-questions, deletion of final *-s*) and they are known to be especially [+plastic] ([24] for Puerto Rican Spanish) and to exhibit a particular preference for SVO order in questions ([22] for Puerto Rican Spanish).

With respect to intonation, we interpret the absence of syntactic marking (wh-word, subject-verb inversion or subject dislocation) for questions as corresponding to a more salient (in terms of pitch height) intonational marking. Hence, wh-questions are mainly characterized by falling patterns, even though the nuclear accent can be low/falling or high. As for yes-no questions, they can be classified by the nuclear tone, low/falling for Catalan and high for Spanish, but also by the final boundary tone. Regarding the final boundary tone, the general tendency points to low tones for language varieties with subject inversion or dislocation, and to optionally high tones for those varieties that do not present syntactic marking in a mandatory way.

As some researchers have suggested, the lack of subject inversion in direct questions may be the syntactic manifestation of a larger shift towards languages becoming more rigid with respect to word order ([26], [27], [22]) with French being the most drastic case among Romance languages. Finally, we would like to highlight that together with syntactic characteristics such as the absence of subject drop, the presence of subject pronouns with infinitival forms (i.e., *para yo hacer esto* 'for me to do this', see [25], 26]) or the lack of subject inversion in questions, the use of a more salient intonational marking can offer insights into the dynamics of language change.

5. Acknowledgments

A preliminary version of this article was presented at the Forschungskolloquium der Romanistischen Sprachwissenschaft. We are grateful to the participants at that meeting for their helpful comments and suggestions. We thank Joan Borràs-Comes, Paolo Roseano and Rafèu Sichel-Bazin for participating unselfishly in the inter-transcriber reliability test of the ToBI transcription and Meghan E. Armstrong, Nick Henriksen and two anonymous reviewers for their comments and advice on the first written version of this paper. Thanks also go to the participants in our experiment as well as the people that helped us to contact potential participants, namely Gotzon Aurrekoetxea, Mercedes Cabrera, Verònica Crespo-Sendra, Irene de la Cruz, Gorka Elordieta, Leire Gandarias, Miriam Rodríguez and Paco Vizcaíno. The research assistant Anne-Kathrin Knecht deserves a special mention for her help in the preparation of this article. This research has been funded by the project FFI2011–23829/FILO awarded by the Spanish Ministry of Economy and Competitiveness.

Abstract

In the literature on prosody/syntax interface, syntactic information is usually considered as playing an important role in deriving the prosodic phrasing of an utterance. NP subjects, for instance, have often been claimed to phrase independently from the VP. It has nevertheless been shown that metrical factors could have an impact on phrasing, and that NPs could be phrased in the same prosodic phrase as the VP, or that the verb could be phrased with the subject. Several methods were used to measure metrical weight: number of syllables, of prosodic words, syntactic branchingness, etc. In order to determine which factors are more important, and how the all interact, we evaluate the weight that different metrical predictors have on prosodic phrasing. This is done by analyzing the phrasing of SVO structures in 200 sentences extracted from various French corpora. From the observation of the data that were semi-automatically annotated, it appears that subjects can be phrased independently or in the same prosodic phrase as the VP, and that objects are rarely isolated from the verb. The analysis reveals interesting results regarding the effect of articulation rate and number of syllables, whereas syntactic-branchingness didn't show any effect.

Index Terms: Prosody, metrical structure, phrasing, interface prosody-syntax, articulation rate

1. Introduction

Several theoretical and experimental studies have shown that multiple factors constrain prosodic phrasing, among which we may mention metrical constraints. Nevertheless, syntactic information are often considered as playing the most fundamental role, regardless of the approach used to account for the mapping between the prosodic structure and the syntactic one. In [1], for instance, it is assumed that edges of prosodic pharses should coincide with edges of syntactic phrase, whereas [2] insists on head-complement relations in determining the prosodic phrases (see for a review of the various approaches [3] and [4]).

Whatever approach is taken into account (end-based or relational), one would predict for French SVO sentences that NP subjects form an independent prosodic phrase, separated from the rest of the utterance, and more specifically the VP (see, for instance, [5] and [6]). On this basis, the sentence in (1) would be phrased in two prosodic groups, as shown in (2):

(1) Le gardien a vu le beau chien de ma voisine

(2) [Le gardien] [a vu le beau chien de ma voisine]

Nevertheless, it has been shown that mapping rules were not sufficient to predict phrasing. Factors such as length of the syntactic phrases could play a crucial role in the prosodic parsing of an utterance. As for SVO structure in French, [7] and [8] showed that NP subjects could be phrased in the same prosodic phrase as the VP when they are short (i.e. when they contain a small number of syllables), and that objects could be separated from the verbal head V to obtain well-balanced phrases. As a consequence the parsing in (3) is completely acceptable for the sentence (1), and maybe even better than the one proposed in (2):

(3) [Le gardien a vu] [le beau chien de ma voisine]

In the literature, the length of the constituents have been evaluated by several means: syntactic branchingness or complexity ([2]), number of prosodic units (generally number of prosodic words, as in [9]) or number of syllables ([10] and [8] among others). The way certain of these factors interact have been analyzed in details in some experimental studies (see [11] and [12] among others). In [12], where four different Romance languages were compared, it has been shown that SVO structures do phrase differently in the four Romance languages under investigation. Nevertheless, the (S)(VO) pattern was the most common for Catalan, Spanish and Italian, while (SVO) is the unmarked phrasing for European Portuguese. In addition, the authors showed that syntactic branchingness, number of prosodic words, and number of syllables had a different impact on phrasing decisions, and interacted in a different fashion across the four languages, leading for example to the production of patterns such as (SV)(O) in Catalan under certain length condition, a pattern which never was found for European Portuguese. A systematic study of the impact of these different factors has never been achieved for French. The goal of this paper is thus to investigate how all these factors interact in French. Due to a limited number of utterances and to the important number of parameters at play, the results presented here are only preliminary.

2. Methods

2.1. Data and participants

The analysis presented here is based on corpus data. We explored a total of 90 minutes of speech recorded by 18 speakers in four different speaking conditions. Among these 90 minutes, 20 minutes consist in the reading of fairy tales by professionals, 20 minutes in political speeches, and the remaining 50 minutes consist in different types of spoken data produced by 8 Parisian speakers recorded within the PFC project [13]. Following the data collection protocol used for the project, each speaker was asked to read carefully at a normal speech rate a journalistic text including 22 sentences (398 words), and then to converse freely in pair for 20 minutes. Among these data, the reading of the text and 3.30 minutes of conversation were taken into consideration for each of the 8 speakers in the present studies. Table 1 gives an overview of the number of speakers and of the duration of the samples.

Table 1: *Composition of the data set*

Speaking Style	Duration (min.)	Nb. of speakers
Fairy tales	19'28	6
Political speeches	21'08	4
Reading (PFC)	18'53	8
Spontaneous (PFC)	30'10	

We controlled for the sex of the speakers, selecting an equal number of male and female for each sub-corpus; however age was not a controlled variable. All participants speak a standard variety of French.

2.2. Labeling of the data and prosodic structure

The recordings were transcribed within Praat [14], and aligned in phones, syllables and words with EasyAlign [15]. All alignments were manually checked and corrected by hand by one of the authors. Then, the orthographic transcription of the data was annotated in PoS with the Dismo software [16]. This allows assigning a phonological status to the different words with respect to their ability to be accented (see among others [17] and [18]), and then segmenting the data in Phonological Words (henceforth PW).

The strength of the prosodic boundaries occurring at the end of prosodic words depends on their phonetic realization. When the last metrical syllable of a prosodic word is associated with a pitch movement, is lengthened, and even followed by a pause, it is considered as corresponding to a major prosodic boundary that may correspond to a major phrase or an IP boundary. In order to analyze intonational phrasing without going into details as for the distinction between major phrase or intermediate phrase on the one hand, and intonational phrase on the second (see [19] among others), the two levels have been grouped together and referred to as *major prosodic phrases* (MaP). The strength of the boundary occurring at the end of each prosodic word has been automatically detected with the Analor tool [20]. On the basis of four automatically measured acoustic parameters (relative syllabic duration, relative f0 average, slope contour amplitude and presence of an adjacent silent pause), the software estimates a degree of strength for the last syllable of each PW on a scale from 0 to 10 (from the least to the most prominent). The calculations rely on two fundamental principles. The first is a quantity principle: the greater the number of acoustic parameters involved in the identification of a prominence and the distance from predetermined thresholds, the stronger the prominence is perceived. The second is a compensation principle, which stipulates that if one of the classic parameters involved in the perception of prominence in French presents a low value and another presents a high value, there will be the same feeling of prominence as if the two parameters involved both presented a medium score. We considered that the right edge of a PW coincides with a major prosodic phrase boundary when the degree of strength associated to the last syllable of the PW reached a score of 4/10.

2.3. Extraction and prosodic encoding of the SVO structure

Using a manual annotation, we extracted from the entire corpus all sentences having a SVO pattern, where S, V and O were not separated by any other kind of linguistic material (appositive clauses, adverbs and other parentheticals), and where S and O consisted of a SN. In addition we restricted ourself to main clauses, leaving aside embedded SVO structure. In total, 198 sentences were extracted. Table 2 gives the distribution among the sub-corpus of the extracted sentences.

Table 2: *Nb of SVO sentences extracted from each sub-corpus*

Speaking Style	Nb. of sentences
Fairy tales	85
Political	28
Reading	67
Spontaneous	29

On the basis of the annotation described in section 2.2, it was possible to assign to each syntactic units of the SVO structure prosodic labels/ features(including F0 patterns, number of syllables, and number of PWs). Due to the uncontrolled character of the data (corpus data), the length of the various units vary greatly, as shown in **Erreur ! Source du renvoi introuvable.**.

Table 3: *Range and mean (standard deviation) nb. of syllables and of PWs for each syntactic constituent*

Synt. Const.	Nb. of Syll.		Nb. of PW	
S	Min.-Max Mean (SD)	1-17 4.8 (2.6)	Min.-Max Mean (SD)	1-4 1.7 (0.9)
V	Min.-Max Mean (SD)	1-8 3.1 (1.6)	Min.-Max Mean (SD)	1-3 1.1 (0.5)
O	Min.-Max. Mean (SD)	1-15 4.7 (2.7)	Min.-Max. Mean (SD)	1-4 1.7 (0.8)

In addition, the syntactic complexity of each S and O (simple nominal head or nominal head with branching complements) was manually coded. The articulation rate of the entire sentence was also automatically calculated by dividing the duration of the entire sentence (and by excluding the time of silent pauses) by the total number of syllables (it is therefore expressed in ms/syll, (see [21]).

3. Results

The analysis of the data, and more specifically of the boundary strength associated at the end of S, V, and O respectively, showed that S and O could be phrased independently from V, or phrased in the same MaP than V. It thus leads to four possible combinations, which were all obtained in our data. Yet, as table 4 shows, the four combinations do not occur with the same frequency.

Table 4: *Distribution of the phrasing obtained for the SVO structures*

Pattern	Count	%
(S)(V)(O)	16	8.1
(S)(VO)	92	46.5
(SV)(O)	4	2
(SVO)	86	43.3

The (S)(VO) pattern is the most frequently observed, followed by the (SVO) pattern. Taken together, these two patterns represent approximately 90% of the data. Cases where both S and O are isolated from V by a major prosodic phrase boundary are quiet rare, and cases where S and V are phrased in a single IP while O is in a distinct IP are even rarer (these two patterns taken together account for 10% of all SVO occurrences)

Due to the small amount of cases for the two last patterns, and in order to simplify the analysis and presentation of the results, we separated the data according to the way S and O were phrased in regards of V. Essentially, we compared the group of sentences where S was phrased with V (N= 90) and the group of sentences where S was phrased in a different IP than V (N=108), *cf.* §3.1; and we compared the group of sentences where O was phrased with V (N= 178) and the group of sentences where O was phrased in a different IP than V (N = 20), *cf.* §3.2.

Data were analyzed by mean of Nominal Logistic Regression within SPSS (v. 21.1). Due to the fact that the number of syllables and the number of PWs were strongly correlated for S ($r = 0.808$, $p < 0.01$), for V ($r = 0.718$, $p < 0.01$) and for O ($r = 0.786$, $p < 0.01$), and in order to avoid effects of co-variables, two different models were run to test the effect of prosodic branchingness. Note that due to the small amount of data, we did not include speaking style as a predictor.

3.1. S prosodic phrasing

First, a model was run with S phrasing status as the dependent variables (possible value: within an independent MaP/within the same MaP as V), and the following variables as predictors: syntactic branching of the element (branching/non-branching), number of syllables in S, number of syllables in V, number of syllables in O, the interaction between the number of syllables in S and the number of syllables in V, and the interaction between the number of syllables in V and the number of syllables in O.

Apart from syntactic constraints, results of the model revealed that the articulation rate has a significant impact on the phrasing of S ($\beta = 0.21$, $z = 20.114$, $p < 0.001$). As it can be seen in Figure 1 below, syllabic mean duration of the SVO sentence is greater (articulation rate slower) in cases where S is phrased as an independent MaP.

An effect of the number of syllables in the subject phrase was also found ($\beta = 0.404$, $z = 4.507$, $p < 0.05$). This shows that the more syllables are contained in S, the bigger the chances for S to be phrased as an independent MaP. In other words, an S containing 12 syllables stands in greater chance to be phrased in a separate MaP, separated from the verb, in comparison with an S containing 2 syllables. Prosodically embedded S constituents contain fewer syllables than prosodically independent S constituents; this can be seen by comparing the mean number of syllables in S when it is phrased as an independent MaPP and when it is phrased in the same MaPP as V (see Figure 2).

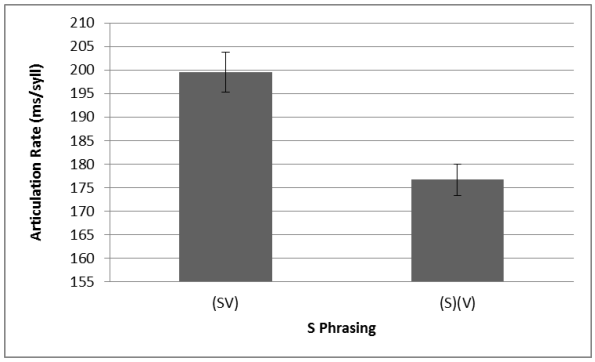

Figure 1: *Articulation rate (in ms/syll) by mean of S phrasing. Errors bars are standard errors from the mean.*

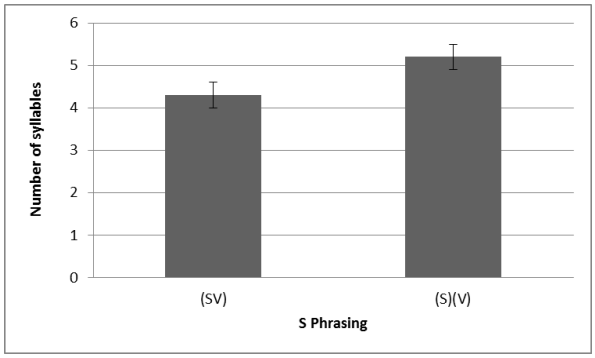

Figure 2: *Number of syllables by mean of S phrasing. Errors bars are standard errors from the mean.*

A marginal effect of the number of syllables in V was also observed ($\beta = 0.582$, $z = 2.896$, $p = 0.079$), revealing that the more syllables V contains, the greater the chances for S to be phrased in a single MaP. Nevertheless, it appeared that the number of syllables in S and the number of syllables in V interact ($\beta = 0.109$, $z = 6.543$, $p < 0.01$). The effect shows that when S is long and V is short, the chances to find a Major Prosodic Phrase boundary after S are stronger than when S is short and V is long. In the latter case, there are smaller chances for S to be followed by an MaP boundary.

The same model with the number of PWs instead of the number of syllables per constituent show similar results, with an effect of articulation rate ($\beta = 0.011$, $z = 6.087$, $p < 0.05$), an effect of the number of PWs in S ($\beta = 1.335$, $z = 6.520$, $p < 0.05$).

3.2. O prosodic phrasing

A first model was run with O phrasing status as the dependent variable (possible values: within a single MaP/within the same MaP than V), and the following variables as predictors: syntactic branchingness of the element (branching/non-branching), number of syllables in S, number of syllables in V, number of syllables in O, the interaction between the number of syllables in S and the number of syllables in V, and the

interaction between the number of syllables in V and the number of syllables in O.

Only the articulation rate appeared to be a significant predictor in this model. Articulation Rate had impact on O phrasing ($\beta = 0.21$, $z = 119.745$, $p < 0.001$), and, as can be seen in Figure 3 below, in the cases where O is phrased as an independent MaP, syllabic mean duration of the SVO sentence is greater (articulation rate slower).

The same model with the number of PWs instead of the number of syllables per constituent produced similar results, again showing solely an effect of articulation rate ($\beta = 0.021$, $z = 13.554$, $p < 0.001$).

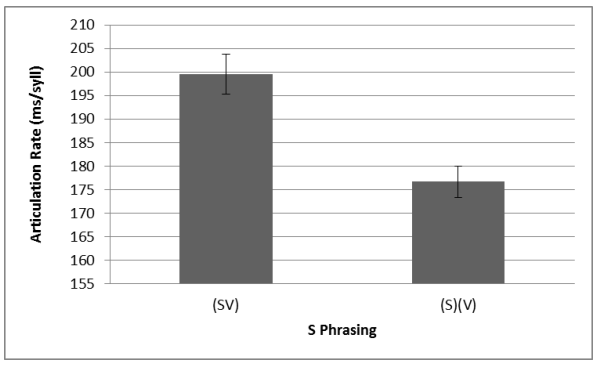

Figure 3: *articulation rate (in ms/syll) by mean of O phrasing. Errors bars are standard errors from the mean.*

4. Discussion

The analysis revealed interesting results regarding the phrasing pattern for SVO, and the effect of the different non syntactic factors constraining prosodic phrasing.

Regarding phrasing patterns, it appeared that S can be phrased with or without V with almost the same probability (in 54.1% of the data, S is phrased as an independent MaP, whereas in 45.6% of the data, it is in the same MaP than V). This is an important result, which indicates that the phrasing of S in a single MaP is not the default pattern in French, contrary to what has been claimed in the literature. In addition, this distribution of the various phrasing patterns shows that French differs from other Romance Language, such as Spanish and Catalan, where S is usually phrased in an independent MaP (see [11] and [12]). On the other hand, Object NP constituents seldom form a single MaPP: they are phrased with the V in more than 90% of the cases.

Regarding the factors constraining phrasing, our results show that syntactic complexity does not seem to be an important parameter to predict the phrasing of SVO structures. Indeed, the effect of syntactic branchingness of either O or S was never significant in our data: it does not help to explain why in some cases S or O are phrased separately or in the same MaP than the V. Articulation rate has a significant effect on phrasing of S and of O, supporting what has been found in the literature regarding the effects of articulation rate on phrasing (see [22] and [23]), i.e.: the faster a speaker articulates, the greater the chances for him to obliterate prosodic boundaries, and therefore to phrase the subject in the same MaP than the V. The number of syllables does not have any effect on the way the object NP is phrased: short or long Os are phrased in the same MaP or in an independent MaP because of different reasons. However, it clearly has an effect on the way the NP subject is phrased, supporting the idea the heavy NP subjects tend to be phrased in independent prosodic phrases, and light NPs to be embedded in one MaP along with the verb that follows (see [8]). It appeared that the number of syllables in V interacted with the number of syllables in S, confirming the idea that balance effects also have an importance on phrasing (see [8]). When calculated in term of prosodic branchingness, i.e. in terms of number of PWs, the lengths of V and O have not been observed to have any effect on phrasing.

It is necessary to conduct further analyses on a larger set of data in order to determine which parameters are the most robust for evaluating prosodic weight in French (number of syllables or number of prosodic words), in particular when analyzing phrasing patterns in SVO structure. According to [11], the choice of on parameter over the other is language-specific.

5. Conclusions

The aim of this paper was to test the impact of different phonological and syntactic factors on prosodic phrasing of French SVO structures. A set of approximately 200 sentences were extracted from 4 corpora of different speaking styles, and were semi-automatically annotated to study prosodic phrasing at the level of the Major Prosodic Phrase. The results have shown that NP subjects could be phrased within the same MaP than the verb, or in an independent MaP. The decision for one phrasing over the other is mainly correlated with articulation rate (the faster the speaker articulates, the greater the chances for the subject NPs to be phrased in an independent MaP) and on prosodic weight, be it calculated in terms of number of syllables or in terms of number of PWs in S (the longer the S, the greater the chances for S to be phrased as an independent MaP). Regarding the phrasing of O, results indicate that this constituent was rarely phrased autonomously. Furthermore, whenever it was realized as an independent MaP, the phrasing obtained was motivated by a slow articulation rate, and not by metrical properties (expressed in terms of number of syllables or in terms of number of PWs). Finally, for both S and O, no effect of syntactic branching was found. Further developments are needed to confirm these results, in particular in enlarging the set of analyzed data.

6. Acknowledgements

This paper is related to the work package “Prosodic phrasing and prosodic hierarchy: a data driven approach” of the Labex Empirical Foundations of Linguistics and is supported by the French Investissements d’Avenir - Labex EFL program (ANR-10-LABX-0083). It is also partly achieved within the research project ANR-CONTINT 2011 PHOREVOX funded by ANR/CGI.

Abstract

Intonation can convey information about how lists are structured into groups, as well as about specific item positions within a group. In Bari Italian, this function is expressed by three different tunes a) a rising contour, signalling that the list has not yet been completed; b) a high-rising contour, marking the penultimate item, i.e. signalling that the end of the list is approaching; c) a falling contour, marking the last item, i.e. cueing the end of the sequence. In this paper we explore the effects of such intonational information on working memory. In particular, we demonstrate that when listeners are requested to recall spoken nine-digit sequences by strictly following their serial order, their performance is significantly better when lists are characterised by tunes of the type described above, compared to sequences whose items are marked by a neutral, peak accent and/or are grouped by inserting a silent pause. We also observed that recall of items marked by specific contours at positions 3, 6 and 9 is particularly enhanced at these positions, whereas in sequences also containing intonational cues to items in penultimate position (2, 5 and 8) recall of those items is not equally improved. Therefore, it appears that in serial recall of spoken sequences, even when a large number of specific intonational cues to serial positions are available, listeners can use only a selection of them.

Index Terms: list intonation, serial recall, working memory

1. Introduction

In prosody research, the role of intonation in signalling discourse structure is widely acknowledged, as it cues hierarchical relationships among phrases within discourse units [1]. Specifically in lists, intonation can convey information about how they are structured into groups of items, as well as about specific item positions within a group. In this paper we explore the effects of the use of such intonational information on working memory, in particular in a serial recall task. This task consists in recalling lists of digits by following their strict serial order of presentation, and it is typically used as a test in psychology for assessing individual's short-term memory span [2]. In this research field, there is quite a large body of literature attesting the relationship between verbal serial recall and prosody, mainly consisting in the observation that lists of spoken items are better recalled when they are presented in groups (so called "grouping effect", see [3], [4], [5] among others). As to the specific role of intonation in enhancing serial recall, [6] and [7] provided evidence that it is limited to the grouping effect, i.e. it is equivalent to that triggered by pause insertion. However, in these studies results might be affected by the scarce control over the most suitable "position-informative" intonation patterns available for use in creating sequence stimuli. We hypothesise that if sequences to be recalled are produced by suitable intonation contours cueing specific positional information of items, listeners can fruitfully make use of them in terms of serial recall enhancement. In previous production and perception studies on Bari Italian, it has been shown that a rich inventory of tunes is available to speakers for signalling hierarchical relationships within discourse units at various levels ([8], [9], [10], see comparable strategies in Dutch [11] [12]), as well as specifically for cueing positional information in sequences. The most typical contours are:

- a rising contour, signalling that the list has not yet been completed ("non-final" contour, L* L-H%);
- a high-rising contour, marking the penultimate item, i.e. signalling that the end of the list is approaching ("pre-final" contour, H* H-H%);
- a falling contour, marking the last item, i.e. cueing the end of the sequence ("final" contour, H+L* L-L%).

The aim of this study is to explore the effect of positional information cued by those tunes in a serial recall task involving Bari Italian listeners.

2. Methodology

We identified two intonational patterns (we called 'Intonation contour A' and 'Intonation contour B') characterised by F0 shapes conveying hierarchical organisation of groups within a sequence, as well as positional information of items across and within groups. In a nine-digit sequence, we determined:

- 'Intonation Contour A', consisting of the "non-final" rising contour at positions 3 and 6, and a low-falling ("final") contour at position 9. Items at initial- and within-group positions (positions 1, 2, 4, 5, 7, 8) all have a peak accent, taken to be the neutral unmarked pattern. A scheme of intonation contour A is shown in Figure 1;
- 'Intonation Contour B', sharing the same intonational patterns of 'Intonation Contour A', except for a) a steep rising pitch accent (followed by a mid-fall) at positions 2 and 5, which pre-signals the end of the first and the second groups, i.e. penultimate position in the two non-final groups within the sequence; and b) a high-rising ("pre-final") contour at position 8 pre-signalling both the end of the third group *and* the end of the whole sequence. Intonation Contour B is schematised in Figure 2.

These two experimental conditions were compared with two further ones, namely:

- 'Grouped by Pause' sequences, where all digits have a peak contour, and sequences are grouped by inserting a pause at the end of each three-digit (sub)sequence, as schematised in Figure 3;
- 'Ungrouped' (Control) sequences, sharing the same intonation of the 'Grouped by Pause', but without pause grouping, as schematised in Figure 4.

We hypothesise that serial recall performance would be:
1) better in both Intonation Contours A and B and the 'Grouped by Pause' conditions than in the 'Ungrouped' (Control) condition (due to the grouping effect);
2) better in both 'Contour A' and 'Contour B' than in the 'Grouped by Pause' condition, because of the absence of intonational marking of item position in the latter condition. In

particular, at least items in positions 3 (last item in the first serial group), 6 (last item in the second serial group), and 9 (last item in the third serial group *and* in the whole sequence) should benefit in terms of recall enhancement;
3) better in 'Intonation Contour B' than 'Intonation Contour A' because of the enhanced hierarchical and positional information conveyed by intonation in certain positions in Contour B, namely: digits at positions 2 ("pre-final" contour= item at mid position in the first group), 5 ("pre-final" contour=item at mid position in the medial group), and 8 ("pre-final" contour=item at mid position in the last group *and* penultimate item in the whole sequence).

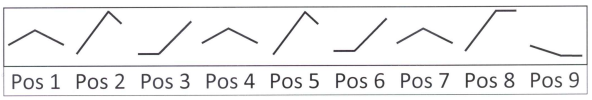

Figure 2: *Schematisation of sequence stimuli as realised according to the 'Intonation Contour B' condition.*

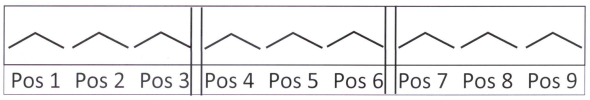

Figure 3: *Schematisation of sequence stimuli as realised according to the 'Grouped by Pause' condition, that is a neutral, peak contour on each item, and item-grouping realised by pause insertion.*

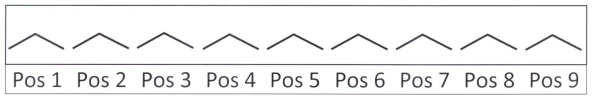

Figure 4: *Schematisation of sequence stimuli as realised according to the 'Ungrouped' (control) condition, that is a neutral, peak contour on each item, and no item-grouping.*

2.1. Stimuli

In order to produce sequences according to the conditions above, three types of stimuli for each digit (1-9) were created:

- type (a), where each digit in the sequence was realised with the unmarked, neutral F0 peak, as described above;
- type (b), where digit sequences were realised with Intonation contour A;
- type (c), where digit sequences were produced with Intonation contour B.

All series for each of the digits were produced by a trained native speaker of Bari Italian (author MS) in the same recording session. Therefore, nine sequences with the same digit (one for each digit) were produced with Intonation Contour A, nine with Intonation Contour B, and nine by realising each item with a neutral, "citation-form" intonation. In this way, all intonational realisations in each position (first, second, third, fourth, etc.) within each contour type were available for each digit. They were saved as individual audio files, and used as "building blocks" for creating all the nine-digit spoken sequences under the four conditions. Stimuli were created by concatenating the individual audio files into nine-digit sequences. In a post-editing step, care was taken that speech signal amplitude was homogeneous in all sequences. Spoken digit realisations of type (a) were used for creating sequences for the conditions 'Ungrouped', and 'Grouped by Pause', in the latter case by inserting a 310 ms silence after digits in positions 3 and 6. Spoken digit renditions of types (b) and (c) were used for creating sequences for 'Intonation contour A' and 'Intonation contour B', respectively. An example sequence for each of the experimental conditions is shown in Figures 5-8. For example, the stimulus for the 'Contour A' condition shown in Figure 7 (sequence: four-seven-three six-one-eight two-five-nine) was realised by concatenating the spoken digit "four" as realised in the first position of the whole 'digit four' sequence with Contour A, with the spoken digit "seven" as realised in the second position of the whole 'digit seven' sequence with contour A, and so on.

We created 68 nine-digit lists from pseudo-random permutation of the 1-9 digits, avoiding two adjacent digits in ascending or descending order, and making sure that a digit did not appear in the same position in consecutive lists. The concatenated nine-digit sequences were created on the basis of these lists, the duration of each sequence averaging 6.4 sec. We produced 17 stimuli for each of the four conditions, for a total amount of 68 stimuli (including 8 to be used for the training session, 2 per condition). All steps for the preparation of stimuli were carried out using Praat software tool for speech analysis [13].

2.2. Subjects

Twenty-nine informants (23 females and 6 males) took part in the experimental sessions. They were aged 20-45 (average =22.4), and reported no speech or hearing deficits. They were students of Psychology at the University of Bari, all born and living in the Bari dialectal area. None of them had a background in linguistics or prosody. They were given one exam credit as a reward for participating in the experiment.

Before starting the task, subjects were tested as to their short-term memory span by means of the standard Digit Span (DS) test of WAIS-R [14], which resulted homogeneous across groups (minimum DS=5).

2.3. Procedure

Participants were tested individually in a quiet laboratory, sitting in front of a computer and wearing a headset with headphones and microphone. They were instructed to listen to each sequence and recall all the nine digits orally by strictly following their order of presentation. Spoken responses were directly recorded to disk. Each list was preceded by a warning tone and 500 ms silence, and after each spoken response subjects could proceed with the next sequence by pressing the spacebar. They were allowed to pause whenever they wanted during the session, and they were encouraged to take a break after every block of 15 stimuli. Participants were asked to recall a total of 60 sequences (15 for each condition), preceded by a short (8 stimuli) training session. The order of presentation was balanced across the subjects. The whole session (i.e. including the DS test) lasted approximatly 40 min for each

informant. The experiment was implemented and run using SuperLab 2.0.

3. Results and Discussion

A mixed factors general linear model was carried out, with: 1) Condition (4 levels: Ungrouped, Grouped by Pause, Intonation Contour A, Intonation Contour B), 2) Serial Group Within the Sequence (3 levels: first, second, third), 3) Within-Group Position (3 levels: first, second, third), as factors.

Results (Figures 9-12) show a very large effect of Condition: $F(3; 84) = 26.42$; $p<0.001$, in that sequences in the 'Ungrouped' (Control) condition are recalled significantly worse than those in the three remaining conditions. This confirms the general findings on serial memory of verbal sequences that they are recalled better when they are grouped prosodically ("grouping effect"). Most interestingly, lists produced with both Contours A and B show statistically better recall performance with respect to those produced by inserting silent pauses between serial groups (Fisher LSD post hoc test, $p<0.05$). This confirms our prediction that intonation plays a specific role in serial recall enhancement beyond the grouping effect. On the other hand, our hypothesis that Contour B sequences would perform better than Contour A sequences is not confirmed. We also found a significant second order interaction effect between Condition, Serial Group and Within-Group Position: $F(12; 336) = 3.06$; $p<0.001$; again, Contour A and Contour B conditions showed better recall performance than sequences Grouped by Pause, but without any difference between Contour A and Contour B sequences. We then looked at recall performance of specific intonationally-marked positions in the sequences, namely positions 3, 6 ("non-final" contour in both Contour A and Contour B conditions), positions 2, 5, 8 ("pre-final" contour in Contour B condition), and position 9 ("final" contour in both Contour A and Contour B conditions). We performed Planned Comparisons between these positions in the relevant conditions, namely:

- position 3 in Contours A/B vs. Grouped by Pause conditions: recall performance was significantly better in both Contour A and Contour B ($p<0.01$);
- position 6 in Contours A/B vs Grouped by Pause conditions: recall performance was significantly better in Contour B ($p<0.05$), but not in Contour A (only approaching statistical significance, $p=0.06$);

- position 9 in Contours A/B vs Grouped by Pause conditions: again, recall performance was significantly better in both Contours A and B ($p<0.01$);
- positions 2, 5, 8 in Contour A vs Contour B conditions: recall performance did not show any statistical difference.

These outcomes indicate that serial recall of items marked by "non-final" contours (i.e. those marking positions corresponding to the end of a serial group) and "final" (marking the end of a sequence) is particularly enhanced. Interestingly, the effect of positional information cued by a "final" F0 contour (position 9) is so strong that it significantly increases the recency effect. On the other hand, listeners did not make use of "pre-final" intonational information during the recalling phase, which is the reason why overall recall performance of Contour B sequences was not significantly better than those with Contour A, contrary to our hypothesis.

Therefore, it appears that there is a limit to the number of intonational cues to positions which listeners can use, and that those marking the end of a serial group (at positions 3 and 6) or the end of the sequence (at position 9) are the most likely to be used.

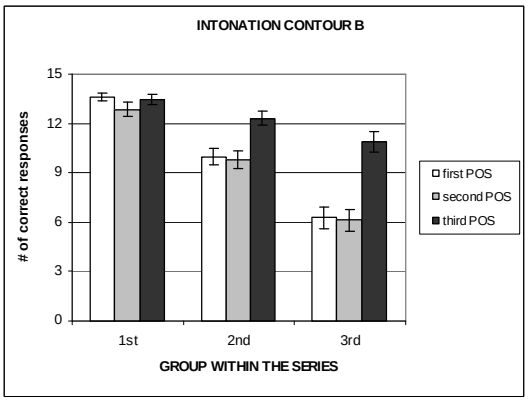

Figure 12*: Correct recall (mean values) across the 3 serial groups within a sequence, and the position within each serial group (first POS, second POS, third POS), for the 'Intonation Contour B'condition.*

4. Conclusions

In this paper, we explored the effects of positional information conveyed by intonation on serial memory. In a serial recall task, we observed that when listeners are presented nine-digit lists with F0 contours marking the hierarchical organisation of items within the sequence, their recall performance is significantly better than in cases where such intonational information is absent. However, it appears that intonational enhancement of serial recall has its limits, since we also observed that even when a large number of specific intonational cues to serial position are available, listeners are only able to make use of a selection of them. Such limitations might be due to cognitive processing needs imposed by working memory.

5. Acknowledgements

We would like to thank Ralf Rummer for helpful discussion and advice, and our student assistants in Bari Mirco Lacalandra and Gabriella Monticelli for help collecting the experimental data.

Prosodic focus-marking in Chinese four- and eight-year-olds

Anqi Yang [1], *Aoju Chen*[1, 2]

Abstract

This study investigates how Mandarin Chinese speaking children use prosody to distinguish focus from non-focus, and focus types differing in size of constituent and contrastivity. SVO sentences were elicited from four- and eight-year-olds in a game setting. Sentence-medial verbs were acoustically analysed for both duration and pitch range in different focus conditions. The children started to use duration to differentiate focus from non-focus at the age of four. But their use of pitch range varied with age and depended on non-focus conditions (pre- vs. post-focus) and the lexical tones of the verbs. Further, the children in both age groups used pitch range but not duration to differentiate narrow focus from broad focus, and they did not differentiate contrastive narrow focus from non-contrastive narrow focus using duration or pitch range. The results indicated that Chinese children acquire the prosodic means (duration and pitch range) of marking focus in stages, and their acquisition of these two means appear to be early, compared to children speaking an intonation language, for example, Dutch.

Index Terms: focus, tone, Mandarin Chinese; L1 acquisition

1. Introduction

The term 'focus' refers to an information structural category and is defined as the new information in a sentence to the receiver [e.g. 1, 2]. This study involves three types of focus, i.e. narrow focus, contrastive focus and broad focus. The former two differ from the latter in the size of the focus constituent, e.g. a lexical word (narrow focus, contrastive focus) vs. a whole sentence (broad focus). Narrow focus and contrastive focus differ in that the latter conveys an explicit contrast to alternatives in the context.

Prosodic focus-marking in adult Mandarin Chinese (hereafter Mandarin) has been extensively studied. It is generally agreed that a focused constituent has a longer duration, a higher pitch level and/or a wider pitch range than the same constituent in the broad focus condition [e.g. 3, 4, 5] Furthermore, the post-focus part of the sentence is usually compressed in pitch (i.e. spoken with a lower pitch level or a smaller pitch range) and duration, while the pre-focus part undergoes little change in pitch or duration [e.g. 4, 6, 7, 8]. However, the difference between narrow focus and contrastive focus is less conclusive. Some researchers have reported that contrastive focus induces a wider pitch range than narrow focus in sentence-initial position when the focused constituent has a certain tonal composition [5]. Yet [9] have found neither pitch range nor durational differences between narrow and contrastive focus.

In contrast, little is known on how Mandarin-speaking children use prosody to mark focus. Studies on other languages have revealed that children learn to use prosody to mark focus in their respective languages in stages [10]. For example, English-speaking children can use accentuation to highlight contrastive focus by the age of three, and from three to six this use of accentuation is further consolidated [11, 12]. Dutch-speaking children can use accentuation to mark focus at the age of four or five but become adult-like in choice of accent type only at the age of seven or eight [10, 13]. Further, they cannot vary the phonetic realisation of a pitch accent in terms of pitch range for focus-marking purposes until the age of seven or eight [14]. The use of duration for this purpose is still not acquired at the age of seven or eight [14].

The current study is a first study examining Mandarin-speaking children's use of pitch and duration in focus-marking. As Mandarin uses pitch not only to mark focus and express other sentence-level meanings but also to distinguishing lexical meanings, acquiring Mandarin entails that children have to learn both functions of pitch. The question that arises is whether Mandarin-speaking children follow a similar developmental trajectory to children speaking a non-tonal language in prosodic focus-marking. As a first step towards addressing this question, we have investigated (1) how Mandarin-speaking children use prosody to distinguish focus from non-focus, (2) how they distinguish focus in different constituent-sizes (narrow focus vs. broad focus), and (3) how they distinguish contrastive focus from non-contrastive focus.

2. Method

2.1 Target sentences

We aimed to elicit 160 SVO sentences from participants: (5 focus conditions x 4 tones in the verbs x 4 tones in the object-nouns x 2 types of verbs and object nouns). The five focus conditions were: (1) Narrow focus on the subject in sentence-initial position (NF-i); (2) Narrow focus on the verb in sentence-medial position (NF-m); (3) Narrow focus on the object in sentence-final position (NF-f); (4) Contrastive focus on the verb in sentence-medial position (CF-m); (5) Broad focus over a whole sentence (BF). Four lexical tones were used in the verbs and object-nouns. Two types of verbs and corresponding object nouns were included (Table 1). Four subject nouns (cat, bear, dog, and rabbit) were evenly distributed over the sentences. Crucially, all words were selected from the words that are acquired by Mandarin-speaking children by the age of three or four [15]. The 160 sentences were split evenly into two lists (List 1 & 2) of 80 sentences such that each list contained all target words and all tonal combinations but not all word combinations of the verbs and objects. Half of the participants produced the sentences on List 1 and the other half produced the sentences on List 2.

Verb – type1	Verb – type 2	Noun - type1	Noun - type 2
T1 rēng (throw)	T1 jiāo (water)	T1 shū (book)	T1 huā (flower)
T2 mái (bury)	T2 wén (smell)	T2 qíu (ball)	T2 lí (pear)
T3 jiǎn (cut)	T3 tiǎn (lick)	T3 bǐ (pen)	T3 cǎo (grass)
T4 yùn (transport)	T4 mài (sell)	T4 cài (vegetable)	T4 shù (tree)

Table 1: Two types of verbs and object nouns

2.2 Speech elicitation

To elicit the target sentences, question-answer dialogues between the experimenter and the child as illustrated in examples (1) to (5) were embedded in a picture-matching game adapted from [10].

(1) Exp: Look! A book, and the book is in the air. It looks like someone throws the book. Who throws the book?

Child: [The rabbit] throws the book. (NF-i)

(2) Exp: Look! A rabbit, and there is also a book. It looks like the rabbit does something to the book. What does the rabbit do to the book?

Child: The rabbit [throws] the book. (NF-m)

(3) Exp: Look! A rabbit, and its arm is stretched out. It looks like the rabbit throws something. What does the rabbit throw?

Child: The rabbit throws [the book]. (NF-f)

(4) Exp: Look! A rabbit, and a book. It looks like the rabbit will do something to the book. I will make a guess: The rabbit cuts the book.

Child: The rabbit [throws] the book. (CF-m)

(5) Exp: Look! This picture is very blurring. I cannot see anything clearly. What happens in the picture?

Child: [The rabbit throws the book]. (BF)

In the game, the child's task was to help the experimenter to put pictures in matched pairs. Three piles of pictures were used. The experimenter and the child each held a pile of pictures; the third pile laid around on the table in a seemingly 'messy' fashion. The experimenter's pictures always missed some information, e.g. the subject, the action, the object or all the three pieces of information. The child's pictures always contained all the three pieces of information. In every trial, the experimenter showed a picture of hers to the child, described the picture and asked a question about it, as illustrated in (1) to (5). The child took a look at the corresponding picture in his pile and answered the question or made a correction (in the CF condition). The experimenter could then look for the right picture in the messy pile and matched it with her own picture to form a pair. Crucially, as rules of the game, the child was asked to answer the experimenter's question in full sentences and not to reveal his pictures to the experimenter.

In order to familarise the child with the game procedure, the experimenter started the game with five practice trials involving all five focus conditions. Prior to the practice session, the experimenter conducted a picture-naming task to make sure that the children would use the intended words to refer to the entities in the pictures.

2.3 Participants

Thirty-six children from three age groups (four-five yrs, even-eight yrs, ten-eleven yrs, twelve per group) participated in the experiment. They were tested individually in a quiet room in their kindergartens or schools in Beijing. In addition, fifteen university students speaking Mandarin were tested as controls, following the same procedure. Considering children's limited concentration capacity, the 80 sentences on each list were elicited in two sessions of 20 – 35 minutes on two different days. The adults and children were both audio and video-recorded during the experiments. The current paper presents results from four four-year-olds and four eight-year-olds.

2.4 Annotation and acoustic analysis

The audio recording from each child was orthographically annotated at three levels using Praat: trial, question from the experimenter, and response from the child. Usable sentences were then carefully selected from the recordings. Responses deviating from the target sentences in choice of word or word order or produced with self-repairs and hesitations were considered unusable and excluded from further analysis. In total, 432 sentences from the eight children were included in the analysis.

The usable sentences were then acoustically annotated at the word level and at the pitch level. Landmarks indicating word-onsets and word-offsets and the locations of the maximum pitch and minimum pitch within each word were inserted in Praat textgrids for each sentence. It is worth noting that Mandarin is a tone language, and each tone has a particular target to reach. According to [16], the pitch contour approximates to or reaches at the target towards the end of a syllable. In this study the tonal targets were taken into account. For Tone 2 (rising tone) and Tone 4 (falling tone), it was presumed that their pitch contour approach to or reach at the high/low target respectively at the syllable offset. To be more specific, the maximum pitch of Tone 2 was always labeled and measured on the right side of its minimum pitch, even though sometimes there was an even higher pitch occurring on the left side due to the influence of the preceding tone. Similarly, the minimum pitch of Tone 4 was obtained on the right side of its maximum pitch. For Tone 1 (flat tone), its maximum and minimum pitch were obtained regardless of their relative order of occurrence. The pitch contour of Tone 3 varied most, and three patterns were observed in the data, namely, fall-rise, rise and fall. When Tone 3 was realised as a fall-rise, it was assumed to have two targets to approach, first the low target and then the high target. In this case, the maximum pitch was obtained on the right side of the minimum pitch. When Tone 3 was realised as a fall, it was assumed to have a low target to approach, and its minimum pitch was obtained at the syllable offset. When Tone 3 was realised as a rise, it was assumed to have a high target to approach, and its maximum pitch was obtained at the syllable offset.

In this paper, we concentrated on the sentence-medial verbs. The verbs were on-focus in the NF-m condition, pre-focus in the NF-f condition and post-focus in the NF-i condition and were thus ideal for direct comparisons between focus and pre-/post-focus. The duration and pitch range (the difference between the maximum pitch and the minimum pitch) of the verbs were calculated and analysed as dependent variables.

To address the first research question, namely, how focus differs from non-focus in child Mandarin, we compared the prosody of the verbs in the NF-m condition (focused) with that in the NF-i (post-focus) and NF-f (pre-focus) conditions. To address the question about size of focused constituent, we compared the prosody of the verbs in the NF-m and CF-m combined narrow focus condition with that of the BF condition. To address the question on contrastivity, we compared the prosody of the verbs in the NF-m (non-contrastive narrow focus) condition with that in the CF-m (contrastive narrow focus) condition.

3. Statistical analysis and results

Mixed-effect modeling was used to assess the effect of fixed factors and the effect of interactions between the fixed factors and the other fixed factors on the dependent variables, i.e.

duration and pitch range of the verbs. There are two kinds of fixed factors: those related to focus directly and the others. The focus-related fixed factors were FOCUS (focus vs. non-focus), SIZE (narrow focus vs. broad focus), and CONTRASTIVITY (contrastive focus vs. non-contrastive focus). The other fixed factors were AGE (four-year-olds and eight-year-olds), TONE OF VERB (four tones for verbs), and TYPE OF VERB (type1 and type2). The random factor was SPEAKER. In the analyses on the effect of the fixed factors, two models were built for each fixed factor, one with only the random factor, and one with both the random factor and the fixed factor. The two models were then compared to each other. A statistically significant difference between these two models indicated a main effect of the focus-related factor. We then looked at the interaction between the focus-related fixed factor and the other fixed factors.

3.1 Focus vs. non-focus

3.1.1 Duration

Regarding the comparison between focus (verbs in NF-m) vs. post-focus (verbs in NF-i), the mixed-effect modelling showed that the main effect of FOCUS was significant ($p < 0.05$). As can be seen in Figure 1, the focused verbs in the NF-m condition were longer than the same verbs in the NF-i (post-focus) condition. There was also significant main effects of TONE OF VERB ($p < 0.05$) and TYEP OF VERB ($p = 0.01$), but no significant main effect of AGE ($p = 0.4$). No significant interaction was found between FOCUS and AGE ($p = 0.80$) or between FOCUS and TONE OF VERB ($p = 0.33$), but was found between FOCUS and TYPE OF VERB ($p < 0.05$). We then used subsets of data to look at the effect of FOCUS within the type 1 verbs and the type 2 verbs separately, and found that the main effect of focus was significant for both the type 1 verbs ($p < 0.05$) and the type 2 verbs ($p < 0.05$). This suggested that the interaction was caused by a gradient difference between type 1 verbs and type 2 verbs. The durational difference between focus and post-focus was larger in the type 2 verbs (0.08s) than in the type 1 verbs (0.04s).

Regarding the comparison between focus and pre-focus (verbs in NF-f), the mixed-effect modelling showed that the main effect of FOCUS was significant ($p < 0.05$). There was also significant main effects of TONE OF VERB ($p = 0.01$) and TYPE OF VERB ($p < 0.05$), but no significant main effect of AGE ($p = 0.44$). No significant interaction was found between FOCUS and AGE ($p = 0.82$), between FOCUS and TONE OF VERB ($p = 0.08$), or between FOCUS and TYPE OF VERB ($p = 0.14$).

The above results indicated that the children realized the focused verbs with a longer duration than the post-focal and pre-focal verbs, regardless the tones or the types of the verbs.

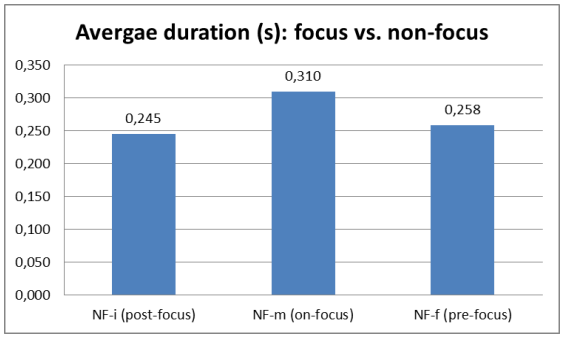

Figure 1: Verb duration in NF-i, NF-m, and NF-f

3.1.2 Pitch range

Regarding the comparison between focus and post-focus, the mixed-effect modelling showed that the main effect of FOCUS was significant ($p < 0.05$). The focused verbs in the NF-m condition had a wider pitch range (84Hz) than the same verbs in the NF-i (post-focus) condition (59Hz). The main effects of TONE OF VERB ($p < 0.05$) was also significant, but the main effect of AGE ($p = 0.53$) and TYPE OF VERB ($p = 0.1$) was not significant. A significant interaction was found between FOCUS and AGE ($p < 0.05$), and between FOCUS and TONE OF VERB ($p < 0.05$), but not between FOCUS and TYPE OF VERB ($p = 0.75$). We looked at the effect of FOCUS within each age, and found that the main effect of FOCUS was significant for the eight-year-olds ($p < 0.05$), but was not significant for the four-year-olds ($p = 0.72$) (Figure 2), so the eight-year-olds used pitch range to differentiate focus from post-focus, but the four-year-olds didn't. We then looked at the effect of FOCUS within each tone, and found that the main effect of FOCUS was significant for Tone 2 ($p < 0.05$) and Tone 4 ($p < 0.05$), but was not significant for Tone 1 ($p = 0.6$) or Tone 3 ($p = 0.28$).

Comparing focus with pre-focus, the mixed-effect modelling showed that the main effect of FOCUS was significant ($p < 0.05$). The focused verbs in the NF-m condition had a wider pitch range (84Hz) than the same verbs in the NF-f (pre-focus) condition (57Hz). The main effect of TONE OF VERB ($p < 0.05$) was also significant, but the main effects of AGE ($p = 0.17$) and TYPE OF VERB ($p = 0.43$) were not significant. A significant interaction was found between FOCUS and TONE OF VERB ($p < 0.05$), but not between FOCUS and AGE ($p = 0.22$) or between FOCUS and TYPE OF VERB ($p = 0.43$). We looked at the effect of FOCUS within each tone using subsets of data. It was found that the main effect of FOCUS was significant for Tone 2 ($p < 0.05$) and Tone 4 ($p < 0.05$), but was not significant for Tone 1 ($p = 0.5$) or Tone 3 ($p = 0.35$).

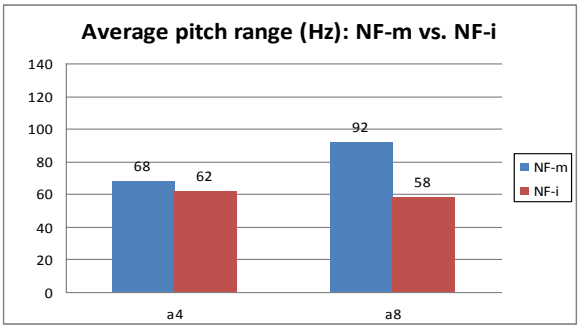

Figure 2: Pitch range in NF-m and NF-i for each age

The above results indicated that both the four- and eight-year-olds could use pitch range to differentiate focus from pre-focus, but only the eight-year-olds could use pitch range to differentiate focus from post-focus. In addition, without looking into each age group, we found that the children as a whole group used a wider pitch range to differentiate focus from post-focus and from pre-focus when the verbs were in Tone 2 and Tone 4, but not in Tone 1 and Tone 3. The four-year-olds' not using pitch range to distinguish focus from post-focus might be caused by their failure to use pitch range in tone 1- and tone-3-verbs.

3.2 Narrow focus vs. broad focus

To examine the realisation of narrow focus compared to that of broad focus, we grouped NF-m and CF-m together as a

combined narrow focus condition (hereafter, the "NF-m&CF-m" condition) with a small focal size, and compared it with the BF condition with a larger focal size. Mixed-effect modeling was adopted and the focus-related fixed factor was SIZE.

3.2.1 Duration

Comparing narrow focus with broad focus, the mixed-effect modelling showed that the main effect of SIZE was not significant ($p = 0.22$). In other words, children did not use duration to differentiate narrow focus from broad focus.

3.2.2 Pitch range

Regarding the comparison between narrow focus and broad focus, the mixed effect modelling showed that the main effect of SIZE was significant ($p < 0.05$). Figure 3 showed that the pitch range of the verbs in the NF-m&CF-m condition was larger than that in the BF condition. The main effect of TONE OF VERB ($p < 0.05$) was also significant, but the main effects of AGE ($p = 0.05$) and TYPE OF VERB ($p = 0.21$) were not significant. No significant interaction was found between FOCUS and AGE ($p = 0.35$), between FOCUS and TONE OF VERB ($p = 0.15$), or between FOCUS and TYPE OF VERB ($p = 0.05$). The results revealed that the four- and eight-year-olds used pitch range to differentiate narrow focus from broad focus, regardless of tones and types of verbs.

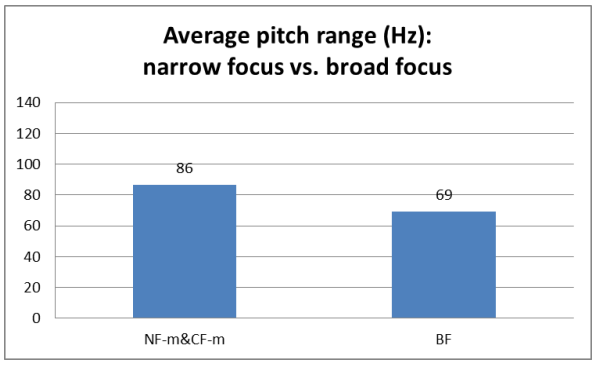

Figure 3: Pitch range of the verbs in NF-m&CF-m and BF

To sum up, children used pitch range but not duration to distinguish narrow focus from broad focus.

3.3 Contrastive focus vs. non-contrastive focus

Regarding the comparison between contrastive and non-contrastive focus, the mixed-effect modeling showed that the main effects of CONTRASTIVITY were not significant for duration ($p = 0.69$) or for pitch range ($p = 0.37$), indicating that the children did not use duration or pitch range to distinguish contrastive focus (CF-m) from non-contrastive (NF-m) focus.

4. Discussion and Conclusions

This study aimed at finding out how Mandarin-speaking children use pitch range and duration to mark focus in comparison with non-focus, how they encode focus with different constituent size, and how they differentiate contrastive focus from non-contrastive focus. With regard to focus, the children from both age groups produced the focused words with a longer duration than the non-focused ones. Further, both the four- and eight-year-olds used a wider pitch range for the focused verbs than for the pre-focal ones, but only the eight-year-olds used a wider pitch range for the focused verbs than for the post-focal ones. In addition, the children as a whole group used pitch range to differentiate focus from post-focus and pre-focus for the Tone 2 and Tone 4 verbs, but not for the Tone 1 and Tone 3 verbs. With regard to the size of the focal constituent, the children used pitch range but not duration to differentiate narrow focus from broad focus. With regard to contrastivity, children did not differentiate contrastive narrow focus from non-contrastive narrow focus using duration or pitch, similar to the findings on adult Mandarin [9].

The results had four implications. First, in previous studies on prosodic focus marking, the non-focus condition varies from study to study. Our results show that the defintion of the non-focus condition can influence the results on the use of prosody in distinguishing focus from non-focus in children. Second, to differentiate focus from non-focus, the children used duration regardless of lexical tone but used pitch range only in Tone 2- and Tone 4-verbs, while to differentiate narrow focus from broad focus they used only pitch range. As such selective uses of duration and pitch range have not been observed in adult Mandarin, these results may suggest that the children have not consolidated the use of pitch or duration. Third, as has been mentioned, to become adult like, Mandarin-speaking children have to acquire both the lexical and post-lexical functions of pitch. Previous studies on the acquisition of Mandarin tones showed that the production of Tone 4 is most adult-like in the production of Chinese 3-year-olds, followed by Tone 1, Tone 2, and Tone 3 [17]. However, in terms of focus-marking, we found that the children used pitch range to mark focus only when the verbs were in Tone 2 and Tone 4 but not in Tone 1 or Tone 3. These indicated that the acquisition of pitch range in focus marking may not be related to the order of tonal acquisition. However, To explicate children's use of pitch, not only pitch range but also the maximum and minimum pitch should be analyzed. Last, corss-linguistically, comparing to Dutch-speaking children, who have not acquired the use of duration in focus-marking at the age of seven or eight [14], the Chinese children acquired the use of duration for focus-marking quite early. Besides, the use of pitch range was in place in the Chinese four-year-olds, though not necessarily in all conditions. This suggested an earlier acquisition of pitch range as well in the Chinese children.

5. Acknowledgements

This study is supported by a VIDI grant (276-89-001) from the NWO (Netherlands Organisation for Scientific Research) to the second author. We would like to express our special gratitude to Min Zhu, Jun Bian, Yian Liang, and Shushuang Yu from Beijing 21st Century International Kindergarten and School, the children and their parents for their full cooperation. We would also like to thank Hua Shu from Beijing Normal University for her support, and Mei Ou, Mengting Huang, Yun Li, and Xingzhi Yao from Beijing Forestry University for administering the tests with the adults. We thank Paula Cox for drawing the pictures, Frank Bijlsma, Sjef Pieters, and Alex Manus for the technical support, and Mattis van den Bergh for statistical support. Last, we thank Xiaoli Dong, Mengru Han, René Kager, Zenghui Liu, Anna Sara Romøren and Wim Zonneveld for their input.

Prosodic effects on vowel spectra in three Australian languages

Simone Graetzer, Janet Fletcher, John Hajek

Phonetics Laboratory, School of Languages and Linguistics, University of Melbourne

{simone.graetzer, j.fletcher, j.hajek}@unimelb.edu.au

Abstract

In this paper, the spectral properties of vowels in three Australian languages are examined with the aim of determining whether prosodic prominence and domain-edge effects on formant frequencies, formant variability and vowel space dispersion can be identified. It is shown that these vowel systems are sufficiently dispersed, with an anchoring of the system by the open central vowel. It is also shown that for Burarra but not for Gupapuyngu or Warlpiri there is some evidence of prosodically-driven hyper-articulation. Finally, the data indicate pre-boundary lengthening in all three languages, which in some cases appears to be associated with changes in vowel quality.

Index Terms: vowel, vowel space, variability, acoustics, dispersion, duration, Australia

1. Introduction

The focus of this paper is on vowel spectra and the systemic variability and dispersion of vowels in disyllabic words in three Australian languages: Burarra, Gupapuyngu and Warlpiri. The paper addresses the interaction and effects of factors such as vowel quality, and prosodic prominence and position in the prosodic domain (word-final or pre-boundary, and word-medial).

1.1. Adaptive Dispersion Theory

Adaptive Dispersion Theory (DT) proposes that vowel contrasts are systemic and relational rather than local and absolute [1]. Each vowel acts as a repeller in a dynamic system. As such, it was originally claimed that adjacent vowels should be roughly equidistant in a system, *i.e.*, (perceptual) vowel contrasts should be maximal, and the acoustic distance between adjacent vowels should reduce as the system size increases. DT also predicted that languages with the same vowel system will exhibit identical F1 distances between adjacent vowels. However, the maximal contrast hypothesis was later modified by Lindblom [1] to allow for the possibility of merely sufficient dispersion, emphasizing sufficient contrast combined with economy of effort. A number of previous analyses of Australian languages, including Burarra and Warlpiri, have indeed found that these vowel spaces are sufficiently, rather than maximally, dispersed [2] [3].

1.2. Prosodic effects on vowel realisation

In commonly studied languages such as English, prosodically prominent vowels are typically less variable and more peripheral in the F2 x F1 space than prosodically weak vowels. Vowels at higher levels of prosodic prominence tend to be produced with greater acoustic expansion or peripherality or with more extreme gestures [4] - [6]. For example, in English, accented /i/ tends to be produced with a more anterior constriction than unaccented /i/ [5], while in French, the stronger the prosodic boundary associated with the vowel /a/, the higher the F1 frequency [7]. Furthermore, prosodic domain-initial (e.g., phrase-initial) positions seem to be 'generally characterised by more "forceful" articulatory gestures' [8] (p. 232). This type of behaviour has been termed prosodically driven 'hyper-articulation' [4] [9]. Typically, vowels are associated with less variability and greater dispersion when prosodically prominent, as part of an overall articulatory expansion of prominent syllables [4] [10]. Stressed vowels are also typically more resistant to coarticulation by adjacent segments than are unstressed vowels [9] [11]. Additionally, there are prosodic domain-final effects on vowels: pre-boundary or phrase-final lengthening can occur [12].

In the context of Australian languages, Burarra vowels are known to undergo some magnitude of vowel reduction in unstressed syllables [13]. In older speakers of the Central Australian language, Arrernte, the low central vowel appears to involve a higher F1 (increased openness) when stressed [14]. In other Australian languages, little evidence has been found of the predicted effect of prosodic prominence on vowels in the F2 x F1 plane, but there is some evidence of an effect of pre-boundary or phrase-final position on vowel realisation. Some vowels in some Australian languages are longer and more peripheral in phrase-final positions [3], while others are lengthened phrase-finally but do not change in quality [14] [15]. In their study of Bininj Gun-wok and Dalabon, Fletcher and Butcher [16] did not find evidence of reduced vowel peripherality in phrase-final position, perhaps due to duration-related expansion of the vowel space in this position. Similarly, Fletcher and Butcher [3] found for a female speaker of another three vowel language with a length distinction, Kayardild, that close vowels tended not to show effects of prosodic context but rather of vowel length phrase-finally (or an interaction between such prosodic effects and length). In Kunwinjku, there is an effect of prosodic prominence on variability, which is greater in unaccented vowels [17]. Finally, in Warlpiri, it appears to be the medial consonant rather than the prominent vowel that undergoes medial strengthening (and lengthening), and this consonant may carry stress [18].

1.3. Research questions and parameters

In the current paper, we set out to determine how vowels in Burarra, Gupapuyngu and Warlpiri differ in F1 and F2 in disyllabic CV1CV2 words. Secondly, we wanted to examine whether vowels differ in F1 and F2, formant variability and vowel space dispersion according to prosodic prominence and to position in the word (V1 or V2). Finally, we wanted to determine whether there is any effect of vowel position on vowel duration in the three languages. As all three vowel systems are relatively small, the issue of an effect of inventory size on variability or dispersion is not addressed here; see [19]. Of the languages considered here, Burarra is a non-Pama-Nyungan language and Gupapuyngu and Warlpiri are members of the Pama-Nyungan family, which includes most

indigenous Australian languages. Burarra and Gupapuyngu are spoken in central and north-eastern Arnhem Land, respectively, and Warlpiri is spoken to the north-west of Alice Springs. These languages have many place and few manner consonantal contrasts and small vowel inventories. Gupapuyngu and Warlpiri have three vowels with a length contrast, while Burarra has five vowels: /i/, /ɛ/, /ɐ/ (hereafter 'a'), /o/ and /u/.

2. Methods

The subjects of this study were nine adult female speakers of Burarra (speakers DP, KF, MW), Gupapuyngu (AM, BT, EG) and Warlpiri (BP, KR, RR) aged between 30 and 65. Typically, three tokens of each word type were elicited. The corpus was collected and digitised by Andrew Butcher. To avoid effects of gender, we limited our analysis to the data available for female speakers in the corpus. All acoustic measurements were carried out in the EMU Speech Database System [20]. The onsets of the vowels were marked at the onset of periodicity and the offsets at the offset of periodicity. F1 and F2 values were measured at the vowel midpoint. All relevant segmentation procedures are described in full by Graetzer [19]. The prosodic prominence of vowels was determined on the basis of published prosodic descriptions, e.g., [13] [18], an auditory impressionistic analysis and an acoustical analysis; we assumed that the vowel carrying a sharp F0 rise to a peak somewhere in or around the syllable rhyme was accentually prominent. Main stress was word-initial in these data. Words were associated with post-lexical (or phrasal) prosodic prominence; therefore, prosodic effects applying to both the utterance/phrase level and the word level were relevant. Statistical and graphical procedures were run in R version 2.14.0 [21] using the EMU-R package. F1 and F2 frequencies (Hz) were extracted from the vowel midpoint ($V1_{MID}$ and $V2_{MID}$) in CV1CV2 words, in which V1 is prominent and V2 is not. In order to compare vowel systems in the three languages, formant frequencies were submitted to the normalisation procedure used in similar studies in the context of vowels [22]: Nearey vowel-extrinsic normalisation [23]. This procedure was conducted on the raw F1 and F2 data by means of a formula and function outlined by Harrington [24]. The distribution of the vowel categories is given in Table 1 (note that no long vowels were present for Warlpiri; however, short and long Warlpiri vowel counterparts have been found to be similar in quality [25]; note also differences in Burarra distribution between V1 and V2). Linear Mixed Model (LMM) procedures were used for investigations of F1 and F2 frequencies, in which the effects of vowel quality and word-medial consonant place of articulation (not discussed here), language group and vowel position (V1/V2; random factor: speaker) were examined. The non-normalised F1 and F2 LMM results were then compared to the normalised results and any differences in significance levels were reported.

Euclidean distances (here termed 'distances') - acoustic straight line distances between vowels in the F2 x F1 plane - were calculated after, e.g., [1] [24], as a measure of the magnitude of hyper-articulation in the vowel space. This procedure is similar to that used by Recasens and Espinosa [22]. The distances were then treated as the dependent variable in an LMM, with the fixed factors of language group and vowel position (random factor: speaker). Levene-type t-tests applied to deviations of observations from the median were run per speaker and formant (F1 and F2) to test for equality of variance between V1 and V2 for Gupapuyngu and Warlpiri, which have three vowel qualities in V1 and V2 position, but not for Burarra, as it has five vowel qualities in V1 position and only three in V2. Wilcoxon signed rank tests for paired samples were calculated for V1 and V2 durations per speaker in order to determine whether there was lengthening of V1 or V2 (α=0.05). Pearson's product moment correlation tests were run for vowel duration and distances, *i.e.*, vowel space expansion, collapsing V1 and V2 categories. Raw and normalised results were not compared in the context of the Levene's and Wilcoxon tests as these were intra-speaker.

Table 1. *The distribution of vowels where BUR = Burarra, GUP = Gupapuyngu, WAR = Warlpiri.*

	V	BUR	GUP	WAR
V1	a	167	152	219
	a:	N/A	107	N/A
	ɛ	36	N/A	N/A
	i	66	48	102
	i:	N/A	50	N/A
	o	84	N/A	N/A
	u	97	110	124
	u:	N/A	87	N/A
V2	a	422	281	199
	i	23	108	110
	u	5	165	136

3. Results

3.1. Normalised and raw F1 and F2 frequencies, variability and euclidean distances

3.1.1. Normalised frequencies

In Figure 1, 95% confidence ellipses in Nearey-normalised formant data extracted at vowel midpoints are shown per language group and vowel position (V1, L; V2, R). The typically close proximity and overlap of the vowel ellipses indicates sufficient rather than maximal dispersion. For Gupapuyngu and Warlpiri, a 'canonical' realisation of a triangular vowel space is observed, with the low central vowel as 'anchor' (see, e.g., Butcher's [2] use of this term). Gupapuyngu displayed greater dispersion than Burarra and Warlpiri in both vowel positions. For Burarra, /a/ acted as anchor in V2, while /ɛ/ and /a/ were equally close to the grand centroid ('X') in V1. In the F2 x F1 space, in both V1 and V2, the difference between Gupapuyngu and Warlpiri mainly involved an upwards shift but also a retraction of /i a/ in Warlpiri relative to Gupapuyngu. In Warlpiri, /i u/ were realised with a lower F1 (increased closeness) than in the other languages. Within each vowel system, point vowels were similarly spaced relative to one another overall. However, when frequency distances between point vowels were compared for Gupapuyngu and Warlpiri, which have identical vowel systems, in F1, in V1 and V2, /a/ was closer to /i u/ in Warlpiri than in Gupapuyngu (there was a relative reduction in the F1 range for Warlpiri), while /i u/ were similarly distant. In F2 in V1, in Gupapuyngu, /a/ was further from /i/ and closer to /u/ than in Warlpiri. F2 distances in V1 were similar in the two languages, but slightly higher (more anterior) in Gupapuyngu. Burarra vowels /ɛ o/ were approximately equidistant between

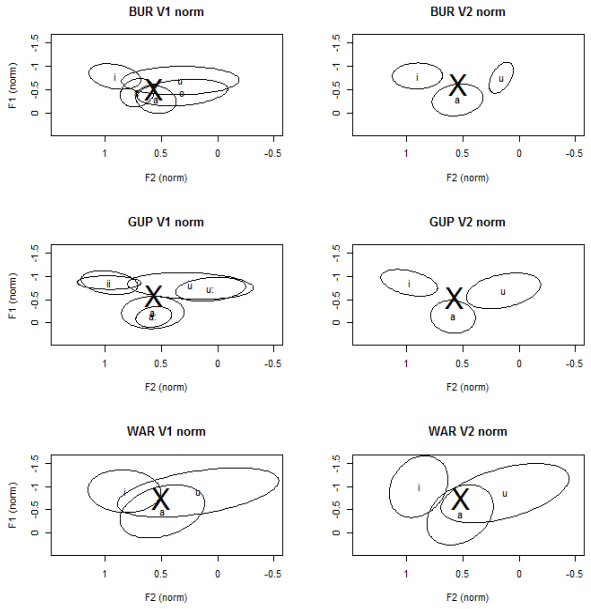

Figure 1: *Nearey-normalised F2 x F1 plots in V1 (L) and V2 (R) conditions (upper: Burarra; middle: Gupapuyngu; lower: Warlpiri); axes in Nearey units.*

the open and close vowels and were very similar in height. Burarra /o u/ were very similar in F2, while /ɛ/ was much lower in F2 (less anterior) than /i/. In V2, Burarra differed from Gupapuyngu and Warlpiri in that /i/ was associated with a similar F1 to /u/, while for the other languages /i/ was associated with a much lower F1 than /u/, *i.e.*, /i/ was a closer vowel than /u/ in these systems. It is clear that /u/ can be realised with little or no rounding given the degree of F2 variability in /u/ and its realisation relative to /i a/ in the vowel space. This is the case particularly for Burarra and Gupapuyngu in V1, in which position there were more /u(:)/ tokens in the corpus.

3.1.2. Raw frequencies - LMM

LMM procedures were used to investigate the effect of vowel position within the word, and thus also prosodic prominence, on F1 and F2 formant frequencies at vowel midpoints in CV1CV2 words. The factor of language group was also included in the model. In the F1 condition, Warlpiri was associated with lower frequencies than Burarra (BUR:WAR, Estimate=-57, SE=28, t=-2, $p<0.05$). Other comparisons were not significant. Vowels in V1 position were typically associated with slightly lower F1 values than vowels in V2 (V2:V1, Estimate=-23, SE=4, t=-5.8, $p<0.0001$). This difference was located in the Gupapuyngu and Burarra data. For Gupapuyngu this pattern appears to be due to a slightly lower F1 (more close vowel) in V1 /a u/, while in Burarra it appears to be due to a lower F1 in V1 /a/. For Burarra it cannot be excluded that this result is due to differing vowel distribution in V1 and V2. Tukey's post-hoc tests indicated that Gupapuyngu, like Warlpiri, was associated with lower F1 frequencies (more close vowels) than Burarra (z=-3.6, $p<0.001$). In a LMM analysis of F2, there was no effect of language group or vowel position. These F1 and F2 results were consistent with those for the normalised data.

3.1.3. Variability (raw frequencies)

Across all vowels, variability tended to be higher in magnitude in F2 - presumably because of coarticulatory effects exerted by surrounding consonants - than in F1, but particularly for /i u/ (Figure 1). Typically, close front vowels varied less than the other point vowels in F1. This was not the case in F2, in which /a/ varied least and /u/ tended to vary most. With the exception of Burarra (but see Table 1), for each point vowel, F1 variability tended to be higher in V2 and F2 variability tended to be slightly higher in V1. According to Levene's tests for Gupapuyngu and Warlpiri, in F1, only one speaker of each language group produced a difference in overall variance between V1 and V2 conditions: EG and KR respectively (GUP EG, $F(1,194)=7.2$, $p<0.01$; WAR KR, $F(1,342)=33.9$, $p<0.0001$). In F2, only one speaker of Warlpiri, BP, produced a difference between conditions ($F(1,232)=9$, $p<0.005$). In the three cases, V1 was associated with less variance than V2, indicating that more variability existed in the prosodically weak, word-final vowel, as would be predicted.

3.1.4. Euclidean distances (raw frequencies)

Across the language groups, as indicated by the distance of vowels from the grand centroid in Figure 1, /a/ tended to be associated with smaller distances of 200 to 300Hz, while /i/ was associated with larger distances of 520 to 775Hz, and /u/ was associated with intermediate to relatively large distances of 440 to 690Hz. In Gupapuyngu, long vowels tended to be more peripheral than short vowel counterparts. For Burarra speakers DP and MW, significantly greater dispersion occurred in V1 than V2 when all vowel qualities were included in V1 (DP, V=8844, $p<0.005$; MW, V=20133, $p<0.05$). The same pattern did not achieve significance for speaker KF (V=2928, p=0.17), perhaps because there were no V2 /u/ tokens for that Burarra speaker. When vowel qualities were reduced to /i a u/ only, to facilitate comparison between V1 and V2, similar results were obtained (DP, W=13806, $p<0.0001$; KF, W=3384, p=0.23; MW, W=13830, $p<0.05$). This pattern of greater expansion in V1 was mainly located in /i u/. When Gupapuyngu short vowels only were considered, distances overall did not differ according to vowel position (AM, V=10414, p=0.4; BT, V=13259, p=0.11; EG, V=2449, p=0.94), which indicated a lack of vowel space expansion in V1 relative to V2. With regard to the Warlpiri speakers, there was greater dispersion in V2 for at least two speakers (BP, V=2200, $p<0.005$; KR, V=5896, $p<0.05$), and this pattern was particularly evident in /i u/, but the difference did not achieve significance for the third speaker, RR (V=5646, p=0.4). In order to compare overall dispersion across languages, an LMM was run with the fixed factors of language group and vowel position with interactions. All main and interaction effects were significant at $p<0.005$ or below. Vowel positions differed strongly at $p<0.0001$ (V2:V1, Estimate=78, SE=37, t=8.3); V1 was typically associated with larger distances; however, this difference was in fact primarily located in Burarra. Gupapuyngu was associated with most dispersion and Burarra with least, while Warlpiri dispersion was intermediate (BUR:GUP, Estimate=191, SE=52, t=3.7, $p<0.0005$; BUR:WAR, Estimate=167, SE=52, t=3.2, $p<0.005$). These results were again consistent with those for the normalised data.

3.2. Vowel duration

Typically in Burarra, /a/ was longer in duration than /i/ and /u/ by >30ms. In Warlpiri, there was a trend in the same direction but in Gupapuyngu, there was little difference overall between vowels. For the majority of speakers, vowels /a i u/ tended to be longer in duration in V2 position (by 40ms in Burarra and Warlpiri and by 90ms in Gupapuyngu, on average), indicating phrase-final or pre-boundary lengthening. For Burarra speakers DP and MW, vowel duration was greater in V2 (DP, V=2310, $p<0.0001$; MW, V=1454, $p<0.0001$). For KF, V1 and V2 did not vary (V=2161, $p=0.44$), but recall that there were no KF /u/ tokens in V2. For all Gupapuyngu and Warlpiri speakers, durations were consistently greater in V2 at $p<0.0001$. The Gupapuyngu short/long vowel distinction in V1 tended to show a 1:1.5 – 1:1.7 ratio, in which the long vowel was 1.5 to 1.7 times the length of its short counterpart. Correlations of vowel duration and distances per speaker (collapsing vowel positions) were performed to test whether expansion related meaningfully to phrase-final lengthening. Correlations were in most cases low or very low at $r < 0.25$. However, four of the nine /i/ tests resulted in low to moderate correlations of >0.4, and two of the nine /u/ tests resulted in low correlations of 0.3. That is, under certain conditions for some speakers, there was a weak positive correlation between vowel space expansion and vowel duration; such correlations were more likely to occur for /i/ than /a u/.

Table 2. *Summary of vowel position results*

Procedure	V1		V2	Comment
LMM F1	V1	<	V2	GUP & BUR
LMM F2	V1	=	V2	No effects
Variability F1	V1	=<	V2	GUP & WAR
Variability F2	V1	=<	V2	GUP & WAR
Distances BUR	V1	>	V2	Esp. in /i u/
Distances GUP	V1	=	V2	No effects
Distances WAR	V1	<	V2	Esp. BP & KR; /i u/
LMM Distances	V1	>	V2	Located in BUR
Duration	V1	<	V2	Except BUR KF

4. Discussion and conclusions

Our first research question concerned how vowels in these languages differ in F1 and F2 in disyllabic CV1CV2 words. Clear evidence was provided of sufficient rather than maximal dispersion in Burarra, Gupapuyngu and Warlpiri vowel spaces, as has been found previously for Burarra [2] and other Australian languages such as Kunwinjku and Dalabon [17]. Typically, for the three languages considered here, /a/ acted as vowel space anchor or pivot. Some differences between the languages' vowel spaces became apparent. The Warlpiri normalised vowel space was found to be slightly more compact and also slightly lower in F1 (more close) than those of Gupapuyngu and especially Burarra. In Burarra, the close vowels tended to be similar in F1, but in Gupapuyngu and Warlpiri, /i/ was lower in F1 than /u/. When F1 distances between vowels were compared in Gupapuyngu and Warlpiri, which have identical vowel systems, F1 distances tended to be slightly larger in Gupapuyngu. These results disconfirm the strong version of the DT hypothesis that languages with the same vowel system will exhibit identical F1 distances between adjacent vowels. In general, /i/ tended to vary least in F1, indicating strong articulatory requirements associated with tongue dorsum raising and fronting and bracing against the hard palate [22] [26]. The finding of high variability in /u/ in F2, which is typically associated with this vowel [22] [26], suggests some fronting and lip unrounding. /a/ tended to vary in both F1 (height) and F2 (anteriority). The large amount of F2 variability and overlap in these vowel spaces can be related to the 'place of articulation imperative' [13]. This constraint requires that, given few vowel contrasts and many (coronal) consonant place constrasts, cues to place are prioritised over vowel quality cues in Australian languages. The role of consonant place in vowel variability and dispersion in these languages will be investigated in future research.

The second research question was whether vowels differ according to prosodic prominence and position in the word (V1 or V2) in F1 and F2, formant variability and vowel space dispersion. Table 2 presents a summary of the relevant findings. Across languages, phrase-final vowels (V2) tended to be slightly higher in F1 (more open), but this pattern in F1 was mainly located in the Burarra data in /a/, and in the Gupapuyngu data in /a u/. There were no effects in F2. Some evidence was presented for some Gupapuyngu and Warlpiri speakers of greater F1 and F2 variability in the word-final vowel, consistent with findings for Kunwinjku [17]. Given the finding of increased duration in V2 across languages, it is likely that any increased variability in V2 is due to phrase-final lengthening rather than the absence of accentuation. Regarding dispersion, typically, for the Burarra speakers, greater dispersion occurred in the prosodically prominent vowel, consistent with previous claims that Burarra exhibits vowel reduction in unstressed syllables, *i.e.*, V2 in this experiment [13]. For two Warlpiri speakers, greater dispersion occurred in the phrase-final, lengthened, vowel. We found in Gupapuyngu that /a u/ were slightly more open in V2 than in V1, indicating increased jaw opening and sonority, which is likely to be the result of lengthening. However, the effect of vowel position on overall dispersion in Gupapuyngu did not reach significance for any speaker. In general, dispersion in the vowel space was not greater in Burarra than in Gupapuyngu in V1 (or V2), despite the former language having a larger inventory size. In fact, Gupapuyngu was associated with the largest magnitude of dispersion overall. The finding that a language with a larger inventory does not necessarily show a larger magnitude of dispersion is consistent with previous findings in European languages, e.g., [22]. Regarding the question of whether there is any effect of vowel position on vowel duration, as mentioned, our results confirm that there is pre-boundary lengthening in Burarra, Warlpiri and Gupapuyngu, in accordance with observations for other Australian languages, e.g., [14]. Typically, vowel duration did not correlate with expansion. However, for some speakers, /i/ showed a weak positive correlation. Further research is needed to separate the effects of position in word and prosodic prominence and to comprehensively investigate prominence effects on word-medial consonants in these languages.

5. Acknowledgements

We would like to thank Andrew Butcher for providing the corpus. We would also like to thank the speakers involved. This research was funded by an Australian Postgraduate Award granted to the first author.

Rhythmic Correspondence between Music and Speech in English Vocal Music

Xi Chen, Peggy Pik Ki Mok

Department of Linguistics and Modern Languages, The Chinese University of Hong Kong
chenxi1099@gmail.com, peggymok@cuhk.edu.hk

Abstract

This study investigates the rhythmic structures of music and speech, and the possible corresponding rhythmic patterns between the two domains in English vocal music. With fifteen English songs as samples, lexical stress of multi-syllabic words is compared with three musical dimensions—metrical stress, duration, and pitch respectively. It was found that in the chosen English songs, there is a good mapping between the metrical stress of music and the lexical stress of lyrics. In addition, the duration and the pitch patterns not only generally match the lexical stress patterns most of the time, but also serve to manifest the prominence of the primary lexical stress on one hand, and to reflect the weakness of the unstressed syllables on the other. In addition to a general good match in rhythm, this study also shows match differences within the three comparisons. Match degrees vary according to different meter patterns. Moreover, pitch takes priority over duration in their respective match with lexical stress of the lyrics. Finally, the primarily stressed syllables match duration and pitch patterns much better than the unstressed ones do.

Index Terms: Musical rhythm, Speech rhythm, English songs

1. Introduction

Widespread consensus exists among musicians and linguists that music and speech have strong parallels in many aspects. Among them, rhythm is widely acknowledged as a crucial prosodic feature in both domains, and rhythmic correspondence is an important locus of interest in this interdisciplinary field. Lerdahl & Jackendoff [1] adopted linguistic framework to compare prosodic structures of music and speech so as to investigate how the prosodic elements such as duration, pitch and intensity create structured rhythmic and melodic patterns in the two domains. Their theory of metrical structures was later developed by Todd's [2] wavelet model analyses to rhythm in music and speech. Recent empirical studies [3, 4] found that the rhythmic features of the language in a geographic location would leave imprint on its local musical instrument. And even for the different dialects of the same language, they have different rhythmic characteristics which are reflected in the local musical styles [5]. Palmer and Kelly [6] discussed the relations between linguistic prosody and musical meter in songs, and found that compound word and nuclear stress rules coincide with musical rules of metrical accent. A very recent study [7] has investigated the degree of stress-meter alignment in French vocal music and found that stronger metrical stress tends to fall on the final syllables of poly-syllabic words and mono-syllabic content words. Thus the two parallel stresses are more likely to be consistent. The author also estimated that this alignment in English vocal music might be better than in French because the lexical stress in English is less controversial than in French, but so far very few studies have systematically examined the rhythmic correspondence in English songs. The present study is designed to fill this gap.

This study investigates the underlying rhythmic correspondence between music and speech in English vocal music. Word stress is a manifestation of rhythm in speech, and there are three categories of word stress in English: primary stress, secondary stress, and unstress [8]. In music, rhythm can be realized in the variation of intensity, duration and pitch [9, 10]. First, musical accent can be presented by metrical structure. Different meter patterns are created by endowing a sequence of beats with different metrical stress, and the stronger one takes the accent [11]. In addition, previous studies showed that as a reliable cue of melodic contour, duration can also present the stress by changing the length of the notes [9] [12][13], and longer notes can emphasize the musical event [14]. Besides, pitch patterns also create stress distinctions by making the pitch of a note higher than its surrounding ones [1] [12] [15]. According to Jones' idea [15] of interval accent, a note higher than its surrounding notes is supposed to be stressed, and a note with lower pitch is supposed to be unstressed. In the present study, lexical stress in multi-syllabic words in lyrics is chosen, and is respectively compared with three dimension of musical rhythm—metrical stress, duration, and pitch. These three comparisons can reveal 1) the situation of stress-meter alignment in English vocal music; 2) whether the duration patterns and pitch patterns can manifest word stress patterns.

2. Method

2.1. Materials

Fifteen English songs were selected. They are famous folk songs, golden oldies, ballads and popular movie songs which are written in different time periods with diverse backgrounds. The styles of the songs are supposed to be simple, smooth, and traditional so as to ensure that they can be easily recognized and sung by most people. The fifteen songs cover the most common meter patterns: 2/2, 2/4, 4/4, 3/4, and 6/8, and there are three songs for each meter. The alignment analysis was based on score analysis, not the sound tracks. The scores with the assigned lyrics were found from the Internet and two university libraries in Hong Kong. For ease of reference, each song is numbered. The information of the selected songs is as following:

2/2: (1) ***Red River Valley*** (Traditional Canadian folk song)
(2)***Take Me Home, Country Roads*** (Lyrics and music by John Denver, Bill Danoff & Taffy Nivert)
(3) ***Tie a Yellow Ribbon round the Ole Oak Tree*** (Lyrics and Music by Russellbrown & Irwinlevine)

2/4: (4) ***Yankee Doodle Boy*** (From *Yankee Doodle Dandy*. Lyrics and music by George M. Cohan)
(5) ***Oh Susanna*** (Lyrics and Music by Stephen Foster)
(6) ***Do-Re-Mi*** (From *Sound of music*. Lyrics by Oscar Hammerstein II; music by Richard Rodgers)

4/4: (7) ***Sound of Silence*** (Lyrics and Music by Paul Simon)
(8) ***Yesterday once more*** (Lyrics and Music by Richard Carpenter and John Bettis)

(9) ***My Heart Will Go On*** (Lyrics by Will Jennings, Music by James Horner)

3/4: (10) ***Green Sleeves*** (English traditional folk song)
(11) ***Moon River*** (Lyrics by Jonny Mercer, music by Henry Mancini)
(12) ***My Favorite Things*** (From *Sound of Music*. Lyrics by Oscar Hammerstein II; music by Richard Rodgers)

6/8: (13) ***Silent Night*** (Lyrics by Joseph Mohr; music by Franz Gruber)
(14) ***We Are the Champions*** (Lyrics by Freddie Mercury, Music by Queen)
(15) ***Dulcinea*** (From *Man of La Mancha*. Lyrics by Joe Darion, Music by Mitch Leigh)

2.2. Procedure

This study includes three parts in which the lexical stress of the lyrics is respectively compared with metrical stress, duration patterns and pitch patterns of music. Since in English, distinguishable lexical stress cannot be found in mono-syllabic words [8], this study only focuses on di-syllabic and multi-syllabic words.

2.2.1. Match between metrical stress and lexical stress

On the score of each song, syllables of disyllabic and multi-syllabic words are circled with their aligned notes, and the categories of lexical stress of the syllables and the metrical stress of the aligned notes are identified and marked.

In the analysis, the three categories of metrical stress of music (major stress, minor stress, and unstress) are respectively represented by capital letters A, B and C, and the three categories of lexical stress in English (primary stress, secondary stress and unstress) are respectively represented by small letters a, b, and c. We follow the convention of western music system for the standard of metrical stress patterns in music [11]. And the English lexical stress patterns are based on the *Oxford Advanced Learner's Dictionary, 8th edition*, published by the Oxford University Press ELT.

In the analysis, each target is a combination of two types of stresses since it includes a syllable which takes a lexical stress, and a syllable-aligned note which is attached to a particular metrical stress. There are altogether nine possibilities of such combinations. Among them, in the cases of Aa, Bb, and Cc, the two types of stresses are consistent, so they match perfectly. In Ac and Ca, the two types of stresses are contradictory. In Ab, Ba, Bc and Cb, the match between the two types of stresses is not as perfect as that in the first group, but is still better than that in the mismatched group. In this way, the nine possibilities can be divided into three match groups—perfect match (Aa, Bb, Cc), secondary match (Ab, Ba, Bc, Cb) and mismatch (Ac, Ca).

After labeling the stress combination patterns of each target, the match degree of each category can be calculated by the following formula: P %= (N_P/ N_t) * 100%, where P stands for any match category; N_P stands for the number of syllables that belong to a particular match category; N_t is the total number of syllables of disyllabic and multi-syllabic words.

2.2.2. Duration analysis

In this section, the target notes are represented by a short underline "_". The relative duration of the two notes adjacent to the target notes is examined as well. Compared with the target note, if the duration of the adjacent note is shorter, then it is marked as "S"; if longer, then it is marked as "L"; if identical, then it is marked as "I". If there is a rest, or if there is no adjacent note (the left position of the initiate note or the right position of the last note), a short dash "-" is used. There are fifteen possibilities as follows:

S_S, S_-, -_S, S_I, I_S, S_L, L_S, I_-, I_I, -_I, L_I, I_L, L_L, L_-, -_L

A capital letter X is used to represent an arbitrary metrical stress. Xa stands for a target in which the syllable takes the primary lexical stress. Xb is a target in which the syllable takes the secondary lexical stress, and Xc is a target in which the syllable is unstressed. In the analyses of both duration and pitch patterns, it was found that the number of Xb cases is quite small (12 out of 685 for duration patterns and 10 out of 687 for pitch patterns), so we only focus on Xa and Xc in this paper.

For the group of Xa, if the two adjacent notes are shorter than the target note, then the prominence of the target note is highlighted auditorily. In a similar way, for the group of Xc, if the duration of the two adjacent notes is longer than the target note, then the target note is heard as weakened. In these two cases, the duration patterns manifest the lexical stress patterns well, and the two types of stresses are in perfect match. The match degree decreases when the adjacent notes are identical to, or worse still, are longer than the target note. The match patterns are classified in Table 1.

Table 1. *Match patterns in duration analysis.*

Duration Patterns	**S_S, -_S, S_-**	**S_I, I_S**	**L_I, I_L**	**L_L, -_L, L_-**
Xa	Perfect match	Moderate match	Poor match	Mismatch
Xc	Mismatch	Poor match	Moderate match	Perfect match

Note: Xa: target with primarily stressed syllables; Xc: target with unstressed syllables

2.2.3. Pitch analysis

In this section, the analysis is similar to that in the duration comparison. If the pitch of the adjacent note is higher than the target note, then it is marked as "H (high)", if lower, then it is marked as "L (low)", if identical, then it is marked as "I (identical)". There are fifteen possibilities of patterns:

L_L, L_-, -_L, L_I, I_L, L_H, I_-, I_I, -_I, H_L, I_H, H_I, H_H, H_-, -_H

The pitch patterns for Xa and Xc are classified as in Table 2 below:

Table 2. *Match patterns in pitch analysis.*

Pitch Patterns	**L_L, -_L, L_-**	**L_I, I_L**	**H_I, I_H**	**H_H, -_H, H_-**
Xa	Perfect match	Moderate match	Poor match	Mismatch
Xc	Mismatch	Poor match	Moderate match	Perfect match

Note: Xa: target with primarily stressed syllables; Xc: target with unstressed syllables

It should be noted that in both duration and pitch analyses, for cases with the patterns of I_-, I_I, and -_I, the target note has the same duration/pitch as its adjacent notes. Thus the duration/pitch pattern has no influence on the manifestation of the lexical stress. In the patterns of S_L, and L_S in the duration analysis, and the patterns of L_H and H_L in the pitch analysis, each case is an ascending scale or descending scale. Thus, the influence of the duration/pitch pattern on the

lexical stress is not clear. The number of such cases is 253 out of 683 in the duration analysis and 269 out of 687 in the pitch analysis. The present study will not focus on these patterns.

3. Results

3.1.1. Stress match

Table 3 shows the degrees of stress match. Regarding the average match degrees of these fifteen songs, the percentage of perfect match is 67.71%. It is 9.05% for secondary match, and 23.39% for mismatch. The degree of perfect match for each song is the highest among the three match categories, and also the percentage is higher than 50% (except 7 and 8).

Concerning the specific meter patterns, songs with 3/4 meter have the highest degree of perfect match whereas songs with 4/4 meter have the lowest degree. However, songs with 4/4 meter do not have a high mismatch degree since they still have a considerable degree in secondary match. It is found that songs with 2/4 and 2/2 meter have the highest mismatch degree (and is much higher than that of the songs with the other three meter patterns), showing that their general match are not as good as other songs. By contrast, songs with 6/8 meter have the lowest mismatch degree, showing that they have very good general match.

Table 3. *Degrees of stress match.*

Meter Patterns	Songs	Perfect Match	Average for each meter	Secondary Match	Average for each meter	Mismatch	Average for each meter
2/2	1)	82.61%	65.84%	0	0.43%	17.39%	33.73%
	2)	62.82%		1.28%		35.90%	
	3)	52.08%		0		47.91%	
2/4	4)	53.25%	57.31%	0	4.00%	46.75%	38.69%
	5)	52.00%		12.00%		36.00%

3.1.2. Duration patterns

In this section, the cases in perfect match plus moderate match in Table 1 are regarded as general match, and the cases in poor match plus mismatch are regarded as general mismatch. The data is reported in Table 4 which shows the specific match cases of each song in the duration analysis.

It is clear in Table 4 that in the group of Xa, 9 songs have more cases in general match than those in general mismatch. 6 songs have more cases in general mismatch than those in general match. If we take all fifteen songs as a whole, for Xa, there are 64 cases in perfect match, 46 cases in moderate match, 58 cases in poor match and 32 cases in mismatch. Thus there are 110 cases in general match, and 90 in general mismatch. As a result, the general match cases outnumber the general mismatch cases.

In Xc, 7 songs have more cases in general match than those in general mismatch, 5 songs have more cases in general mismatch than those in general match, and 3 songs have the same number of cases in general match and in general mismatch. If we view the fifteen songs as a whole, for Xc, there are altogether 36 cases in perfect match, 80 cases in moderate match, 26 cases in poor match and 82 cases in mismatch. Thus, there are 116 cases in general match and 108 cases in general mismatch. As a result, the general match cases again outnumber the general mismatch cases.

Table 4. *Matching cases in duration analysis.*

Duration Analysis	Xa		Xc	
	Song number	Total	Song number	Total
GM > GMi	1), 4), 5), 6), 9), 10), 12), 13), 14)	9	1), 4), 5), 6), 7), 9), 12)	7
GM = GMi	--	0	2), 10), 14)	3
GM < GMi	2), 3), 7), 8), 11), 15)	6	3), 8), 11), 13), 15)	5

Note: GM: general match; GMi: general mismatch.

3.1.3. Pitch patterns

Table 5 shows the data concerning the specific matching cases of each song in the pitch analysis.

Table 5. *Matching cases in pitch analysis.*

Pitch Analysis	Xa		Xc	
	Song number	Total	Song number	Total
GM > GMi	1), 2), 3), 5), 6), 7), 9), 10), 11), 12), 13), 14), 15)	13	3), 4), 6), 7), 10), 11), 12), 14), 15)	9
GM = GMi	--	0	2), 9), 13)	3
GM < GMi	4), 8)	2	1), 5), 8)	3

Note: GM: general match; GMi: general mismatch

According to Table 5, for Xa, 13 songs have more cases in general match than those in general mismatch. 2 songs have more cases in general mismatch than those in general match. With regard to the whole picture of the match cases of the 15 songs, there are 82 cases in perfect match, 59 cases in moderate match, 43 cases in poor match and 49 cases in mismatch. Thus for Xa, there are 141 cases in general match and 92 cases in general mismatch. So there are more general match cases than general mismatch cases.

As for Xc, 9 songs have more cases in general match than those in general mismatch, 3 songs have more cases in general mismatch than those in general match, and 3 songs have the same number of cases in both general match and general mismatch. For a more general view, in Xc, there are 74 cases in perfect match, 26 cases in moderate match, 43 cases in poor match and 35 cases in mismatch. As a result, there are 100 cases in general match and 78 cases in general mismatch. Again, the general match cases outnumber the general mismatch cases.

4. Discussion

From the results of the degrees of stress match, it is clear that for all the songs except 7) and 8), the percentage of perfect match significantly outnumbers the other two match categories. Besides, all the songs have fewer than half of the cases with mismatched stress patterns. Therefore, it can be concluded that, the general good match situations between metrical stress in

music and lexical stress in lyrics are dominating in English songs. Concerning the five specific meter patterns, songs with 3/4 and 6/8 meters have the best stress mapping, whereas songs with 2/2 and 2/4 meter patterns have the most unsatisfactory stress mapping. The reason for this may be due to the difference of the characteristics of the meters. 3/4 and 6/8 meters are in relatively free and relaxing style whereas 2/2 2/4 and 4/4 meters are more compact and strict. Consider that many rhymes and marching songs are written in 2/2, 2/4 and 4/4 meters whereas waltz and barcarolles which are commonly used to dance to are written in 3/4 and 6/8 meters. 6/8 meter is often considered as the double sets of 3/4 meter. Since it has more beats (6 beats) as well as one minor stress per measure, its meter space allows more flexibility in accommodating lexical stress.

Songs with 2/2 and 2/4 meters have the highest percentages of mismatch degree. Since in most cases, songs with 2/2 and 2/4 meters can be naturally written into 4/4 meters due to their very similar auditory features, our selected 2/2 and 2/4 meter songs can be analyzed as 4/4 meter songs. Under such condition, the match situation is totally different as Table 6 shows. The mismatch degrees for these songs sharply decline. This is because when compared with 2/2 and 2/4 meters, 4/4 meter features the strictness like them on the one hand, and has a minor stress which mediates the major stress and the unstress on the other, thus adding the possibilities of secondary match and providing this meter with more flexibility. This is also the reason why the stress match degree for 4/4 meter ranks between that of 2/2 and 2/4 meters.

It should be noted that a song can be written in different meter signatures. It is common that songs of a binary meter can be written in any other binary meters but resulting little auditory difference for the audience (same situation for songs of triple meters). Besides, composers may develop the original piece to a special version by adding syncopations and anacruses to arouse feelings of out of expectation. These factors may cause a different matching result. In this study, however, the selected songs are original versions or the accepted earliest English versions to avoid the above factors.

Table 6. *2/2 and 2/4 meter songs analyzed as 4/4 meter songs in stress match.*

Song number	Meter pattern	Perfect match	Secondary match	Mismatch	Mismatch average
1)	**2/2**	47.92%	35.42%	16.66%	6.84%
2)		83.33%	12.82%	3.85%	
3)		69.57%	30.48%	0.00%	
4)	**2/4**	70.13%	24.68%	5.19%	2.81%
5)		83.87%	12.90%	3.23%	
6)		58.33%	41.67%	0.00%	

As for the duration analysis and pitch analysis, it is found that most of the selected songs have good mapping between duration/pitch patterns and lexical stress distributions for both the primarily stressed syllables and the unstressed syllables. In these songs, the duration/pitch patterns of the musical notes correspond with lexical stress patterns very well to highlight the primary lexical stress and weaken the unstressed syllables auditorily. However, there exist variations of match degrees between the two analyses. Table 7 incorporates the general match situations in duration analysis and pitch analysis. The ratio between general match and general mismatch shows the match degrees. The higher the ratio is, the higher the match degree is. The result shows that pitch patterns have higher match ratios than those of duration patterns for both primarily stressed syllables (1.53 vs. 1.22) and unstressed syllables (1.28 vs. 1.05). In this sense, it can be inferred that in English songs, the pitch match is more prominent than the duration match. Phonetically, pitch is a more important cue than duration in the manifestation of English lexical stress [16] [17]. Our data show the same patterns in English songs. Thus, it can be concluded that vocal music shares common rhythmic features with speech.

In addition, it can be seen from Table 7 that cases of primarily stressed syllables have higher match degrees than those of unstressed syllables in both duration analysis (1.22 vs.1.05) and pitch analysis (1.53 vs. 1.28). So the primarily stressed syllables have better mapping between lexical stress and duration patterns as well as pitch patterns than that of unstressed syllables. It should be noticed that duration analysis and pitch analysis have unequal total numbers of general match cases plus general mismatch cases. This is because this study has excluded the cases in which the patterns have no explicit influence on the lexical stress (see the end of 2.2.3).

Table 7. *Ratios between general match and general mismatch.*

Analysis	Patterns	GM	GMi	GM/GMi
Duration analysis	**Xa**	110	90	1.22
	Xc	116	110	1.05
Pitch analysis	**Xa**	141	92	1.53
	Xc	100	78	1.28

Note: GM: general match; GMi: general mismatch; Xa: target with primarily stressed syllables; Xc: target with unstressed syllables

It is also noticed from Table 3, Table 4 and Table 5 that, the song *Yesterday Once More* (No. 8) is found to have very poor rhythmic match in all three aspects (the perfect match degree is low in stress match, and the general mismatch cases outnumber the general match cases in both duration and pitch analyses). However, this song is classic and popular. *Yesterday Once More* used to be the highest-debuting single in 1973 (according to *Cash Box*, a music trade magazine). And until now, it is still among the most popular golden oldies in many places. What makes this song universally loved by so many people even though it has such a poor rhythmic mapping? It is likely that there are some other songs in similar situation. Are there any special rhythmic patterns or rhythmic interactions which make them auditorily harmonious despite their poor rhythmic match? These questions await investigation in further studies.

In summary, the current study shows that there is a good correspondence between metrical stress in music and English lexical stress. Besides, most of the selected songs have good mappings between duration/pitch and English word stress, and the duration patterns/pitch patterns in music can manifest English word stress in most cases. The pitch match is more prominent than duration match in the analysis. In addition, primarily stressed syllables have better mapping between lexical stress and duration patterns/pitch patterns than unstressed syllables. The good rhythmic correspondence between lyrics and music may be because that the composers and lyricists take special care to match the rhythms in melody with the stress in lyrics when they compose melody for pre-existing lyrics or write lyrics for a pre-existing tune. However, there might be variations of match degrees for the two types of work. It remains unclear which one has better rhythmic mapping in English vocal music. This is also an interesting question for further research.

Speech rhythm and vowel raising in Bulgarian Judeo-Spanish

Christoph Gabriel [1], *Elena Kireva* [1,2]

Abstract

The study investigates selected prosodic characteristics of (Sofian) Bulgarian Judeo-Spanish, a diaspora variety of Spanish spoken by descendants of the Jews expelled from Spain, all of them bilingual speakers with Bulgarian as their dominant language. While exhibiting some few relics from Old Spanish on the segmental level, Judeo-Spanish shows a puzzling similarity with Bulgarian with respect to speech rhythm and vowel raising. It is shown that the two languages spoken by the bilinguals, Bulgarian and Judeo-Spanish, pattern alike in displaying almost the same rhythmic values (except for %V) ([1], [2], [3], [4], [5]) and that raising of unstressed /a/ and /o/ as is typical of the variety of Bulgarian spoken in Sofia also regularly occurs in the Judeo-Spanish data. Our findings show that Judeo-Spanish is crucially influenced by Bulgarian, thus suggesting that it has largely converged toward the surrounding language on the phonological level.

Index Terms: Judeo-Spanish, Spanish, Bulgarian, language contact, speech rhythm, vowel raising

1. Introduction

Judeo-Spanish (JUSPA) emerged in the Middle Ages in a socio-political context marked by the contact of several languages. The Sephardic Jews living in Spain formed an ethno-sociological group different in customs and beliefs from the non-Jewish population. Their main vernacular was (Medieval) Spanish, while they used Hebrew in ritual and educational contexts. After the expulsion from Spain in 1492, their vernacular developed independently of Iberian Spanish due to contact with the new surrounding languages, among them Bulgarian. The Bulgarian variety of JUSPA is spoken by a rather small group of about 250-300 (at least) bilingual speakers with Bulgarian (BULG) as their dominant language, the JUSPA community of Sofia being even much smaller. The oldest living native speakers were born around 1920, the youngest in the 1960ies ([6], [7]). The use of JUSPA is restricted to informal communication within the community; in 1998, *Club ladino*, a community center for Sephardic Jews, was founded in the city center of Sofia.

Apart from the remarks included in general presentations (e.g. [8]), the literature on JUSPA phonology is rather sparse. Both the segmental and the tonal properties of the variety of Judeo-Spanish spoken in İstanbul (Turkey) have recently been investigated ([9] and [10]; the only study explicitly dealing with the phonemic system of Bulgarian JUSPA stems from the mid 1970ies ([11]). The prosody, in particular speech rhythm and vowel raising, of the variety in focus has not been investigated until now.

2. Phonological properties of JUSPA

This section highlights selected properties of JUSPA in comparison with the surrounding language BULG on the one hand and (Castilian) SPA on the other.

SPA exhibits an unmarked vowel system with the five phonemes /i, e, u, o, a/; BULG., in addition, has a phonemic schwa /ə/ ([12]) that also forms part of the JUSPA vowel system, albeit restricted to word-medial stressed syllables in Bulgarian loan words ([11]). A striking feature that has a crucial impact on speech rhythm is the presence or absence of vowel reduction ([1]). While completely absent from SPA ([13]), Bulgarian presents reduction (or rather raising) of the vowels /o, e, a/ that are realized as [u, i, ə] in unstressed syllables, e.g. [ˈrabutə] *работа* 'work' vs. [rəˈbotnik] *работник* 'worker' ([12], [14], [15], [16]). However, in the variety of BULG spoken in Sofia the raising of vowels commonly only affects /a/ and /o/, which surface in unstressed position as [ə] and [u], respectively, while the front vowel /e/ is hardly ever reduced to [i] ([14]). Interestingly, (Sofian) JUSPA also presents the feature of vocalic reduction ([11]), presumably as a consequence of its long-lasting contact with Bulgarian. Note in this context that vowel reduction has not been attested in other varieties of Judeo-Spanish (see, e.g., [9] concerning the variety spoken in İstanbul). Figure 1 depicts the process of vowel raising as is attested in Sofian BULG and JUSPA.

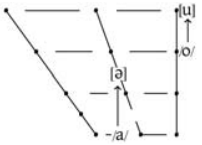

Figure 1: *Vowel raising in Sofian BULG and JUSPA.*

Regarding its consonantal system, JUSPA has preserved some features from Medieval Spanish, e.g. the sibilants /ʃ, ʒ/ (e.g., *bajo* [ˈbaʃo] vs. SPA [ˈbaxo], *mujer* [muˈʒeɾ] vs. SPA [muˈxeɾ], the [±]voiced contrast of the alveolar fricatives /s/ vs. /z/ ([11]), [17]). A reason for the maintenance of the rich sibilant system in JUSPA might be seen in the fact that the BULG consonant system also includes the phonemes /s z ʃ ʒ/ ([18]).

Concerning its rhythmic properties, (Castilian) SPA is traditionally classified as a typical syllable-timed language that strongly prefers regular sequences of CV syllables and completely lacks vowel reduction ([19]). Seen from the phonetic side, SPA is characterized by a high proportion of vocalic material (%V) and rather low values for the durational variability of both V and C intervals, as compared to stress-timed languages such as English ([1], [4], [20]). BULG, as opposed to SPA, exhibits complex syllable structures, allowing for up to three consonants in both the onset and the coda, i.e. (CCC)V(CCC), and presents vowel raising (see above), but usually no complete deletion of unstressed vowels as occurs, e.g., in English ([21], [22]). It is thus "less stress-timed" than English; its speech rhythm may thus be characterized as being of a mixed type ([23]). Until now, there is no work investigating the speech rhythm of JUSPA. For the current study, we hypothesize that the bilingual speakers (at least partially) transfer the rhythmic values from BULG to JUSPA, i.e. we assume that the rhythmic values shown in the

speech production of both of their languages are situated between the ones for SPA on the one hand and for Bulgarian, produced by monolingual speakers, on the other. Concerning the production of unstressed vowels, we expect the bilingual speakers to raise unstressed /a/ and /o/ in their production of JUSPA, due to transfer from BULG.

3. Methodology

3.1. Speakers

We collected data from five female bilingual JUSPA/BULG speakers, aged 80 to 88 (recordings Sofia, September 2012). Although they were born and raised in different places in Bulgaria (Kyustendil, Pazardzhik, Kazanlak, Samokov, and Karnobat), all of them have been living in Sofia for more than 60 years and speak the Sofian variety of BULG. The bilingual subjects were recorded in both of their languages (JUSPA and BULG_B(ilingual)). Five monolingual BULG speakers (1 ♂, 4 ♀, ages 26–34) and five monolingual speakers of (Castilian) SPA (3 ♂, 2 ♀, ages 24–34) serve as control groups. The Bulgarian subjects were born and raised in Sofia; the Spanish speakers were all born in the Castilian dialect area and raised in Madrid. The monolingual BULG speakers were recorded in Sofia in September 2012 (BULG_M(onolingual)); the (Castilian) SPA control data were gathered in Madrid in September 2011.

3.2. Material

The material gathered for the analysis of vowel raising and speech rhythm consisted of reading of the fable *The North Wind and the Sun*, recorded in BULG_M, BULG_B (*Северният вятър и слънцето*), JUSPA (*El ayre del norte i el sol*), and (Castilian) SPA (*El viento norte y el sol*), respectively. The data were recorded with a Marantz hard disk recorder (PMD671) and a Sennheiser microphone (ME64) and analyzed using *Praat* ([24]).

3.3. Analysis of vowel raising

In order to demonstrate that Judeo-Spanish also exhibits vowel raising like the contact language Bulgarian, both an auditory and an acoustic analysis were performed. First, all unstressed /a/ and /o/ occurring in the data recorded from the bilingual speakers (i.e. JUSPA and BULG_B) were transcribed by the second author (who is a native speaker of Bulgarian) according to their auditory properties as being reduced or unreduced. In a second step, two raters, both native speakers of Bulgarian, were asked to determine every single unstressed /a/ and /o/ as being realized as [a] or [ə] for /a/, and as [o] or [u] for /o/. For the final results of the auditory analysis, every vowel which was defined as being reduced by the second author and by at least one of the raters was counted as being reduced. The transcription agreement between the three raters amounts to 86 % for JUSPA and to 89% for BULG_B.

Subsequently, all stressed and unstressed /a/ and /o/ occurring in the data collected from the bilinguals were analyzed acoustically. In order to compare the formant frequencies of the unstressed vowels with the ones of the stressed ones in both of their languages, we measured the formants of all stressed and unstressed /a/ and /o/ in the JUSPA and the BULG_B data. All /u/ and /ə/ (we refer here to the Bulgarian /ə/ that occurs in both stressed and unstressed position) were also taken into account in order to compare the formant frequencies of the unstressed /a/ and /o/ with the respective values of /u/ and /ə/. Material produced with creaky voice or disfluencies was excluded from the acoustic analysis.

The first two formants of the above mentioned vowels were extracted using the *Praat* function Formant Track and running a script that provides three scores for F1 and F2 of each vowel (measured at the 25%, 50%, and 75% temporal points of the vocalic duration). Since the two data sets (BULG_B and JUSPA) differ with respect to the occurrences of syllable structures (CV, CVC, CCV, etc.) and regarding the segments that precede the vowels as syllabic onsets (plosives, nasals, liquids, etc.), we used only the values obtained from the measurements in the middle of the vowel in order to avoid co-articulation effects.

The values obtained from the formant tracker were checked randomly by the second author; incorrect values were respectively changed in the overall results, following [25]. We calculated the mean F1 and F2 values for stressed and unstressed /a, o/ occurring in both JUSPA and BULG_B. The occurrences of stressed and unstressed /u/ were grouped together for both languages, since /u/, as opposed to /a/ and /o/, is not expected to exhibit stress-dependent qualitative differences in Bulgarian. The same holds for stressed and unstressed /ə/.

3.4. Analysis of speech rhythm

For the rhythmic analysis, the whole data recorded in BULG_M, BULG_B, JUSPA, and SPA were segmented into vocalic and consonantal intervals.

Following [2, 26], the boundaries between V and C intervals were determined on the basis of formant structure and pitch period and set at the point of zero crossing of the waveform. Pre-pausal and phrase-final intervals were considered for the analysis since possible effects of final lengthening were likely to be reflected in the measures ([2], [4]). According to [4], we treated glides as belonging to the V intervals if there was no friction attested in the data. For plosives and affricates following a stretch of silence (pause) the beginning was placed at 0.05s prior to the burst, given that their boundaries can hardly be determined on the basis of the aforementioned criteria ([27]). Silent pauses and material affected by any kind of speech disfluency were excluded from the analysis.

Using the software *Correlatore* ([28]), we calculated both the proportion of vocalic material in the speech signal (V%) and the durational variability of vocalic and consonantal intervals as expressed by the variation coefficient VarcoV/C and the Pair-wise Variability Index (VnPVI, CnPVI, CrPVI). VarcoV/C is a speech rate normalized version of ΔV/C, which expresses the standard deviation of vocalic and consonantal intervals; the PVIs differ from both ΔV/C and VarcoV/C in computing the durational variability in successive V/C intervals instead of calculating the variability of V/C intervals over the whole acoustic signal; see [1], [2], [3], [4], and [5].

4. Results

The analysis of vowel raising and speech rhythm showed that the two languages spoken by the bilingual speakers, i.e. JUSPA and BULG_B, pattern alike with respect to both vowel raising (similar formant frequencies) and speech rhythm (comparable values for the rhythm metrics).

4.1. Vowel raising

Table 1 represents the results of the auditory analysis and shows the occurrences of reduced /a/ and /o/ in JUSPA and BULG_B.

Table 1. *Occurrences of reduced and unreduced /a, o/ in unstressed positions in JUSPA and BULG_B.*

	JUSPA		BULG_B	
	№ of /a/ and /o/	%	№ of /a/ and /o/	%
reduced /a/	135 /a/	75.5%	108 /a/	84.5%
unreduced /a/		24.5%		15.5%
reduced /o/	107 /o/	36%	70 /o/	71%
unreduced /o/		64%		29%

According to the outcomes of our auditory analysis, the bilingual speakers realized /a/ as [ə] in 75.5% of the cases in JUSPA and in 84.5% in BULG_B. The realization of /o/ as [u] amounts to 36% in the JUSPA data and to 71% for BULG_B. Summarizing, raising of /a/ and /o/ occurs more frequently in BULG_B than in JUSPA.

Tables 2 and 3, below, present the formant frequencies for the data gathered from the bilingual informants. The results of the acoustic analysis clearly show that the bilingual speakers exhibit vowel raising in both JUSPA and BULG_B.

Table 2. *Mean formant frequencies for JUSPA (Hz).*

	stressed /a/	unstressed /a/	stressed /o/	unstressed /o/	/u/
№	51	135	77	107	48
F1	877	633	602	413	348
F2	1491	1635	1067	1067	904

Table 3. *Mean formant frequencies for BULG_B (Hz).*

	stressed /a/	unstressed /a/	stressed /o/	unstressed /o/	/u/	/ə/
№	29	108	70	70	28	84
F1	847	520	578	385	330	490
F2	1650	1721	1094	1066	1032	1617

As can be seen in Tables 2 and 3, the material recorded comprises different numbers of stressed and unstressed vowels (i.e. 51 stressed /a/ and 135 unstressed /a/ for JUSPA, but 29 stressed /a/ and 108 unstressed /a/ for BULG_B, etc.). As for the formant frequencies, while the mean F1 values for stressed /a/ are almost the same in both the JUSPA and the BULG_B productions (877 Hz for JUSPA and 847 Hz for BULG), this is not the case for the mean F2 values which are 1491 Hz for JUSPA and 1650 Hz for BULG_B. Regarding /a/, it can be said that unstressed /a/ is frequently produced as [ə] in both bilingual languages (mean F1 value 633 Hz for JUSPA and 520 Hz for BULG_B). Thus, we observe a statistically significant difference between the F1 scores for stressed and unstressed /a/ in both JUSPA and BULG_B (dependent t-test: D=244.8±20.5, t(4)=26.709, p<0.001 for JUSPA; D=347.7±34.2, t(4)=22.745, p<0.001 for BULG_B).

Nevertheless, unstressed /a/ is more likely to be reduced (or rather: raised) in BULG_B (F1=520 Hz and F2=1721 Hz) than in JUSPA (F1=633 Hz and F2=1635 Hz), since the values for BULG_B are closer to those of stressed or unstressed /ə/ (see Table 3: F1=490 Hz and F2=1617 Hz). These findings confirm the outcomes of the auditory analysis in which the raters defined /a/ as [ə] in 84.5% of the cases for BULG_B and in 75.5% of the cases for JUSPA. The picture doesn't change when the realization of unstressed and stressed /o/ is taken into account: The mean F1 and F2 values for the stressed /o/ are quite similar in JUSPA (F1=602 Hz and F2=1067 Hz) and in BULG_B (F1=578 Hz and F2=1094 Hz). Although, according to the auditory analysis, unstressed /o/ seems to be realized as [u] twice more in the BULG_B speech than in the JUSPA material, the mean F1 and F2 scores for both bilingual varieties are nearly equal (F1=413 Hz and F2=1067 Hz for JUSPA; F1=385 Hz and F2=1066 Hz for BULG_B). The mean formant frequencies for unstressed /o/ pattern with the F1 and F2 values for /u/ rather than with the F1 and F2 scores for stressed /o/ in both varieties. However, the differences between the mean F1 and F2 scores for unstressed /o/ and for /u/ are higher in the JUSPA productions than the same ones in the BULG_B data. Nevertheless, the difference between the F1 scores for stressed and unstressed /o/ in both varieties is statistically significant (D=189.3±30.9, t(4)=13.697, p<0.001 for JUSPA; D=196.4±25.1, t(4)=17.482, p<0.001 for BULG_B).

4.2. Speech rhythm

Table 4 summarizes the values obtained from the analysis of the fable *The North Wind and the Sun* for SPA, JUSPA, BULG_B, and BULG_M. The scores for the two varieties spoken by the bilingual speakers are quite similar (except for %V), the values for VarcoV und VnPVI largely being situated between those obtained from the analysis performed on the SPA and the BULG_M data.

Table 4. *Mean values of six rhythm metrics for SPA, JUSPA, BULG_B, and BULG_M.*

	%V	VarcoV	VarcoC	VnPVI	CrPVI	CnPVI
SPA	40.4	43.3	39.8	36.6	40.6	46.3
JUSPA	45.6	45.3	42.3	43.6	60.3	45.7
BULG_B	38.6	44.1	41.1	44.3	58.1	47.5
BULG_M	33.7	49.7	38.1	49.8	50.9	45.1

While BULG_M displays the lowest proportion of vocalic material, BULG_B, SPA, and JUPSA show higher values for %V. As for the variability of vocalic intervals, the VarcoV and VnPVI scores for JUSPA and BULG_B are almost the same: More precisely, they are situated between those obtained from the analysis performed on the data produced by the two control groups (i.e. BULG_M and SPA). The differences between SPA on the one hand and JUSPA, BULG_B, and BULG_M on the other for the VnPVI values are statistically significant (SPA vs. JUSPA p=0.036, SPA vs. BULG_B p=0.018, and SPA vs. BULG_M p<0.001). Regarding the variability of consonantal intervals, both bilingual varieties exhibit quite similar values for VarcoC, CrPVI, and CnPVI. Considering the normalized metrics (VarcoC and CnPVI), it can be said that all four varieties pattern together showing similar variability of consonantal intervals; however, taking into account the values for the non-normalized or raw Pair-wise Variability Index for consonantal intervals (CrPVI), BULG_M and SPA display a lower variability of consonantal intervals. Figure 2 represents the distribution of the four varieties under discussion over the %V/VnPVI plane.

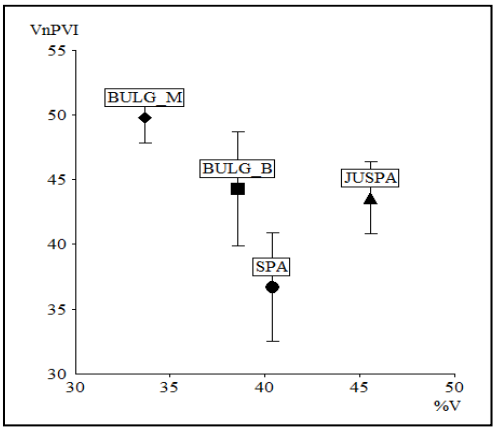

Figure 2: *Distribution of BULG_M, BULG_B, JUSPA, and SPA over the %V/VnPVI plane.*

5. Discussion

We interpret the results of our rhythmic analyses as follows: Regarding the proportion of vocalic material (%V) and the variability of V intervals (VarcoV and VnPVI) for BULG_M and SPA, it is expected that BULG_M displays a greater variability of vocalic intervals, but lower percentages for vocalic material (%V) than SPA, due to the presence of vowel reduction in Bulgarian. These expectations are confirmed by the results shown in Table 4 (see also Figure 2). Regarding the variability of C intervals (as is expressed by VarcoC, CrPVI, and CnPVI, respectively), the results confirm previous findings reported in, e.g., [21], who showed that Bulgarian (a language that presents complex consonant clusters and thus long C intervals almost throughout the whole speech signal) exhibits a variability of consonantal intervals similar to those of syllable-timed languages such as Spanish (a language with simple structures and thus presenting continuously short C intervals). This similarity becomes obvious when the values for the speech-rate normalized PVI (CnPVI) are taken into account (46.3 for SPA and 45.1 for BULG_B).

Interestingly, BULG_B patterns with JUSPA rather than with BULG_M in displaying almost the same rhythmic values (except for %V), which can be explained by the influence from Judeo-Spanish, the other language used by the bilingual speakers. The (unexpectedly) high %V values for JUSPA can be explained by the fact that the speakers read the fable in Judeo-Spanish slower as compared to their reading of the Bulgarian version of the text (regarding the influence of speech rate on rhythm see [21], [29], [30]). The reason for this might be the fact that their predominant language is Bulgarian and they are not accustomed to the use of Judeo-Spanish in its written form. Regarding the variability of V intervals, expressed by VarcoV and VnPVI (see Figure 2 for the latter), both BULG_B and JUSPA display intermediate scores situated in between those of SPA and BULG_M. The lower variability of V intervals in the BULG_B as compared to BULG_M once again might be interpreted as an effect of 'syllable-timed influence' from JUSPA in the bilingual speakers. The higher VnPVI value for JUSPA as compared to the one for SPA, in turn, suggests 'stress-timed influence' from Bulgarian and may be interpreted as an effect of vowel reduction (or rather: vowel raising), a phonological feature that is completely absent from (Castilian) SPA and has presumably been transferred to JUSPA from the dominant language Bulgarian in the bilingual speakers. Regarding the variability of C intervals, the differences between the languages investigated are less clear (see Table 4). However, the two varieties spoken by the bilingual speakers, JUSPA and BULG_B, once again display similar values.

To sum up, the phonological shape of the diaspora variety JUSPA patterns with its contact language Bulgarian in several respects: It presents vowel reduction (or rather: vowel raising) in the same way as the Sofian variety of Bulgarian does (raising of /a/ and /o/ to [ə] and [u] in unstressed position). Regarding the variability of vocalic intervals, it exhibits intermediate values, located in between those of the variety of Bulgarian spoken by monolingual speakers in the capital of Sofia (BULG_M) and Castilian Spanish (SPA). These findings can be attributed to the long-standing contact with Bulgarian and to convergence of two phonological systems (Bulgarian and Spanish) in the bilingual speakers.

6. Conclusion

Sofian Judeo-Spanish phonology is characterized by two opposite aspects: Some segments, e.g., the sibilants /ʃ/ and /ʒ/ mentioned in section 2, above, are maintained from Medieval Spanish, thus, at least partly, attributing a conservative character to the variety investigated here. The innovative features, though, are more striking, since both the feature of vowel reduction (or rather: vowel rasing) and the rhythmic properties are (at least partially) transferred from the surrounding language Bulgarian to Judeo-Spanish. To put it bluntly, it may be stated that the bilingual JUSPA/BULG_B speakers practically use the same phonology for both of their languages − at least regarding the aspects investigated in the present study. This might be due to the fact that the first Sephardic Jews who arrived in the Ottoman Empire (today: Bulgaria) and started acquiring Bulgarian as an L2 drew on the resemblances between the two phonological systems in order to avoid high cognitive costs in language processing (see [31]). During the initial period, they might have had two distinct phonologies, while the segments that belong to both of the systems, such as the sibilant phonemes, increasingly converged with respect to their concrete phonetic realization. In a further step, the two systems might have completely converged, insofar that phonological features not belonging to the Judeo-Spanish system (such as vowel raising) were integrated as well. It is even conceivable that the contemporary bilingual JUSPA/BULG_B speakers dispose of one phonological system only, i.e. the Bulgarian one, as a result of an entire convergence on the phonological level.

All things considered, we argue that the variety of Judeo-Spanish nowadays spoken in Sofia (JUPSA) is a typical contact variety that exhibits features of the languages involved in the situation of linguistic contact. Our results by and large confirm the view that the sound shape of a given language is more likely to adopt features from other languages in contact situations than is the case for core-syntactic properties such as, e.g., the ordering of verb and object (OV vs. VO) [32].

7. Acknowledgements

We would like to express our gratitude to A. Benet and S. Cortés for providing us with the *Praat* script we used and to A. Bakardzhiev for modifying it according to our needs. Further thanks you to V. Druchkiv (UKE Hamburg-Eppendorf, Germany) for his help with the statistical analyses.

The role of stress perception in the assignment of written accent in Spanish

Sandra Schwab[1], *Carla V. Jara Murillo*[2]

Abstract

The aim of this investigation is to examine whether the adults' difficulty in placing the written accent in Spanish words is related to their ability in perceiving stress. The following variables were also taken into account in this study: the participant's education level (academic and non-academic), the stimulus lexical status (words and non-words), accentual pattern (proparoxytone, paroxytone and oxytone words) and length (2, 3 and 4 syllables). Participants performed a stress identification task and a word spelling task. Besides the effects of lexical status, education level and accentual pattern, results show an effect of the stress perception in the assignment of the written accent: stimuli with a correctly identified stress were more likely to be correctly written (i.e. with or without written accent) than the incorrectly perceived stimuli. This finding reinforces the idea that there is a relationship between prosodic and written skills.

Index Terms: stress perception, written accent, Spanish

1. Introduction

In Spanish, lexical stress is distinctive and therefore its placement is variable. As it is well known, stress distinguishes Spanish words such as *límite* (['limite] *limit*), *limite* ([li'mite] *(that) I limit*) and *limité* ([limi'te] *I limited*). Thus, it can appear on the last syllable of the word (oxytone word), on the penultimate syllable (paroxytone word) or on the antepenultimate syllable (proparoxytone word)[1]. However, the paroxytone pattern is by far the most general. It has been shown in [1] that in a corpus of 9219 Spanish words including propaxytone, paroxytone and oxytone words (excluding monosyllabic and unaccented words), 80% of the words were paroxytone, whereas approximately 17% of the words were oxytone and 3% were proparoxytone. The paroxytone pattern can thus be considered as the default accentual pattern in Spanish.

The normative spelling system establishes the following rules for placing Spanish written accent. In oxytone words, where stress is on the last syllable, a written accent is required if the word ends with -n, -s or with a vowel (e.g. *educación*, *voté*). In paroxytone words, where stress is on the penultimate syllable, a written accent is required if the word ends with a consonant other than -n and –s (e.g. *cárcel*, *carácter*). Finally, in proparoxytone words, where stress is on the antepenultimate syllable, a written accent is always required (e.g. *tránsito*).

It has been frequently noted that in Spanish orthography, the most common spelling mistake is the omission of the written accent. This comes out as the result of several investigations on different Spanish written corpora (e.g. [2], [3], [4]). In the case of Costa Rica (the variety under study in this investigation), similar results were found in a study with children (primary school) [5]. As far as adults are concerned, [6] found that 84% of the spelling errors in an adult Costa Rican written Spanish corpus (COCAE) were due to the omission of the written accent. Besides other reasons (e.g. education level, lack of attention, etc.), the difficulty in placing the written accent might be explained by the difficulty in perceiving stress. In that respect, [7] mentioned that 46% of the participants (students at the very beginning of their studies in *Pedagogy in Spanish*) had difficulties in identifying the stressed syllable. The possible relationship between spelling errors and stress perception (among other variables) was examined in 10-year children in [8]. They found that what they called the "stress awareness" (i.e. identification of the stressed syllable in non-words) was a good predictor of the spelling errors. They concluded that the prosodic skill (i.e. stress sensitivity) influenced the performance in word spelling task in 10-years children.

The aim of this investigation is to examine whether the adults' difficulty in placing the written accent is related to their ability in perceiving stress. The participant's education level (academic and non-academic) is also taken into account in this study. Moreover, as far as the stimuli are concerned, we consider the lexical status (words and non-words), the accentual pattern (proparoxytone, paroxytone and oxytone words) and the length (2, 3 and 4 syllables).

2. Method

2.1. Participants

Thirty-two Costa Rican participants (all from the San José region) took part in this experiment. They were divided into two groups. The first group was composed of 16 non-academic participants (henceforth "non-academic") (5 males and 11 females, age range: 18-70 years, mean age = 42.75). All of them had attended middle- or high-school level education, where they were taught Spanish grammar and orthography. The second group was composed of 16 students and professors from the faculty of Arts and from the faculty of Sciences of the Universidad de Costa Rica (henceforth "academic") (6 males and 10 females, age range: 19-51 years, mean age = 29.19).

2.2. Material

The auditory stimuli used in this experiment consisted of 96 items (48 real words and 48 non-words), recorded by a Costa Rican female speaker. The stimuli were prepared according to the following criteria. The real words were 48 Spanish words of two, three and four syllables, divided in proparoxytone (PP;

[1] Note that some adverbs ending in *-mente*, have two accented syllables (e.g. *comúnmente* [ko,mun'mente], *commonly*) and that some words, due to enclitics, present a stress on the forth to last syllable (e.g. *comiéndoselo* [ko'mjendoselo], *eating it*).

e.g. *únicos*)[1], paroxytone (P; e.g. *acabo*) or oxytone words (O; *además*)[2]. Twenty-one words required a written accent (e.g. *líder*) and 27 did not (e.g. *rosas*). The words with written accent were mainly taken from the COCAE corpus, as they generated a large number of errors ([6]). As far as the non-words were concerned, they were stimuli of two, three and four syllables (with PP, P or O accentual pattern) that were created by combining (in a random way but following the Spanish phonotactics) the syllables of the real words. This set comprised 27 non-words with written accent (e.g. *tébar*) and 21 without it (e.g. *meper*)[3].

2.3. Procedure

The experiment was run online with the *Labguistic* platform (www.labguistic.com). It was divided into two parts: *Perception* and *Spelling*. In the first part (Perception), participants heard a stimulus and had to indicate the position of stress (on the last syllable (O), the penultimate syllable (P) or the antepenultimate syllable (PP)). In the second part (Spelling), participants heard a stimulus and had to write it (with the instruction to place the written accent, if necessary).

The exact same stimuli were played in both parts (although not in the same order). Each part was composed of three sections, each one corresponding to the two, three or four syllable stimuli. Words and non-words were mixed together and presented in a different random order for each participant. The participants could hear each stimulus twice, if needed.

2.4. Data analysis

The responses given in the *Spelling* part were corrected according to the following criteria. We considered as correct responses the words (and non-words): 1) with two possible spellings, as there was no way to decide which spelling was the correct one (e.g. v/b; *boté* vs *voté*); 2) with a substitution of a letter with no implication for the presence of the written accent (e.g. *tía* instead of *día*); 3) with a substitution of a letter with an implication for the presence of the written accent (e.g. *rodes* instead of *ródez*); 4) with the addition of a letter with no implication for the presence of the written accent (e.g. *púdiro* instead of *údiro*), 5) with the omission of a letter with no implication for the presence of the written accent (e.g. *pasesa* instead of *pasesas*). We excluded the words (and non-words) with the addition or omission of a letter with an implication for the presence of the written accent (e.g. *mapovol* instead of *mapovo*; *simeracta* instead of *simeráctar*). Moreover, we collected the correct/incorrect responses of the *Perception* part.

We analyzed the data by means of mixed-effects logistic regression models in which participants and stimuli were entered as random terms ([10], [11]). For the sake of clarity, the results and figures are presented in percentages, although all statistical analyses have been performed on raw data.

[1] Note that disyllabic words could not be proparoxytone.

[2] We made sure that the lexeme frequency (taken from [9]) was not only similar across the three pattern ($F(2, 45) = 0.93$, n.s), but also in the two, three and four syllable words ($F(2, 45) = 0.88$, n.s).

[3] Although non-words do not exist in Spanish, they would follow the same Spanish accentuation rules as real words. For example, the oxytone non-word [me'peɾ] is written *meper*, and the paroxytone non-word ['teßaɾ] is written *tébar*.

3. Results and discussion

3.1. Spelling performance

A first model was run with the spelling correct/incorrect response as a dependent variable and with the following predictors: the participant's education level (academic/non-academic), the stimulus lexical status (words/non-words), the stimulus accentual pattern (PP, P, O), the stimulus length, and the participant's perception response (correct/incorrect). Given that the stimulus length had no effect and did not interact with other variables, a new analysis was run without it and without all non significant interactions.

3.1.1. Role of lexical status

As can be seen in Figure 1, results showed an effect of lexical status, with more correct responses for real words than for non-words ($F(1, 3033) = 33.08$, $p < .001$), independently of the other variables. Thus, it seems easier to correctly spell (i.e. to place or not the written accent) the real Spanish words than the invented words. It is also worth it noting that the scores are very high (88.36% in average), which suggests that the task is not particularly difficult for the participants. Moreover, it is important to observe the absence of an interaction between the lexical status and the educational level, which means that the difference between words and non-words is similar in academic and non-academic participants.

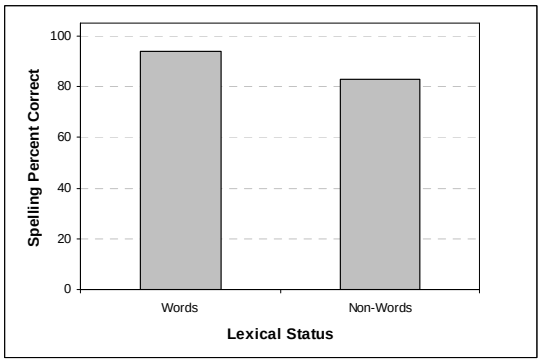

Figure 1: *Spelling percent correct as a function of lexical status.*

3.1.2. Role of education level and accentual pattern

Figure 2 presents the spelling percent correct as a function of the accentual pattern and education level. Despite the very good global performance, results show an effect of education level ($F(1, 3033) = 12.66$, $p < .001$): academic participants present more correct responses (93.38%) than non-academic participants (83.34%)[4]. We also observed an effect of accentual pattern ($F(1, 3033) = 4.26$, $p < .05$). Post-hoc analyses show more correct responses for PP (90.60%) and O (91.64%) than for P (85.33) ($p < .05$).

[4] Given that age and gender were not similar across academic and non-academic participants, we ran a model with age and gender as predictors to make sure that these variables were not responsible for the differences observed between academic and non-academic participants. None of the variables (or their interaction) has an effect on the spelling response.

More interestingly, we note an interaction between the education level and the accentual pattern ($F(1, 3033) = 4.08$, $p < .05$). As can be seen in Figure 2, the difference between academic and non-academic is more important in PP than in P or O ($p < .05$). Moreover, academic participants present more correct responses for PP and O than for P, whereas non-academic participants present more correct responses for O than for PP or P. In other words, it seems that academic participants have more difficulties with P stimuli, while non-academic participants have more difficulties with PP and P stimuli.

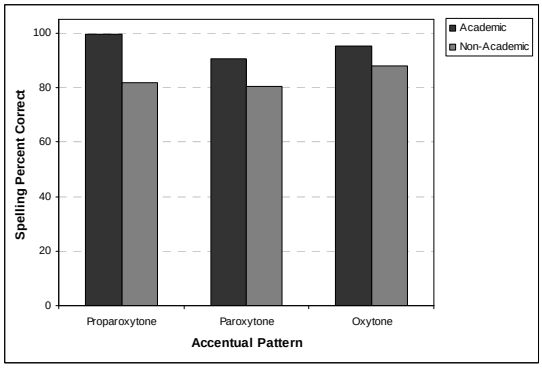

Figure 2: *Spelling percent correct as a function of accentual pattern and education level.*

3.1.3. Role of Stress perception

Interestingly, we observe an effect of the perception response on the spelling responses ($F(1, 3033) = 14.13$, $p < .001$). As can be seen in Figure 3, the stimuli with a correctly identified stress are more likely to be correctly written (i.e. with or without the written accent) than the incorrectly perceived stimuli.

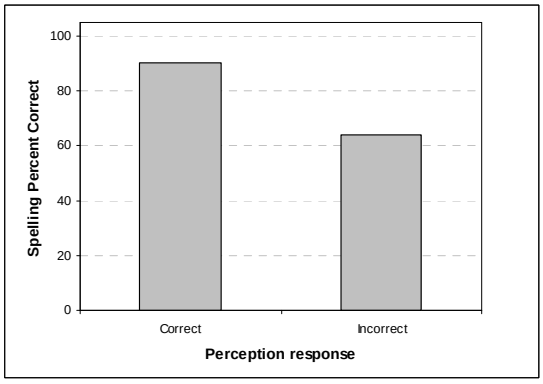

Figure 3: *Spelling percent correct as a function of the perception response.*

However, as shown in Figure 4, the effect of the perception response is modulated by the accentual pattern ($F(1, 3033) = 8.06$, $p < .001$). In fact, the effect of perception is smaller in P than in PP or O (independently of the education level) ($p < .05$). Finally, results show an interaction between the perception response and the education level ($F(1, 3033) = 17.28$, $p < .001$).

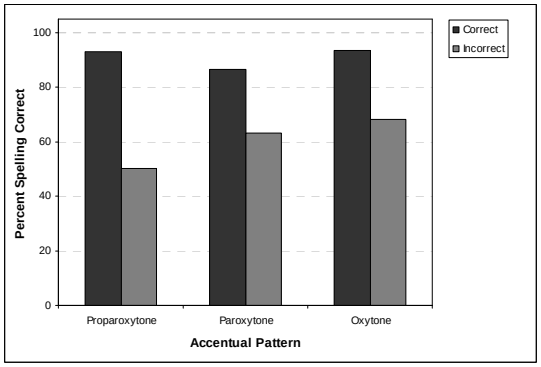

Figure 4: *Spelling percent correct as a function of the accentual pattern and the perception response.*

As can be seen in Figure 5, the difference between correct and incorrect perception responses is bigger in academic than in non-academic participants ($p < .05$). In other words, the perception of stress seems to play a more important role in academic than in non-academic participants.

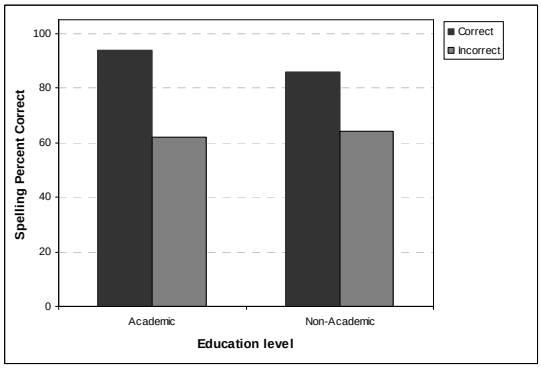

Figure 5: *Spelling percent correct as a function of the education level and the perception response.*

In order to explain the bigger importance of stress perception in academic than in non-academic participants, we ran an analysis with the perception response as the dependent variable and with the following predictors: the participant's education level (academic/non-academic), the stimulus lexical status (words/non-words), the stimulus accentual pattern (PP, P, O), the stimulus number of syllables. The results show, among other effects[1], an effect of education level: academic participants are better in identifying stress position than non-academic participants (98.63% and 88.54% respectively).

Figure 6 presents the spelling percent correct as a function of perception percent correct and education level. As can be seen, academic participants present less variability in their perception responses than non-academic participants (the standard deviation for academic participants is 1.65 and it is 15.73 for non-academic participants).

[1] Besides the effect of education level ($F(1, 3040) = 3.39$, $p < .001$), results of stress perception show an effect of lexical status, with more correct responses for words than for non-words ($F(1, 3040) = 5.29$, $p < .05$), an effect of the number of syllables, with more correct responses for disyllabic stimuli ($F(1, 3040) = 16.44$, $p < .001$), but no effect of accentual pattern.

Therefore, the fact that the academic participants' perception performance is not only higher, but also more invariable than the non-academic participants' performance may explain why perception plays a more important role in academic than in non-academic participants.

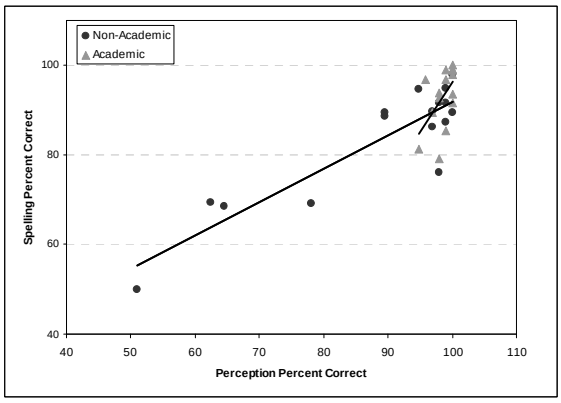

Figure 6: *Spelling percent correct as a function of perception percent correct and education level.*

3.2. Error analysis

In the error analysis, we examined whether the errors (N = 354) came from the addition of the written accent (henceafter "Added Written Accent"; e.g. *fluidéz* instead of *fluidez*) or from the absence of the written accent (henceafter "Missing Written Accent"; e.g. *carcel* instead of *cárcel*). Results show first that *Missing Written Accent* errors (N = 236) are more frequent than *Added Written Accent* errors (N = 118) ($\chi^2(1, N = 354) = 39.33$, $p < .001$). In other words, participants missed more written accents than they added.

Then, an analysis was run with the error type (Missing/Added Written Accent) as dependent variable and with the following factors: education level (academic/non-academic), lexical status (words/non-words) and accentual pattern (PP, P, O) and the interactions between these variables. No main effect was significant. Only the interaction between education level and lexical status was significant ($F(1, 350) = 6.40$, $p < .05$). Figure 7 presents the percent *Added Written Accent* error as a function of lexical status and education level.

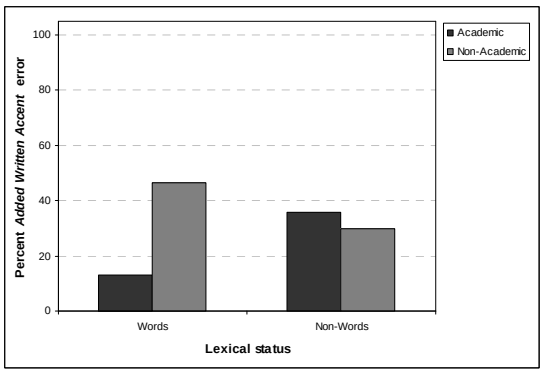

Figure 7: *Percent "Added Written Accent" error as a function of lexical status and education level.*

As can be seen, non-academic participants present more *Added Written Accent* errors than academic participants in words, while they present in non-words the same number of *Added Written Accent* errors as the academic participants. In other words, non-academic participants tend to erroneously add a written accent to a greater extent than academic participants, especially in real words.

4. General discussion

The aim of the investigation was to examine whether the adults' difficulty in placing the written accent in Spanish words was related to their ability in perceiving stress. We also took into account the following variables: the participant's education level, the stimulus lexical status, accentual pattern and length.

While results showed no effect of the stimulus length, they showed an effect of lexical status (i.e. more correct spellings for words than for non-words). This finding might suggest that the presence of the written accent is stored in the mental representation of the words. However, further research is still needed to confirm this hypothesis. An effect of education level was also observed, which indicates that academic participants mastered to a greater extent the Spanish written accentuation rules than non- academic participants. More interestingly, we found an effect of accentual pattern, with less correct responses for paroxytone stimuli than for proparoxytone or oxytone stimuli. We already mentioned that the paroxytone pattern is the default accentual pattern in Spanish. Yet, determining how frequently the paroxytone words require a written accent may explain why this pattern presents more errors. To do this, we analyzed a corpus composed of formal written Spanish texts (CODIMEP-CR-XXI). It contained 124'000 tokens, which corresponded to 11'370 types (i.e. different words). We found that 16% of the words have a written accent. Among those, 53% were oxytone, 31% were proparoxytone and 16% were paroxytone. It is important to note that, among the paroxytone words with written accent, only 15% corresponded to words ending in consonants other than -n and -s. (e.g. *dólar*), while 85% corresponded to words ending with hiatus (e.g. *día*). Yet, our paroxytone stimuli with written accent always showed this infrequent spelling (e.g. *líder*, *cárcel*, *fácil*, etc.). Moreover, taking into consideration that the default pattern in Spanish is paroxytone [1] and that only 16% of Spanish words require written accent, from which 85% are proparoxytone or oxytone (corpus CODIMEP-CR-XXI), we can assume that Spanish paroxytone words with written accent are much less frequent that paroxytone words without written accent. Yet, our stimuli included the same number of paroxytone items with and without written accent (words and non-words). This might explain why there are more errors in the spelling of paroxytone stimuli.

Finally, we observed an effect of the stress perception in the assignment of a written accent: stimuli with a correctly identified stress are more likely to be correctly written (i.e. with or without written accent) than the incorrectly perceived stimuli. However, this effect is weaker in paroxytone words and in non-academic participants. Taken together, these results confirm the hypothesis that the adults' difficulty in placing the written accent in Spanish is related to their ability in perceiving stress. In other words, there is a relationship between prosodic and written skills, as it was showed for reading in [8].

Abstract

In Hungarian intonation research a common framework developed by Varga (2002; [1]) is to categorize the intonation within the domain of accent groups by *character contours*. We propose a linear parameterization of a subset of these contours derived from polynomial stylization. These parameters were used to train classification trees and support vector machines for contour prediction. Parameter extraction and training was carried out on the original F0 contours of spontaneous speech data as well as on three differently normalized variants suppressing fundamental frequency level and range effects. The highest accuracies were obtained for classification trees and F0 residuals after midline subtraction, but the overall performances were rather poor. Nevertheless, a significant improvement of the results was achieved by a Hidden Markov model to predict the correct label sequence from the partly erroneous classification output.

Index Terms: intonation, Hungarian, character contours, stylization, labeling

1. Introduction

An established approach in Hungarian intonation research is to describe fundamental frequency (F0) curves in terms of *character contours (CC)*. This framework was developed by Varga [2, 1] and follows the tradition of contour-based intonation representations [3, 4] that focus on the contour properties of F0 rather than treating it as a sequence of tone targets [5].

Varga [1, p. 33] defines a CC as a *"discrete, meaningful speech melody"* with a *"characteristic shape"*. Its domain is a syllable sequence consisting of an initial accented (*"major-stressed"* [1, p. 33]) syllable and all following syllables till the next accented one or till the end of the intonation phrase. We refer to this sequence by the term *accent group* (AG) in the following.

According to [1] in Hungarian eleven character contours (and an appended contour that is not necessarily related to an AG) can be distinguished. The nine main contours are illustrated in Figure 1. They can be divided into three major classes: *i. front falling* (left column) *ii. sustained* (middle column), and *iii. end-falling* (right column). The abstract meanings assigned to these major classes are *self-contained*, *forward-pointing*, and *yes-no interrogative*, respectively.

For contour-based as well as for tone-sequence intonation models numerous machine learning techniques have been developed to derive the intonation representation automatically from the signal. Among the established techniques to learn categorical intonation labels from acoustic features are neural networks [6], decision trees and predicate logic learning rules [7], Hidden Markov models [7, 8] classification and regression trees [9], support vector machines, and instance-based learning [10]. [11] and [12] extract intonation categories in an unsupervised bottom-up fashion by means of clustering. The extraction of non-categorical parametric intonation representations is generally treated as an optimization task in an analysis-by-synthesis framework to minimize the distance between the observed F0 contour and the contour generated by the parameterization [13, 14, 15].

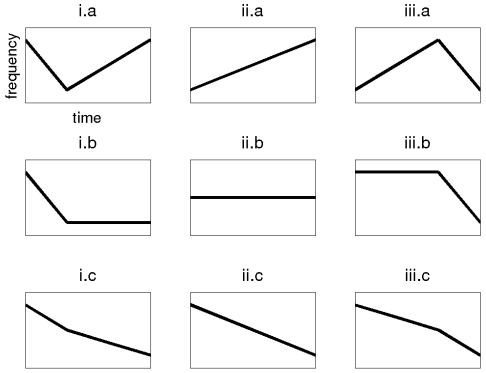

Figure 1: *Nine of the eleven character contours proposed by Varga [1, p. 43].*

Despite of this extensive literature on automatic intonation labeling, to our knowledge no approach has yet been published to extract the described character contours from the signal automatically. The aims of this study are thus to develop an appropriate F0 parameterization linking the signal to the character contour inventory and to train classifiers for automatic F0 labeling.

2. Data and preprocessing

The examined data consists of 50 Hungarian spontaneous speech utterances from collaborative dialogs by 10 Hungarian speakers. Each utterance forms a single intonation phrase (IP). Within each IP the accent groups were manually segmented following the definition of section 1, and the character contours were manually labeled by phonetic expert native speakers (the second and the third author of this study). In total, the data contains 140 AGs each linked to a character contour.

F0 was extracted by autocorrelation (Praat 5.3, sample rate

100 Hz). Voiceless utterance parts and F0 outliers were interpolated by piecewise cubic splines. The contour was then smoothed by Savitzky Golay filtering using third order polynomials in 5 sample windows and transformed to semitones relative to a base value. This base value was set to the F0 median below the 5th percentile of an utterance and serves to normalize F0 with respect to its overall level.

2.1. Normalization

To reduce the influence of F0 register on the local character contour shapes we generated three F0 residual variants. To capture the register in terms of its level and range [16] we fitted a base-, a mid-, and a topline for the IP. The baseline and the midline represent different aspects of the F0 level, whereas the F0 range information is provided by the time-varying span between the base- and topline. The robust fitting procedure that is motivated and explained in greater detail in [17] has already been applied for boundary strength [17] and prosodic phrase examinations [18]. The procedure is illustrated in the left panel of Figure 2 and consists of the following steps:

- A window of length 200 ms is shifted along the F0 vector with a stepsize of 10 ms.
- Within each window the F0 median is calculated
  - of the values below the 10th percentile for the baseline,
  - of the values above the 90th percentile for the topline, and
  - of all values for the midline.

  This gives 3 sequences of medians, one for the base-, the mid-, and the topline, respectively.
- Within each median sequence outliers are replaced by linear interpolation.
- Finally, for all three median sequences linear polynomials are fitted.

From this register stylization three F0 residuals were generated as can be seen in the right panel of Figure 2:

- the **baseline residual** by subtraction of the baseline from the F0 contour,
- the **midline residual** by subtraction of the midline from the F0 contour, and
- the **range residual** by normalizing each F0 value to the range between base- and topline at the corresponding position. These local reference points are set to 0 (baseline) and 1 (topline), respectively.

For the first two residuals the influence of register level is suppressed, whereas the impact of range is reduced for the third residual.

3. Parameterization

3.1. Method

Within each accent group segment we parametrized the original F0 contour as well as all residuals to derive a character contour representation. As can be seen in Figure 1 all contours can prototypically be represented by single lines or line pairs. We derived these lines the following way:

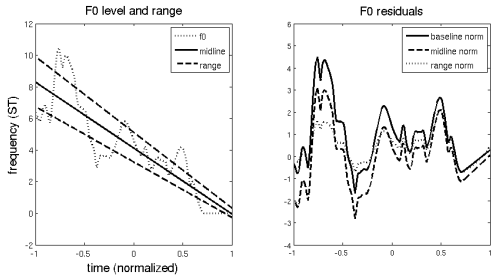

Figure 2: **Left:** *Extraction of a base-, mid- and topline within an intonation phrase to account for F0 level and range varying over time.* **Right:** *F0 residuals after level subtraction (baseline or midline) and range normalization.*

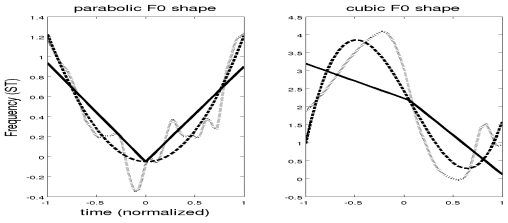

Figure 3: *Third-order polynomial stylization of F0 shapes.* **Left:** *Parabolic shape indicated by the absence of a turning point within the given time interval. The extreme value is selected as the split point* **Right:** *Cubic shape, where the turning point serves as the split point.*

- A third order polynomial was fitted to the F0 contour within an AG. Time was normalized to the interval from -1 to 1.
- The extreme values and the turning point of this polynomial within the normalized time interval were calculated from the polynomial's first and second derivative, respectively.
- If the polynomial neither contains a turning point nor an extreme value in the examined time interval, a **linear** F0 shape can be deduced that can sufficiently be characterized by a single line.
- If the polynomial contains only an extreme value but no turning point, this indicates a **parabolic** F0 shape in the examined time window. The extreme value is taken as the split point for subsequent line pair fitting. An stylization example for parabolic F0 shape is shown in the left panel of Figure 3.
- The existence of a turning point gives indication for a **cubic** shape. Since for these shapes two extreme values can occur in the examined interval, instead of choosing one of them in an ad-hoc manner, we select the turning point as the split point for subsequent line pair fitting. The right panel of Figure 3 shows a stylization example for cubic F0 shapes.
- The split point serves to divide the polynomial into two parts. Separately for the first and the second part a straight line is fitted passing through the split point by means of linear regression with zero intercept.

From this parameterization single line character contours can be described by the slope s of the regression line. Two-line

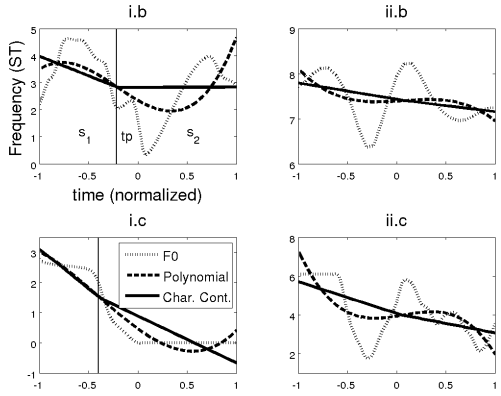

Figure 4: *F0 parameterization: Prototypical examples for each character contour.*

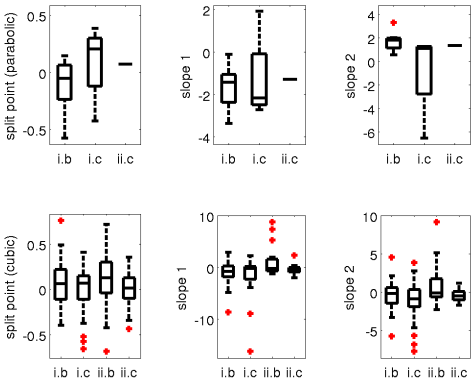

Figure 5: *Parameter distributions for the available character contour classes for parameterizations of parabolic (top row) and cubic shapes (bottom row).*

CCs are represented by a set of three features: sp: the position of the split point within the normalized time interval, s_1: the slope of the regression line form the beginning of the AG to the turning point, and s_2, the regression line from the turning point to the end of the AG. Since in our data only a single F0 shape was identified as linear it was subsumed to the set of parabolic shapes simply treating the line midpoint as the split point. Due to the lack of comparability between the different split point definitions the subsequent examinations and classifications were carried out separately for parabolic and cubic contours. Prototypical character contour stylization examples are given in Figure 4.

3.2. Relation between parameters and character contours

For the parabolic shape parameterizations none of the parameters differed significantly with respect to the character contour. For the cubic shape parameterization in contrast both slopes s_1 and s_2 showed significant differences across the contour classes for the original F0 contours and the residuals resulting from base- and midline subtraction (ANOVAs with s_1 resp. s_2 as dependent and character contour as independent variable. For s_1: $F[3, 113] = 4.08$, $p < 0.01$, and for s_2: $F[3, 113] = 3.51, p < 0.05$). With reference to Figure 1 one would expect more strongly negative slopes for $ii.c$ as opposed to $ii.b$ and for $i.c$ as opposed to $i.b$, but a Tukey-Kramer post-hoc test ($\alpha = 0.05$) only revealed significant differences for both slopes between the major classes i and ii. Nevertheless the expected tendencies can be seen in Figure 5.

4. Automatic Labeling

4.1. Features and preprocessing

We defined two different feature sets: a CC feature set as well as an extended set, which are presented in Table 1. For the extended feature set a sequential feature selection was carried out using the Matlab function *sequentialfs* to find the feature subset which is best in the sense of an optimality criterion. In our case the error to be minimized was calculated from the mean silhouette over all data points. We adopted this cluster evaluation measure to judge the goodness of separability of CC types by the respective feature combination. The mean silhouette $\hat{S}$, whose values range from -1 (bad) to 1 (good separability) was transferred to an error measure e ranging from 0 to 1 by $e = \frac{1-\hat{S}}{2}$. Subsequently the CC features as well as the selected features of the extended set were orthogonalized by means of a principal component analysis.

Table 1: *Feature sets for character contour classification.*

Feature	Description	CC	Extended
sp	position of split point	+	+
s_1	slope of first line	+	+
s_2	slope of second line	+	+
s_d	s_1-s_2	–	+
sp_y	F0 value of split point	–	+
$\text{coeff}_{0..3}$	polynomial coefficients	–	+

4.2. Classifiers

Separately for parabolic and cubic contours we trained classification trees (CART) [19] and support vector machines (SVM) [20] with a linear Kernel function to predict the character contour type from the respective feature set. For the training the Matlab functions *classregtree* and *svmtrain* with their default initializations were used.

4.3. Automatic label correction

In a postprocessing step we tried to improve the classification performance by treating the task of automatic labeling as a noisy channel problem: a correct label sequence (the expert annotation C) cannot be observed directly but only in form of a defective channel output O, which is given by the outputs of our classifiers. Thus label correction is basically the same as revealing the most probable hidden label sequence C that underlies the classifier output O: $\hat{C} = \arg\max_C[P(C|O)]$. We addressed this problem by Hidden Markov modeling (HMM). For the transition probabilities a linear interpolated uni- and bigram model was trained. Counts were smoothed by Good-Turing discounting.

5. Results

5.1. Classification accuracies

The accuracies for both classifiers CART and SVM, for the parabolic and cubic F0 contours and all its residuals, and for the CC and the extended feature set are presented in Tables 2 and 3. The accuracies were measured by means of leave-one-out evaluation. It turned out that:

- parabolic contours can be classified with higher accuracy than cubic contours. This can mainly be explained by the fact that parabolic contours were observed only for three of the four contour classes.
- F0 level normalization has a positive impact on CART performance while for the SVM performance rather range normalization is crucial.
- The best results were obtained by a CART trained on the reduced CC feature set and on midline residuals.

Table 2: *Character contour classification accuracies for classification trees.*

	CC feature set		extended feature set	
	parabolic	cubic	parabolic	cubic
original	69.23	29.91	53.85	23.08
baseline residual	76.92	30.77	69.23	36.75
midline residual	**84.62**	**43.59**	69.23	30.77
range residual	62.50	35.96	62.50	39.47

Table 3: *Character contour classification accuracies for support vector machines.*

	CC feature set		extended feature set	
	parabolic	cubic	parabolic	cubic
original	69.23	34.18	53.85	33.33
baseline residual	69.23	36.75	53.85	30.77
midline residual	69.23	35.04	69.23	32.48
range residual	75.00	41.22	68.75	42.98

5.2. Accuracies after error correction by HMMs

We trained HMMs to map the partly erroneous output of our best classifier (the CART classifying F0 midline residuals based on CC features) to the correct labels of the manual annotation.

In a tenfold cross validation it turned out that the performance could be improved with high significance (Mann-Whitney test, $z = -2.5809, p < 0.005$). The result is presented in Figure 6.

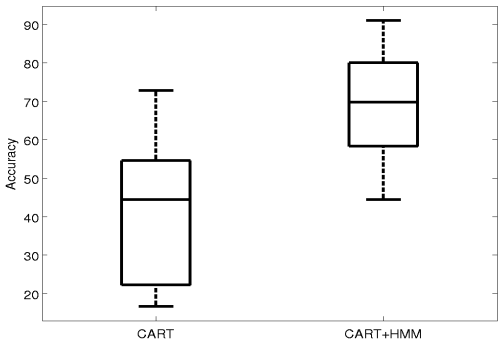

Figure 6: *The classification correction by means of an HMM leads to a significant accuracy improvement.*

6. Discussion and Conclusion

The findings of this study suggest that the application of the character contour framework on spontaneous speech is challenging. First, in our data only four character contour types had been observed which is only a subset of the contour inventory of [1]. This is partly to be explained by the shortcoming that our data does not contain questions, so that end-falling characters are very unlikely. But it also indicates that the other contour types are very unevenly distributed in spontaneous speech (*i.a* and *ii.a* from Figure 1 have not been observed at all). This uneven distribution in spontaneous speech was already observed by [1, p. 52]. In his data 60% of the contours were of type *ii.b*, whereas all *iii*-types taken together only occurred in less than 2% of the accent groups. Second, in spontaneous speech the extracted character contour parameters, slopes and turning point, overlap to a high extent across different contour classes so that it is difficult to relate a realized contour to its underlying prototype.

Principally, the parameterization proposed here is not strongly affected by the first drawback that not all contour types are contained in our data. The parameterization is extendable to the remaining contours, since for the observed contours their prototypes can be described by means of one or two line slopes.

Automatic labeling in contrast is heavily affected by the second drawback of parameter value overlap making it difficult to distinguish and identify character types in spontaneous speech. Also the usage of additional features as polynomial coefficients did not turn out to be gainful. Thus, the automatic labeling of character contours remains a difficult task.

Nevertheless, a significant improvement was achieved by postprocessing the classifier output with HMMs. From this finding we draw two conclusions. First, since postprocessing accounts for the left label context in terms of transition probabilities, one can infer that context plays a role for label assignment. Neither standard CARTs nor SVMs consider context, if it is not explicitly contained in the feature vectors. Context might be introduced by additional features (which requires more training data than available for this study) or by an appropriate normalization of the given features. The latter would be an interesting issue to be addressed in a follow-up study. Alternatively, one could directly use HMMs for intonation label assignment. However, using HMMs as a separate postprocessing classifier also has its benefits which brings us to our second conclusion: the learnability of correct labels from erroneous ones indicates that there are systematic correspondences between the classification output and reference labels. This finding might be of more general use for applications that automatically correct the output of labeling tools.

Finally, comparing the results between different classifiers and F0 normalization methods, one can see that normalization generally increases classification performance, but not in a uniform way for all classifiers. More systematic examinations are needed to get better insight into these complex relations.

Local and global convergence in the temporal domain in Polish task-oriented dialogue

Maciej Karpiński[1], Katarzyna Klessa[1], Agnieszka Czoska[2]

Abstract

Conversational parties tend to mutually adapt their communicative behaviour in a number of dimensions, from the level of physical aspects of speech signal and gesture, utterance properties, up to the level of mental representations. In the present study, an attempt is made to track the process of convergence in the temporal domain both as a global tendency and a local phenomenon. The material under study consists of two sets of task-oriented dialogues recorded with or without eye contact (telephone conversations) between the speakers. All the recordings were segmented into syllables and analysed in terms of speech rate and syllable timing pairwise variability (s*nPVI)* for each speaker as well as for the correlations between the speakers in each pair. Global convergence tendencies were proven to be weak but some influence of dialogue settings and gender was found. The results seem to support the hypotheses that the alignment-related processes remain under the influence of many factors related to the dialogue flow and cannot be modelled as simply incremental.

Index Terms: alignment, convergence, timing, dialogue, recording scenario

1. Background and previous studies

It is generally agreed that participants of dialogue tend to mutually accommodate, align and converge in various domains [1,2] that include the phonetic level of utterances [3,4,5,6,7], lexicon and syntax [8], postures, gestures and facial expressions [9,10,11] and, ultimately, mental models of situations [2,12].

Alignment is sometimes viewed as an almost automatic process based on priming [13] but it may be well driven by conscious communicative strategies [14]. Increased alignment has been shown to predict better communication efficiency, outcomes, and, presumably, better results of common task solving [15,16,17]. On the other hand, convergence has its limits: when mimicry goes too far it may result in the impression of parody. Moreover, in many communicative situations alignment may not work as a fully symmetrical process of increasing convergence between speech parameters of dialogue participants. Due to a higher social position, more assertiveness or some other factors, one of the dialogue parties may become the leader, while the other may decide to take a more subordinate role just not to inhibit the flow of communication [18].

The temporal aspects of dialogue interaction early attracted the attention of researchers, especially on the grounds of conversational analysis, where the precision in the arrangement of turn-taking has been often stressed [19]. More recently, formal approaches to turn-taking modelling have become more influential [20,21,22] and some more light has been shed on turn-boundary phenomena [7]. A number of studies have been devoted to the convergence of phonetic and especially of prosodic parameters of speech between conversational partners [23,4,24,25,26,28]. Nevertheless, many other aspects of the prosodic and temporal dynamics of dialogue remain less explored or, although extensively analysed, they still require more empirical evidence. Speech rate interdependencies in dialogue have been analysed in a limited number of studies, e.g. [3,5]. This type of prosodic alignment may be highly sensitive to various phenomena typical of spontaneous communication (hesitations, repairs, pauses, etc.) as well as the characteristics of the communication situation (external distractors) that can easily distort or disrupt it.

2. The aim of the study

According to the results of the abovementioned studies, the parties of dialogue tend to align locally or globally, and this process may also include convergence in the temporal domains, e.g., in the domain of speech rate and speech rhythm irregularity. The aim of the present study is to explore this type of convergence in the recordings of two types of Polish task-oriented dialogues (mutual visibility vs. lack of mutual visibility). Speech rate changes and speech rhythm irregularities may reflect important aspects of dialogue flow, including various dialogue fluency stages as well as task realisation stages and, in general, the quality of dialogue interaction [29].

3. Data and analysis

3.1. Recordings, segmentation and transcription

The recordings of task-oriented dialogues come from two Polish corpora: DiaGest2 corpus [30] and the Paralingua corpus [31]. Altogether, we analysed data based on the recordings of 40 voices, 20 from each of the corpora: 15 female speakers and 5 male speakers from the DiaGest2 corpus; 12 females and 8 males from the Paralingua corpus. All the recorded sessions were either conversations of two female speakers or a male and a female (no dialogues between two male interlocutors). In the DiaGest2 corpus, the task of the participants resolved itself in re-creating a figure made of paper by one of the participants (Instruction Follower, IF) according to instructions by the other (Instruction Giver, IG).

Only IG could see the original figure. IF was provided with all the materials necessary to re-construct the figure. IG and IF could see each other. All the IFs were females while there were five females and five males among the IGs. The speakers were given a time limit of 5 minutes to solve the task. The recordings from the Paralingua corpus dialogue were obtained based on a dialogue task in which the speakers were asked to find the differences between two pictures of a room. The task was to co-operate with the interlocutor in order to find as many differences as possible in the shortest possible time. The major differences between the tasks in DiaGest2 were the asymmetry (DiaGest2) vs. symmetry (Paralingua) of speakers' roles and mutual visibility (DiaGest2) vs. the lack of mutual visibility (Paralingua).

The material used for the present study was segmented into syllables. It was transcribed orthographically on the word level of segmentation and phonemically on the syllable level. Filled pauses were marked on a separate tier. Two software tools were used for transcription and annotation: Praat [32] (annotation and transcription of the DiaGest2 corpus) and Annotation Pro [33] (annotation and transcription of the Paralingua corpus as well as further annotation-mining and analyses of both corpora).

3.2. Analysis of speech rate changes and syllable duration variability

The data were explored using a "moving time window" approach, where a selected parameter was measured and averaged for each speaker within the window that was moving along the time axis. A similar method was used in [5,34] where additionally weights were used in the formula applied to measurements of accommodation of various acoustic/prosodic features, e.g., pitch, intensity or speech rate (thus using a weighted mean, where the interval durations were the weights). Four different window sizes were tested (5, 10, 30 and 60 seconds) in order to choose the optimum one, while the step was calculated as a proportion of the window size (33% in each case). Extremely narrow ones resulted in a substantial number of empty frames (i.e., not including any speech on one or both sides of the conversation) and thus did not support time-aligned analysis of dialogue turns. Applying very wide time windows helped to avoid this issue but, on the other hand, it might have concealed small-scale phenomena. As a consequence, the time window size was a result of a compromise. For most of the below calculations, the size of 30 seconds was applied as the smallest one that allowed to avoid empty frames.

Two timing-related parameters were taken into account. A "net" measure of speech rate (henceforth *NSR*) was calculated as the number of syllables within a time window (including those partially contained in the window as the respective fractions and excluding all kinds of pauses) divided by their total duration. Additionally, using a similar "moving time window" approach, a syllable-based *nPVI* (henceforth *snPVI*) [35] was calculated for each time window and each speaker in the dialogues under study. In case of the segments partially contained in a given window, their total durations were used in the *nPVI* formula. The *nPVI* was used with syllable-sized segments; cf. [36,37,38,39] as regards the definitions and plausibility of basic units for the analysis of pairwise variability.

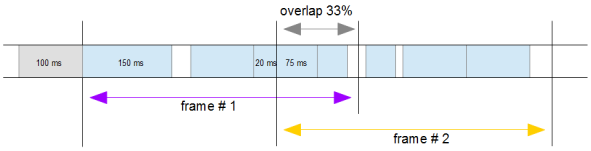

Figure 1. Segment rate moving average scheme

The transcripts prepared in Praat were converted to Annotation Pro native format and processed further using two Annotation Pro plug-ins specifically designed for the abovementioned calculations of *NSR* and *nPVI* (available from http://annotationpro.org/plugins/).

The results were exported as CSV files and analysed using SPSS statistical package (IBM Corp., 2012). Analyses included descriptive statistics calculated for all the speakers and dialogues, and regression analyses as well as some others, inspired by the data themselves.

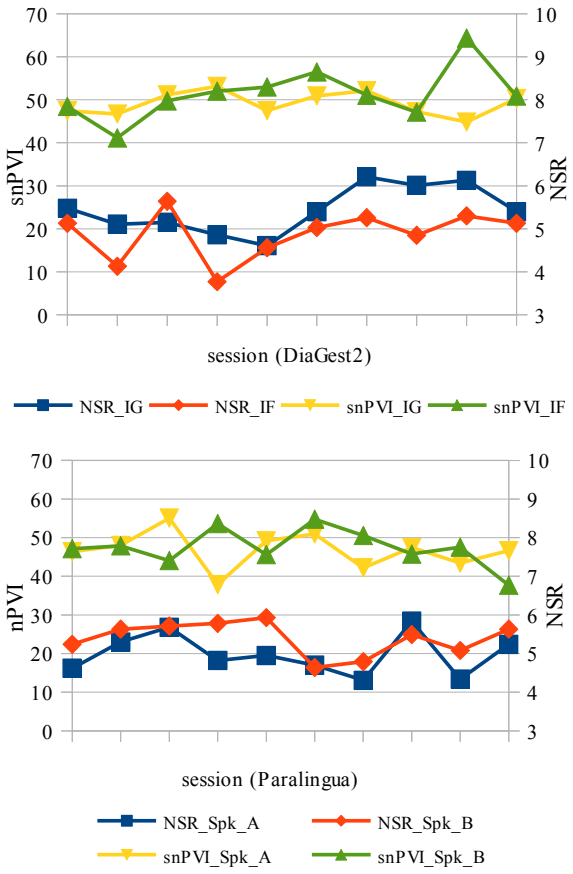

Figure 2. Mean normalised speech rate and mean snPVI for DiaGest2 (upper panel) and Paralingua (lower panel) dialogues

3.2.1. Speech rate analysis

The mean values of *NSR* calculated from 30-second time windows 5.23 (std.dev.=0.93, range=1.2–8.4) for DiaGest2 and 5.13 (std.dev.=1.01, range=3.2–7.4) for Paralingua. The difference between the mean values of the NSR for the two data sets turned out to be non-significant at p=0.05. DiaGest2 data were analysed additionally to test the difference between IG and IF speech rate (using Student's t-test). For the

difference was significant for both the 30-second time windows (IG mean=5.43, std.dev.=0.99; IF mean=4.88, std.dev.=1.19; p>0.0001) and the 60-second time windows data (IG mean=5.51, std.dev.=0.72; IF mean=4.92, std.dev.=0.86; p>0.0001).

Linear regression analysis was carried out for the data based on 10, 30 and 60 second time windows. While for the smallest window size no significant results have been found in the two corpora, with a 30 second window, four significant results of regression analysis were found in the DiaGest2 data and one in Paralingua. For the 60 second window, one significant result of regression was found in each corpus.

Significant results for the 30 second time window were found in dialogues 2 (R=0.314, p=0.024), 6 (R=0.629, p<0.001), 8 (R=0.415, p=0.007) and 9 (R=0.39, p=0.013) from the DiaGest2 data and dialogue 12 (R=0.432, p=0.006) from the Paralingua corpus. The significant results for the 60-second frame were found in different dialogues: dialogue 3 (R=0.617, p=0.021) from the DiaGest2 corpus and dialogue 7 (R=0.983, p=0.008) from the Paralingua corpus.

The results may suggest that alignment, understood as linear correlation between the speech rates of interlocutors, occurres rarely in this kind of task dialogues. On the other hand, when the phenomenon takes place, the correlation is very strong (98% in dialogue 7 from the Paralingua data) or medium (40%–60% in the other dialogues). Moreover, local alignment (30-second time window) occurred more often, than the global one. In this data alignment occurred more often in dialogues which participants had different roles (IG and IF). Although IF's speech rate showed a global tendency to be lower, the difference did not prevent the occurrence of alignment, but might even encourage it.

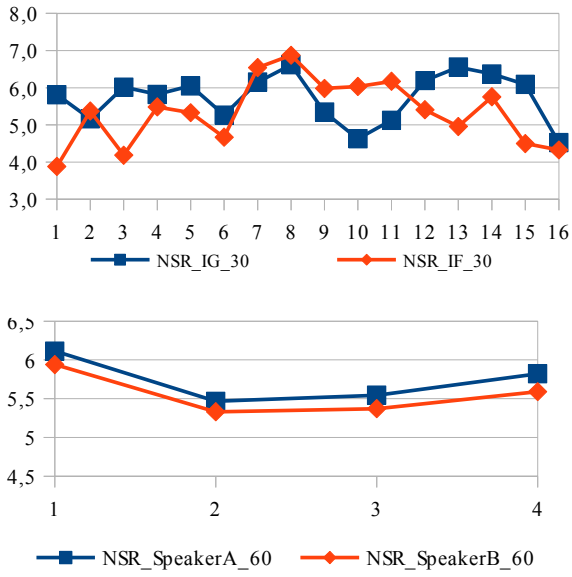

Figure 3. *NSR* changes in dialogue 6 from DiaGest2 corpus (30 second window; upper panel) and in dialogue 7 from Paralingua (60 second window; lower panel)

An additional Chi-squared test was used to test the hypothesis that alignment would be more frequent when interlocutors are of different sex. Significant and strong results were found for the DiaGest2 data alone (Pearson's chi-squared=23.333, p<0.001) in contrast with non-significant results for the Paralingua data (Pearson's chi-squared=1.667, p=0,4). The results were not significant for the 30-second time window data including both DiaGest2 and Paralingua results (Pearson's chi-squared=3.3, p=0.069). In DiaGest2 data three occurrences of alignment were found between participants of different sex (out of five mixed pairs), and only one (dialogue 2) in a dialogue between two women. This may suggest that there is a higher probability of the occurrence of the local alignment between interlocutors of different sex. When it comes to the 60-second time window, the two cases of alignment found occurred in dialogues between two women (due to the small number of alignment occurrence no Chi-squared test was performed). This result may suggest further differences between local and global alignment.

3.2.2. The analysis of snPVI

The mean value of *snPVI* (30-second time window) equalled to 50.6 (std.dev.=8.8, range=20.4–80.30) for DiaGest2 and 48.2 (std.dev,=6.1, range=35.2–70.1) for Paralingua. The difference between the mean values of *snPVI* between the DiaGest2 and Paralingua data turned out to be statistically significant at p<0.01. DiaGest2 data were analysed additionally to test the difference between IG and IF speech rate. For the difference was significant for the 30-second time windows (IG mean=49.22, std.dev.=6.58; IF mean=51.41, std.dev.=11.84; p=0.041) but non-significant for the 60-second time windows data (IG mean=48.27, std.dev.=9.15; IF mean=49.73, std.dev.=12.69; p=0.39).

For the values of the *snPVI* linear regression analysis was carried out for each pair of speakers using 30 and 60 second time windows. Results were found significant (p<0.05) for two pairs for each size of the time window in the DiaGest2 data and for three pairs at 30 second time window in the Paralingua data set.

The significant results for 30-second window were found in dialogues 6 (R=0.306, p=0.026) and 10 (R=0.338, p=0.014) from the DiaGest2 data and dialogues 2 (R=0.502, p=0.022), 14 (R=0.896, p=0.004) and 15 (R=0.816, p=0.005) from the Paralingua data. The significant results for the larger time window were found in dialogues 6 (R=0.86, p<0,001) and 7 (R=0.631, p=0.011) from the DiaGest2 data.

Again alignment occurred rarely, but the correlations were often medium (dialogue 2 from DiaGest2) or strong. Only two weak correlations were found within the local time window data (dialogues 6 and 10 from DiaGest2). Like previously, local alignment occurred more frequently than global and there was more alignment in the DiaGest2 corpus. The difference in the mean *snPVI* between IG and IF participants has disappeared for the 60-seconds time window data but prevailed for the local data.

Significant results (the occurrence of alignment) were found in dialogue 6 from the DiaGest data for both measures for the local time window, and in both windows for *snPVI*. This dialogue seems to be exceptional, since all the other dialogues show alignment only once across all the analyses.

Chi-squared tests were also performed for the *snPVI* alignment results. Significant results were found for the DiaGest2 data (Pearson's chi-squared=25.0, p<0.001 for 30-second frame, Pearson's chi-squared=25.0, p<0.001 for 60-

second frame). The results are the same, since alignment occurred in both cases within two mixed pair dialogues.

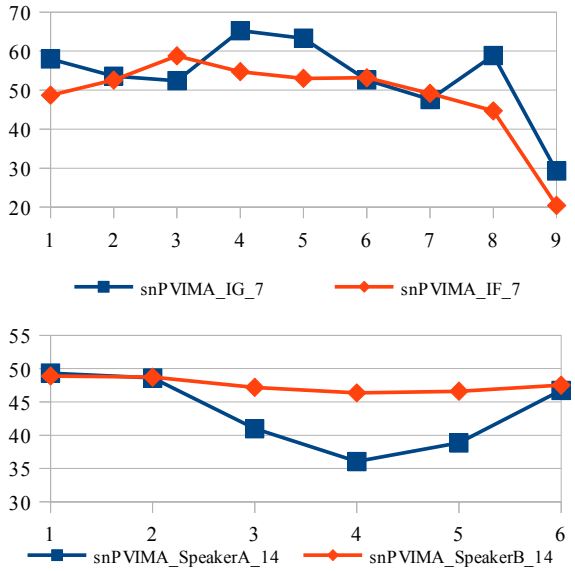

Figure 4. *snPVI* changes in dialogue 7 from DiaGest2 corpus at 60-second time window (upper panel) and in dialogue 14 from Paralingua corpus at 30-second time window (lower panel)

The results were not significant for the data from both corpora analysed together (Pearson's chi-squared=1.818, p=0.479 for 30-second frame, Pearson's chi-squared=2.716, p=0.127 for 60-second frame) or the Paralingua data separately (Pearson's chi-squared=1.27, p=1.0 for 30-second window). Results obtained from the DiaGest2 data may suggest a correlation between interlocutors sex and the probability of alignment. This suggestion may be strengthened by the fact, that two, out of three cases of alignment from the Paralingua data occurred in mixed pairs. However, the test results were non-significant for the whole data.

4. Conclusions and further work

In the present study, an attempt was made to explore and detect inter-speaker convergence in the dimensions of speech rate *(NSR)* and syllable timing pairwise variability *(snPVI)*. According to Kousidis [34], alignment in task-oriented dialogues may be much more difficult to detect. Nevertheless, such attempts have been made, e.g. [28], although results are not always clear-cut.

The overall speech rate means observed for both of the analysed corpora are similar (5.23 vs. 5.13 syll/sec) although the min-max range appeared to be wider in the DiaGest corpus (the overall rates are also in line with the rates for Polish normal reading rate [39]). Malisz [40] reported a higher overall mean around 6.9 syll/sec for Polish dialogues but using only fluent and coherent utterances with no unintelligible parts, false starts or hesitation markers while in the present work all utterances were used with the only exception of the segments labelled as filled pauses that were arbitrarily excluded from the analyses.

The results may suggest that the SR co-variability may be prevalently a local phenomenon that tends to occur most clearly within homogeneous, fluent stretches of conversation and may work very quickly and precisely as in the case of syllable boundary alignment [7]. On the other hand, it does not exclude the possibility of long-term, more permanent speech rate and syllable length variability accommodation even in the participants of task-oriented dialogues [23,34]. Verification of this claim, however, requires studies on larger corpora so that less prominent tendencies can be detected.

The influence of participants' gender on the level of *NSR* and *snPVI* convergence was also investigated. The results for the DiaGest data are coherent with Street's observations [3] and show less convergence in female-female pairs. As no influence was observed in the Paralingua data, one may hypothesize that the results may be somehow related to the mutual visibility condition. However, the factor of mutual visibility may somehow account for worse results in the timing-related convergence independently of gender matching.

In the DiaGest2, more manual activity (re-contructing a figure made of paper) was necessary while in Paralingua task, the participants had to scrutinize images (in order to find differences). It is difficult to judge which of the tasks tended to consume more attention and re-direct it from the partner to an object.

The differences in the overall ranges of *NSR* and *snPVI* might reflect the discrepancies in timing strategies applied depending on the presence or absence of "symmetry" in the task-solving roles. These observations are aimed to be further investigated also using other methods of syllable duration analysis, e.g. those accounting for deceleration/acceleration patterns [41,42] as well as more detailed analysis of pausing schemes. Note that although filled pauses were excluded from the present computations, it was observed that in DiaGest the number of pauses was considerably higher for IGs than for IFs while in Paralingua the number of pauses produced by the interlocutors was similar even though the total number of pauses was similar in both corpora. This, however, also requires further analyses as the proportion of the total speaking time between the dialogue participants should be taken into account.

Further research will include the analysis of alignment of timing-related phenomena in shorter stretches of speech between major changes of the conversation stages or topic shifts, fluency breakdowns and other phenomena that may significantly influence (hinder) the process of alignment between speakers.

Acknowledgements

Recording of the Paralingua database was supported from the financial resources for science in the years 2010–2012 as a development project (O R00 0170 12). DiaGest2 corpus comes from DiaGest2 project (N N104 010337, 2009-2010).

Speech and song synchronization: A comparative study

Beatriz Raposo de Medeiros[1], *Fred Cummins*[2]

Abstract

Does synchronization among speakers or singers require the presence of a beat? Is an implied underlying pulse or meter relevant? We set out to explore synchronization among speakers and singers as they speak or sing a variety of texts. We compare metrically strong nursery rhymes with non-metered prose. We compare singing in genres with two very different types of rhythm (samba and rock), and we compare sung and spoken versions of texts. In each case, we ask whether the rhythmic qualities of the texts facilitate synchronization. The metrical structure of the nursery rhyme does not facilitate synchronization compared to prose, while the simple beat of rock music does help. Further comparisons are provided in the text.

Index Terms: synchronous speech, song, syncopation, stress timing

1. Introduction

The ability of speakers to synchronize when reciting a common text is clearly seen in the ubiquitous practices of protest and prayer worldwide. Many such texts are over-practiced, as in the mantra-like repetition found in the Catholic rosary, or the texts are very short and are repeated rhythmically, as in most protest chants. In the former case, over-practice may help to support synchronization as the temporal patterns, while somewhat irregular, become predictable by virtue of familiarity. In the second, the speech borders on the musical through the use of emphatic beats, and perhaps also simply through repetition, as in the speech-to-song illusion [1].

Studies of synchronization among speakers have hitherto used the kind of pragmatically vacuous text so familiar from such classic corpora as the TIMIT or CSLU speaker recognition corpora [2, 3, 4]. While these studies have revealed much about the formal characteristics of synchronized speaking, much remains to be explored in assessing the influence of one or other text type, and the influence of music-like regularities in the process of synchronization. The role of periodicity and meter in particular warrant attention, as most theories of the temporal control of action would suggest that periodicity is beneficial, or even necessary, for synchronization [5], and yet prior studies have verified that synchronization of speaking is possible in the absence of any demonstrable periodic structure [6, 4].

We adopt a stance with respect to speech that sees it as temporally structured, coordinated movement. In this, our explorations lie within a long tradition stretching back to Stetson who famously characterised speech as "movement made audible" [7]. We also adopt a dynamical perspective, viewing synchronization among speakers as a form of entrainment [8, 4]. If we use a relatively strict definition of synchronization as "doing the same thing at the same time", there are relatively few truly synchronized behaviours. These include military marching, some sports such as swimming, rowing, trampolining and diving, some forms of dancing, and music making in unison. All of these activities have at least one of the following two features, and some have both: There may be a clearly perceptible beat or isochrony to the behaviour, and/or the temporal evolution of the activity is strongly scaffolded by inertial, elastic, or gravitational constraints. Synchronous speaking, we note, not only frequently lacks overt periodicity, but it is also achieved in the absence of any such strong physical scaffolding [9].

While the use of a dynamical systems vocabulary provides us with a rich set of tools for approaching such coordinated behaviour within and between speakers, it leaves us with something of a conundrum, as synchronization among speakers can take place in the absence of any clear periodic structure [4], although, as noted, group chants frequently tend towards music-like repetition. We are therefore motivated to explore synchronization phenomena in which we vary the underlying temporal anchoring of the utterances, including utterances that are clearly periodic in underlying form, and those that are clearly non-periodic. To this end, we here explore both sung and spoken texts, with varying amounts of simple periodicity. A basic question we pose is whether periodicity actually facilitates synchronization, as a common-sense intuition suggests it ought.

The work presented here examines synchronization among speakers as we vary the speech material being spoken. In a first comparison, we look at synchronization of metrically regular versus metrically irregular speech, using a prose text and a nursery rhyme as central examples. In the second comparison, we use songs, shorn of accompanying music. We compare the synchronization in samba with synchronization found in rock. We also obtain spoken versions of the sung texts to allow a direct comparison of speech and song.

In surveying the large and poorly mapped lands between speech and song, this study is necessarily exploratory in spirit. The essential questions to be addressed are these:

- Will synchronization be facilitated by the presence of strong metrical structure in spoken texts (Nursery rhyme versus prose)
- Will rhythmic complexity affect the degree of synchronization observed (rock versus samba)
- Will synchronization be facilitated by the presence of an underlying, implied, musical beat (singing versus speaking)

2. Different Types of Speech

Four types of source text in Brazilian Portuguese provide the material of this study: one prose text, a nursery rhyme, a samba song and a rock song. The text in prose was extracted from a

novel (*Um Sopro de Vida (A Breath of Life)*, by Clarice Lispector) and was chosen for possessing short and long sentences, as well as short and long words and topicalization, aspects commonly founded in oral speech. Prose's principal feature is to offer an irregular sequence of accents without any metrical structure. We use a nursery rhyme as a form of poetry in which metrical structure is more regular and in which beat expectations are maximally strong. Nursery rhyme recitation in group is a very common situation in infant-caretaker play in many cultures.

As regards the songs, we chose two different rhythmical types: a rock song (*Aluga-se*) and a samba song (*Preciso me encontrar*)[1]. For each song we obtained both a sung version and a spoken version, in order to see whether the musical meter would facilitate synchronization. We perceive, intuitively, that the rhythm of samba differs from that of rock, marking them as quite distinct. We refer to the rhythm of samba as syncopated, which positions the genre within a family of Latin American rhythms (e.g. salsa, habanera). In the case of rock, syncopation is not obligatory, and even, in some cases, this is not desirable (e.g. heavy metal).

Singing is understood in the present study, as well as in a previous study [10], as a specific variant of speech we can call sung speech. Despite being relatively rare among linguistic studies, comparisons between singing and speaking can raise interesting questions about how apparently very different systems, such as language and music, fuse so well in song.

3. Singing as a Type of Speech

Singing is a ubiquitous phenomenon, though its function can greatly vary among human groups. Popular song is widespread in Western culture and, broadly speaking, is consumed as entertainment. In the particular case of Brazilian song, there are many types of songs that could be categorized by theme or rhythm, however the present study will focus on only two types: samba and rock. Popular song is the most prevalent genre in Brazil and is profoundly integrated into everyday social life. It is no overstatement to say that the song is Brazil's music. A typical feature of several types of Brazilian song is singing together: From the very popular rural work songs to the urban *rodas de samba*[2]. The first samba composers, those from the early 20th century, did not have any formal musical education, and so did not read or write scores. Samba composition was oral, writing down only the lyrics and repeating the melody many times in order to memorize it. Some Brazilian song scholars have suggested that the melody of samba bears the hallmarks of the intonation patterns of Brazilian Portuguese, though this remains largely untested. It is a point we revisit in the discussion.

Singing is a kind of hybrid phenomena in which speech and music meet. The songs chosen for use in this study are from two different rhythmic genres: samba and rock. Despite their differences, both genres allow an easy fusion of text and music. The principal difference lies in how the rhythmic phrases in these songs are related to the underlying stream of pulses, as discussed in the next section. Comparisons between speech and singing may shed a light on both segmental and prosodic characteristics of speech, showing how musical constraints adapt to language constraints and vice-versa [11, 12, 10, 13]. In this sense, it appears entirely plausible to consider the song a kind of speech.

[1]The rock song *Aluga-se*, by Raul Seixas and the samba song *Preciso me encontrar*, by Candeia are very popular in Brazil.

[2]*Roda de Samba*: name given to a *samba* session, where people sit in circle or around tables, playing instruments and singing together.

Fig. 1 illustrates some of the radical temporal differences found between the sung and spoken manifestations of the same text. The extreme prolongation of the final word only makes sense within a musical context.

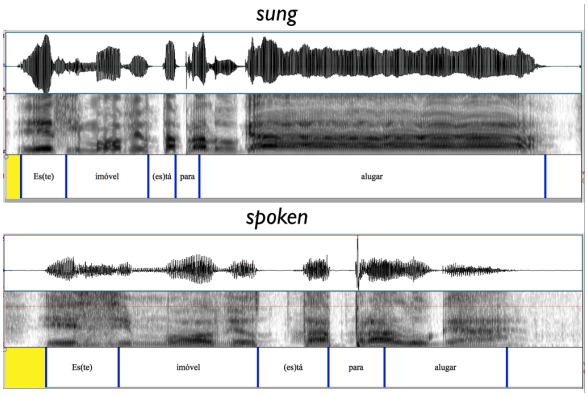

Figure 1: Samples of sung (top) and spoken (bottom) utterances from the rock song. Timescales differ between panels.

3.1. Different Song Rhythms

In our exploratory study here, we consider the relation between speech timing and metrical structure in both a poetic and musical context. Furthermore, we enrich the exploration of the relation between speech and musical rhythm by considering two types of musical rhythm: a simple 4/4 rock rhythm and a more complex samba rhythm.

A samba meter typically uses two beats per measure, and is thus a binary rhythm. When samba is transcribed, the conventional time signature is 2/4. Around these two beats, an off-beat system is built that is traditionally and commonly known as the samba syncopated rhythm. Specifically, there is a recurrent accent displacement that prevents a note from aligning with the second beat of the bar. This shift is caused by an sixteenth-note (semi quaver) of short duration that occurs just before the second beat, extending into and beyond the second beat. Another possible (and very frequent) accent shift is created by a bar-final sixteenth-note elongated and extending into the beginning of the following bar. Both accent shifts may be seen in Bar 3 of the score in Fig. 2.

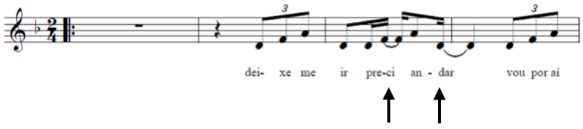

Figure 2: First four bars of Preciso me encontrar (*I need to find myself*). Brazilian *samba* by Candeia. Bar 3 depicts the typical rhythmic gestalt of samba and two common kinds of accent shifts.

As with other syncopated rhythm structures found in music, samba off-beats, as shown here, constitute the scaffold of a complex rhythm, as it can be characterized as shifting the initially proposed accent in a very specific way. There is some controversy as to whether the accent shifts found in Brazilian music stem from an African origin, or whether they are better

understood as a Westernization of the complex polyrhythms of the African sources [14].

It would be overly simplistic to describe rock rhythms as non-syncopated. Syncopation is not unusual in rock. It is a well-known and salient characteristic of related genres such as ska and reggae, and is found to some degree in many mainstream examples of rock music [15]. However, a great deal of rock music displays a fixed 4-beats-to-the-bar meter, in which musical notes are aligned with the beats, strong accents occur in metrically strong positions, and the position of the beats is clearly signalled by the drum track (See Fig. 3). Where samba has an obligatory syncopation, it remains a stylistic option in rock.

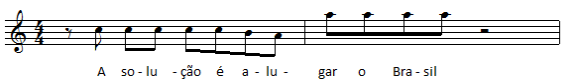

Figure 3: First two bars of Aluga-se (*For rent*). Brazilian rock by Raul Seixas.

4. Methods

Ten dyads were recorded, of which five were all female, three were male-male, and two were mixed sex. Subjects were aged between 25 and 45. All subjects reported no known problems with speaking or hearing. All were self-professed competent singers, and all were native speakers of Brazilian Portuguese.

Six texts provided six different experimental conditions. Texts are described in Section 2 above, and include a nursery rhyme, a prose excerpt, a sung samba song, a sung rock song, and spoken versions of the samba and rock lyrics. For each text, subjects were recorded in pairs, and were asked to remain in synchrony with one another. Choice of key and tempo was left to the subjects themselves. All singing/speaking was unaccompanied by music or an overt beat of any sort. Prior to recording, subjects signed an informed consent and read a text in prose (not recorded) in order to practice. Recordings were made using head mounted microphones (Shure SM10A) connected to a Marantz (PMD 661). Subjects stood facing each other inside the booth (Whisperroom 4872S) 1.3 meters from each other and began speaking/singing after the words "One, two, three. Ok" said by the researcher.

All recordings were segmented into sentence-length units: 7 for prose, 6 for the nursery rhyme, 13 for samba (sung and spoken) and 18 for rock (ditto). All 750 dyadic recordings were used in the subsequent analysis. The longest sentence belonged to prose, containing 36 syllables, and the shortest sentence was a rock verse, having 4 syllables. None of the sentences exceeded 11 seconds in duration.

A quantitative estimate of asynchrony was computed for each sentence using the method introduced in [4]. Two time aligned utterances are compared. Each is first represented as a sequence of Mel-Frequency Cepstral Coefficients. The sequences of MFCC vectors are then subjected to time warping, and the amount of warping necessary to map one utterance onto the other provides a quantitative estimate of the asynchrony between them. The measure is normalised by the number of time windows in the sequences, so that asynchrony values for shorter and longer sentences are comparable. The algorithm has been found to be most reliable when the calculation of the amount of warping, as indexed by the area under the warping curve, is restricted to voiced portions of the speech [4].

5. Results

Asynchrony values are not distributed normally, but are skewed right, due, in part, to some relatively large outliers. All asynchrony values were therefore first log transformed. Fig. 4 shows the distribution of asynchrony scores for the six conditions. The units of the asynchrony calculation are derived from the area under the warping function.

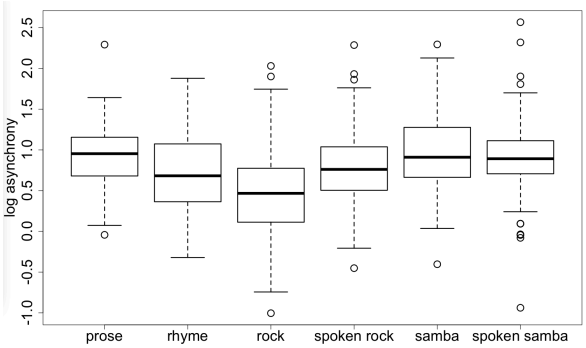

Figure 4: Boxplot of the distribution of log-transformed asynchrony scores for six different texts.

We are interested in specific planned comparisons that are of theoretical interest. The choice of comparisons is driven by our curiosity about the role of an underlying beat which may be pronounced and unambiguous (rock, nursery rhyme), present but subtle (samba) or absent (prose). Furthermore, we have available to us a comparison between sung and spoken lyrics within each genre. For each comparison, we conduct a simple t-test, and all t-tests are subject to a conservative Bonferroni correction to protect family-wise error rates.

The first comparison of interest is between prose and the nursery rhyme. Unexpectedly, the small difference in asynchrony observed between these two conditions was not significant (t(116)=2.4, n.s.), so there was no clear benefit of the regular meter in the nursery rhyme compared to the prose.

The next comparison examines synchronization in the sung versions of the rock song and the samba. Here, there is a marked difference. t(294)=8.1, $p < .001$. As expected, synchronization is greater in the rock condition than the samba, though we withhold interpretation of these results until the discussion.

The rock song was both sung, and spoken. The difference between these two is also highly significant, and as expected, synchrony is greater in the sung version. t(345)=5.8, $p < .001$. A similar comparison for the samba did not yield any difference between the sung and spoken conditions, however. t(255)=1.0, n.s.

A final comparison was done to look at the two conditions that contain the clearest metrical structure: the sung rock song and the spoken nursery rhyme. Here, a small difference was significant after correction of the p-value: t(118)=3.4, $p < .05$. Synchrony was greater for the rock song than the nursery rhyme.

6. Discussion

A naive assumption that we set out to test is that periodicity, overt or implied, would facilitate synchronization among speak-

ers/singers. Although this hypothesis seems to be entirely in accord with common sense, there is room for doubt. The remarkable ability of speakers to synchronize in the absence of any overt or implied periodicity has now been well documented [6, 4]. Most strongly synchronized activities that humans engage in make use of external constraints to facilitate synchronization, and these take the form of a regular pulse and/or the structuring of the behaviour through the presence of strong inertial or gravitational constraints [9]. Synchronous speech exhibits neither property, while singing without musical accompaniment, as here, makes use of an implied beat.

To start with the spoken domain proper, we were somewhat surprised to find that the regular meter of the nursery rhyme did not seem to facilitate synchronization compared with prose reading. This result is consistent with past findings that speech synchronization does not require periodicity, but is at odds with the simple hypothesis that periodicity will necessarily facilitate staying in time with one another.

The picture changes when we compare rock to samba. Now the strong and clear periodicity underlying the rock produces a clear advantage compared with the more fluid and complex rhythms of samba. The underlying musical pulse also ensures that the sung rock is considerably more synchronous than the spoken version. The same comparison for the samba yields no advantage at all for the musical, sung version.

Song lyrics are conventionally sung, and embedded within the temporal structure of the song. It is possible that asking singers to speak lyrics instead of singing them may generate some confusion as to just how much of the musical structure to reproduce. For example, Fig. 1 shows a sung phrase in which the final word is massively prolonged. Subjects may have been uncertain about whether to reproduce such temporal effects in speaking. One might argue that any such uncertainty due to the instructions ought to influence rock and samba productions alike, and this is clearly not the case. However an alternative account might argue that there is a more intimate link between the rhythms of samba and those of speech, so that the kind of gross temporal exaggeration found in rock (see Fig. 1) is less likely to occur. While it does not settle the matter, the present investigation opens a potential empirical route of approach to such a discussion.

Both the sung rock text, and the spoken nursery rhyme text are metrically structured, yet the presence of an underlying meter does not facilitate synchronization in the same way for the two genres. Further investigation of the differing manifestations of temporal structure in speech and singing will have to be sensitive, not only to meter, but also to the conventions of the genre. Nursery rhymes, it appears, belong squarely in the speech camp where temporal expectations are very different from the musical domain.

The sampling of texts presented in this study is neither comprehensive, nor even representative of the many differentiations one could make in the grey area between speech and music. However, they are sufficiently diverse to illustrate some important characteristics of the relation between overt temporal form and underlying metricality and structure. Perhaps the clearest message to be gleaned is that periodicity by itself is neither essential to, nor required for, highly synchronized coordinated movement among simultaneous speakers. Much of the legacy treatment of rhythm in the study of human behaviour has tended to conflate the distinct concepts of periodicity and rhythmicity, to the extent that the mere presence of periodicity in an observed phenomenon is oftentimes sufficient for it to be labelled "rhythmic". But the rather ill-defined concept of "rhythm" is called upon to do duty in many contexts, from the mysterious oscillations found deep within brains to the aesthetic gyrations of pairs of dancers. From what we have seen here (and elsewhere), it is apparent that the term rhythm picks out quite different things in different domains. The rhythmicity of a nursery rhyme is not the same as that of a rock song, or a samba song, which are, again, mutually distinct. The coordinative relations observed in the temporal signatures of these diverse behaviours must be understood with respect to the skills shared by performers, the conventions of specific genres, and perhaps also the nature of the bond between practitioners.

Abstract

Languages with primarily delimitative function of word stress commonly make use of accentual phrases (APs) in their intonational phonology (e.g. Tamil or French). Slovak and Hungarian are genetically unrelated but geographically close languages with word-initial lexical stress. In this paper we compared the stylised f0 of single accent groups (AGs) with the f0 level pattern of the entire intonational phrase (IP) to test if AGs are relevant for the intonational phonology of Slovak and Hungarian. Steep f0 slopes with a recurring pattern (rising or falling) and large deviations from IP level patterns were interpreted as evidence for the autonomy of the AG in the given language. The results suggest that in Hungarian, accent groups form an independent unit with a falling pitch contour. Such evidence was not found for Slovak.

Index Terms: prosodic phrasing, accentual phrase, intonation modelling, Hungarian, Slovak.

1. Introduction

Most prosodic models [1, 2, 3] assume that the highest prosodic unit is the intonational phrase (IP) that is marked by final and potentially initial boundary tones (or edge tones), phrase-final lengthening and an optional pause following the phrase. Other models subordinate the IP to a higher-level unit, such as the utterance, e.g. [4]. The smallest prosodic phrase is the prosodic word (PW). Two other units, the intermediate phrase (ip) and the accentual phrase (AP) are located between the intonational phrase and the prosodic word [5]. Whereas IPs and PWs are present in all languages, ips and APs are optional. (See [6, p. 444] for an overview of the presence or absence of certain prosodic units for a set of languages.)

Both Hungarian and Slovak have lexical stress on the left-most syllable of a prosodic word (apart from Eastern Slovak dialects with penultimate stress). In Hungarian, lexical stress is fixed to the first syllable, i.e. *INtonáció* 'intonation' (the "accent" sign marks long vowels and not stress). In Slovak, stress can be optionally moved from the word-initial syllable if the word is preceded by a preposition, e.g. *HOry* 'hills', *DO hory* 'to the woods'. Hence, Slovak lexical words may combine with preceding monosyllabic prepositions and possible clitics following this word into a prosodic word with left-most stress.

In Hungarian, pitch accents are typically realised within the initial syllable of the accented word. In Slovak, pitch targets might be aligned within or after the accented syllable, but it is not clear if this is due to phonological differences or phonetic implementation.

In languages with fixed stress towards the left or right edge of the word, stress is often used as the onset or offset of a prosodic phrase [5], while the other edge of the phrase is marked by a boundary tone. In languages in which sequences between two accents form an accentual phrase (AP), the edge tones often show a regular pattern. Tamil for example has phrase-initial L* tones and AP-final H tones (Ha).

[5] describe accentual phrases in the following way: (1) an AP can contain only one pitch accent, (2) there is a boundary tone at the other edge of the prosodic unit, (3) the edge tone is insensitive of stress, i.e. its realisation is independent of stress location, (4) APs are characterised by a recurrent rising or falling pattern depending on the language.

Given the observed correlation between fixed lexical stress position and relevance of AGs for the intonational phonology of a particular language, we investigate if left-headed prosodic words in Slovak and Hungarian also constitute a prosodic unit that is marked by tonal (f0) means. While initial efforts in building a ToBI system for Slovak prosody do not propose units below intermediate phrases [7], previous work on Hungarian suggests that pitch accents indeed initiate APs within intonational phrases [8, 9].

In left-headed accentual phrases, pitch accents are always preceded by a prosodic boundary and thus automatically function as an edge marker. This would explain the relatively frequent occurrence of pauses before accented words in unexpected positions in Hungarian, e.g. between a definite article and an emphasised noun [10]. In this case, the pause can be interpreted as an additional cue marking the phrase boundary and thus strengthening the emphasis on the pitch-accented word. Apart from our theoretical interest in the phrasal organisation of Slovak and Hungarian prosody, the function of the phrase types can help to gain a better understanding of underlying communicative intentions and also to enhance the effectiveness of speech recognition and the naturalness of speech synthesis.

The analysis presented here is based on the assumption that an accentual phrase has its own f0 slope in form of a rising or falling pitch contour, and that this pattern is independent of the overall pitch contour of the intonational phrase. Second, since APs are characterised by the frequent occurrence of the same pattern (e.g. rising pattern for French and Tamil), the frequent occurrence of a given pattern is interpreted as a further evidence for the presence of APs in the language.

2. Material and methods

50 Slovak and Hungarian spontaneous utterances forming a single IP were selected from collaborative dialogues (5 utterances

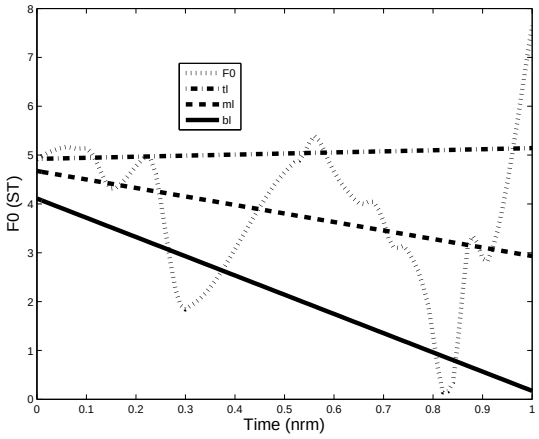

Figure 1: *Stylised top-, mid- and baseline.*

of 10 Slovak and 10 Hungarian speakers, respectively). All IPs had a low phrase-final boundary tone. Only IPs with at least two pitch accents were used for the analysis. Both IPs and pitch accents were identified manually by a phonetically trained native speaker (1st and 3rd author of this paper). Analysis was based on the f0 level and the range pattern throughout the IP and the accent group (AG), ranging from one accented syllable till the last unaccented syllable before the next pitch accent or the IP boundary. The Slovak material consisted of 157 accent groups and the Hungarian samples of 130 accent groups.

2.1. F0 extraction and preprocessing

F0 was extracted by autocorrelation (Praat 5.3, sample rate 100 Hz). Data were further processed in Matlab. Voiceless utterance parts and f0 outliers were interpolated by piecewise cubic splines [11]. The contour was then smoothed by Savitzky-Golay filtering using third order polynomials in 5 sample windows and transformed to semitones relative to a base value [12, 13]. This base value was set to the f0 median below the 5th percentile of an utterance and served to normalise f0 with respect to its overall level.

2.2. Stylisation

To capture the f0 register in terms of its level and range [14] we fitted a base-, a mid-, and a topline separately for the IP and all AGs within this IP (Fig. 1). The midline represents the f0 level, whereas the base- and topline provide the f0 range information. The robust fitting procedure that is motivated and explained in more detail in [15] consists of the following steps:

- A window of 200 ms length is shifted along the f0 vector with the step size of 10 ms.
- Within each window the f0 median is calculated
  - of the values below the 10th percentile for the baseline,
  - of the values above the 90th percentile for the topline, and
  - of all values for the midline.

  This gives 3 sequences of medians, one for the base-, the mid-, and the topline, respectively.
- Within each median sequence outliers are replaced by linear interpolation.
- Finally, for all three median sequences linear polynomials are fitted.

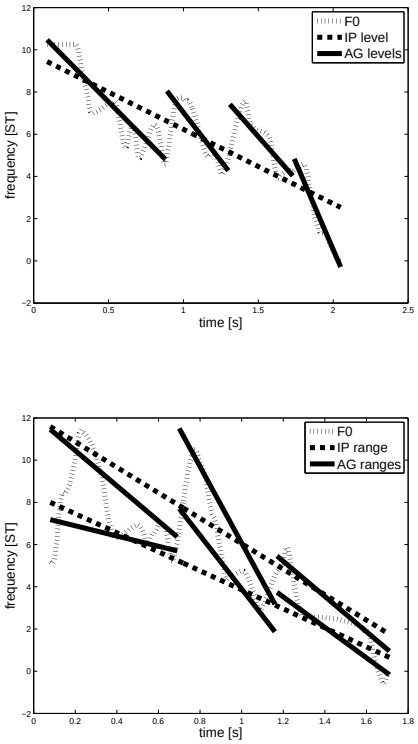

Figure 2: *IP and AG level (top) and range (bottom) patterns for Hungarian.*

2.3. Features

If accentual phrases play a role in the intonational phonology of a language, they should show a significant difference from the corresponding part of the intonational phrase in terms of local f0 level deviations and f0 ranges. In other words, the slope of the f0 midline of a given AP is supposed to be steeper than that of the IP, and the range larger than can be expected on the basis of the overall top- and baseline differences in the IP.

We extracted features to capture first the general AG register and second its deviation from the IP.

Level

For the f0 level, the AG pattern is represented by the slope of the fitted midline (*mlslope*), as shown in the left graph in Figs. 2 and 3. AG deviation was measured (1) with respect to shape in terms of the absolute slope difference of the AG and the IP midlines (*mlSlopeDiff*), (2) with respect to overall distance given by the root mean squared deviation of the AG line from the corresponding section of the IP line (*mlRms*, and (3) with respect to local differences by subtracting the corresponding values of the

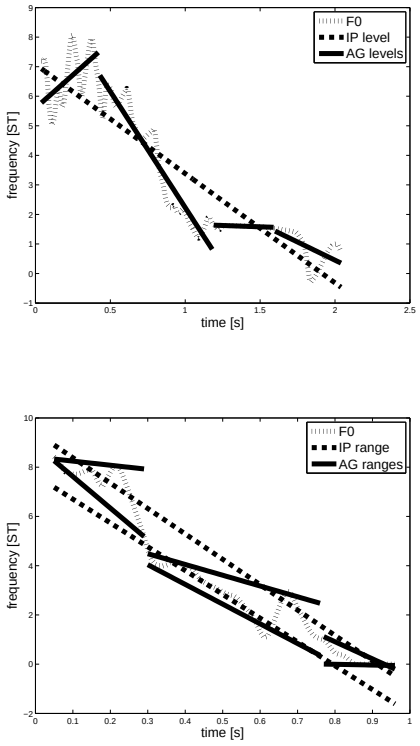

Figure 3: *IP and AG level (top) and range (bottom) patterns for Slovak.*

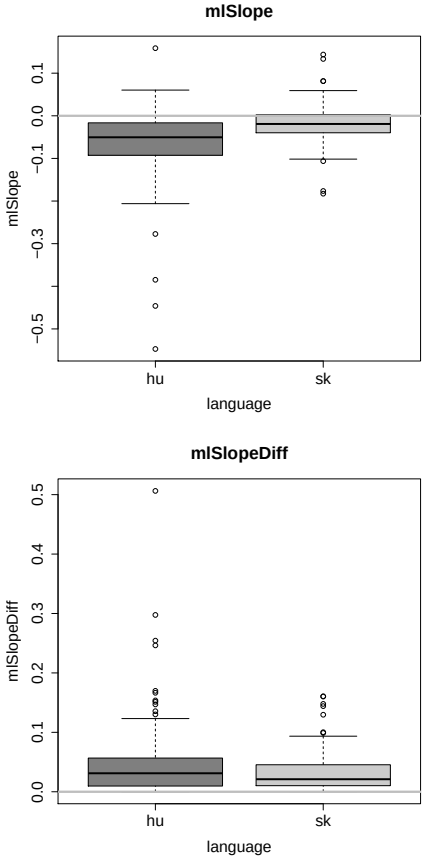

Figure 4: *Slope (mlSlope) and absolute slope difference (mlSlopeDiff) for Hungarian and Slovak. The grey line indicates 0.*

IP line from the initial and the final f0 values of the AG line (*mlInitYDiff, mlFinYDiff*).

Range

Next to level deviations, AGs can be set apart from their underlying IPs by the AG range, see the bottom graphs in Figs. 2 and 3. We thus measured the range of each AG in terms of the root mean squared deviation between its base- and topline (*rangeRms*).

The expected acoustic correlates for the presence of accentual phrases are prominent f0 movements reflected in high AG range values (*rangeRms*) as well as considerable local level deviations between the AG and the IP expressed in high values for the features *mlSlopeDiff, mlRms, mlInitYDiff*, and *mlFinYDiff*. Results were compared by means of t-tests. First, a one-sample t-test was carried out for the features for both languages, i.e. results were compared to a sample with $mean = 0$. Subsequently, Hungarian and Slovak samples were compared to each other. If the data were not normally distributed, the Mann-Whitney test was carried out instead. The equality of variances was tested by the Levene test that is also applicable to non-normally distributed data. Significance level was set to $p = 0.05$.

Languages with falling or rising APs are expected to have mostly negative or mostly positive slopes that differ considerably from the IP slope. At the same time, the onset and/or the offset of the AG slope is supposed to differ from the corresponding section of the IP. Additionally, larger overall distances (root mean square distances) and larger ranges demonstrate a greater autonomy of the AG as a prosodic phrase.

3. Results

3.1. Slope

The majority of slopes (*mlSlope*) was negative in both languages. Absolute slope differences (*mlSlopeDiff*) were larger for Hungarian (Fig. 4). Mean slopes and mean slope differences differed significantly from 0 in both languages, and also between the two languages. All differences were highly significant ($p < 0.0001$).

The overall distance (*mlRms*) between the AG midline and the corresponding IP section (Fig. 5) differed significantly from 0, but not between the two languages ($p = 0.24$).

3.2. Local initial and final AG–IP difference

The distance between the AG and the IP midlines was calculated both for the onset (*mlInitYDiff*) and the offset (*mlFinYDiff*) of the AG. Larger distances refer to a larger deviation and thus a larger independence of the AG midline. The distance was expressed in absolute values.

Both AG-initial and AG-final distances were significantly larger than 0 in both languages ($p < 0.01$) (Fig. 6). Onset

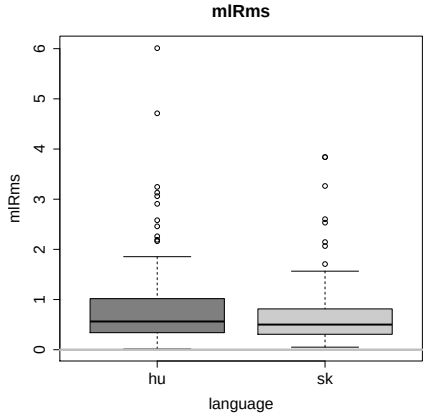

Figure 5: *Root mean square between the AG and IP midline (mlRms for Hungarian and Slovak. The grey line indicates 0.*

distances were significantly larger in Hungarian than in Slovak, whereas offset distances did not differ between the two languages.

3.3. Range

Finally, the range between the base- and the topline was compared for the AG. It was assumed that a larger range within the AG shows the autonomy of the AG as a separate prosodic unit.

Ranges differed significantly from 0, but not between languages ($p = 0.67$).

4. Conclusions

AGs show a falling pattern in both languages, i.e. their f0 slope is steeper than the IP slope. This tendency is more clear-cut in Hungarian than in Slovak. The onset and the offset of the AG slope deviate from the IP slope for both languages, while the distance of the onset is greater in Hungarian than in Slovak. F0 slopes in Slovak are rather flat, and the tendency for uniform patterns is not present. In other words, the findings do support the hypothesis that Hungarian prosody involves accentual phrases, but the evidence is less clear for Slovak.

One possible reason for the flatness of Slovak f0 slopes is that the AGs might have a non-linear pattern. As was said before, the f0 maxima of pitch accents are often delayed in Slovak which might cause a rising-falling pattern or be triggered by it. This option needs further testing by non-linear stylisation.

A future large-scale study will involve more languages without fixed lexical stress. This would allow to specify the interrelation of f0 slopes and prosodic phrases in a more detailed way.

Final devoicing of /l/ in Reykjavík Icelandic

Nicole Dehé

Fachbereich Sprachwissenschaft, Universität Konstanz, Germany

nicole.dehe@uni-konstanz.de

Abstract

Icelandic has a phonological process which devoices sonorants after voiced segments in domain-final position, but to date the category of the relevant domain and potential further factors affecting it have not been identified. The present paper studies final devoicing of /l/, by which /l/ is realized as the voiceless lateral fricative [ɬ] in domain-final position. It reports on the results of an experimental reading study designed to test the exact environments of this process and the implications for a prosodic hierarchy for Icelandic. The results suggest that devoicing of /l/ is bound by the prosodic utterance. All instances of /l/ were devoiced in utterance final position. Within the utterance, final devoicing is optional, but the frequency of its application reflects the syntactic and prosodic hierarchy such that it is most frequent at a clause/an IP-boundary, significantly less frequent at a syntactic XP-edge and it almost never occurs within a syntactic XP.

Index Terms: final devoicing, sonorant devoicing, Icelandic, prosodic hierarchy, /l/

1. Introduction

Icelandic has a phonological process which devoices sonorants "after voiced segments in phrase-final position" [1]. According to [2], this process is very common in modern Icelandic speech, indicates a break in the utterance and the end of a phonological phrase or utterance, and is likely to co-occur with a boundary tone (T%). According to [3], "phrase final devoicing in consonants is […] practically obligatory". The devoiced /l/ is phonetically realized as voiceless lateral fricative (rather than, for example, devoiced lateral approximant, e.g. [3]). Examples are given in (1) (from [4]).

(1) a. Jón er á bíl [ˈpiːl] í dag.
Jón is on car today (' John is driving today.')

b. Jón er á bíl. [ˈpiːɬ]

While this process has been described, for example, in the works mentioned above, its distribution has never been studied systematically and formulations such as "the end of (some sort of) a phonological phrase or utterance" [2] are very vague. At the same time, a prosodic hierarchy has not yet been established for Icelandic. For the level of the Intonational Phrase (IP), it has been observed that the tonal inventory of Icelandic has two boundary tones terminating the IP (L% and H%) and that the IP is the domain for declination ([5], [6]). As for a level between the prosodic word (PWd) and the IP (e.g. phonological phrase, intermediate phrase; see [7] for an overview of hierarchies suggested in the literature), conclusive evidence has not yet been provided. To date there is only preliminary evidence from the environment of another phonological process (word-final vowel deletion, see [8]) as well as preliminary evidence for phrase accents L- and T-, i.e. the edge tone of the intermediate phrase (see [6]), but more systematic research is necessary, especially regarding tonal events. The blocking and/or application of phonological processes have long been taken as evidence for the existence of categories in the prosodic hierarchy; e.g. Visarga in Sanskrit for Utterance level (see [9]), Italian Gorgia Toscana for IP level and Raddoppiamento Sintattico for ip level (see [10] for the latter two) to name but a few. The present paper reports on an experiment designed to test the environment of final devoicing of /l/ in Icelandic and the implications for a prosodic hierarchy in Icelandic.

2. The experiment

A reading task was designed to produce data on final /l/ in different positions. Four contexts were considered: utterance-final, clause-final, XP-final and XP-internal. The clause-final context was chosen because according to current prosodic theory, a clause in the syntactic structure is predicted to coincide with an IP in the prosodic structure (see [11], [12]). Similarly, the XP-final context was chosen because an XP in the syntactic structure is predicted to coincide with an ip in the prosodic structure ([11], [12]). Neither IP- nor ip-boundary are predicted to occur XP-internally. Since a prosodic hierarchy has not yet been established for Icelandic on the basis of tonal and/or other kinds of phonological evidence, the target contexts were chosen according to these predictions.

All target words ended in /l/ after a vowel. As a rule, Icelandic word stress falls on the initial syllable. To control for the potential effects of lexical stress, target words were monosyllabic (stress condition) and disyllabic (non-stress condition). To control for the potential effect of the following segment and voicing assimilation, the target words were followed by vowels (voiced condition) or by voiceless fricatives (/s, f, θ/) and in two cases voiceless plosives (/p, t/) (voiceless condition). Example target words and some following units are given in Tables 1 and 2.

	Example target words
mono-syllabic	kál (/ˈkʰauːl/ 'cabbage', ACC-Sg)
	stól (/ˈstouːl/ 'chair', ACC-Sg)
di-syllabic	blómkál (/ˈplouːm. kʰauːl/ 'cauliflower', ACC-Sg)
	viðtal (/ˈvɪð.tʰal/ 'interview', ACC-Sg)

Table 1. *Example target words.*

	Example words following target
voiced	en ('but'), í ('in')
	ömmu ('grandmother', GEN-Sg)
voiceless	sem (Rel-Prn), frá ('from')
	systur ('sister', GEN-Sg)

Table 2. *Examples of words following target words.*

Given that final devoicing has been described as indicating a clear break in the utterance and that a boundary tone has been considered likely to co-occur with final devoicing (see [2]), the predictions with respect to position were as follows:

- Final devoicing occurs, and is likely to be obligatory, at the end of an utterance.
- Final devoicing occurs, and is likely to be obligatory, at the end of an IP, i.e. at the end of a clause in the syntax.
- Final devoicing may occur, if bounded by a level between PWd and IP, at the end of a syntactic XP, specifically between object and adjunct, a position likely to coincide with a phonological phrase boundary in prosodic structure.
- Final devoicing does not occur XP-internally, a position likely to correspond to a PWd boundary in the prosodic structure and not a position where a break in the utterance would be expected.

2.1. Materials

The experiment considered three factors: position (4 levels: utterance-final, clause-final, XP-final, XP-internal), stress on the target syllable (2 levels: stressed, unstressed) and voicing of the following sound (2 levels: voiced, voiceless). Overall, 56 sentences were created, fourteen of which are given in (2) through (5) as examples. Eight sentences had the target word in utterance-final position; of these, four target words were mono-syllabic (see (2)a), and four disyllabic (see (2)b). Sixteen sentences had the target words in clause-final position; eight (four monosyllabic, four disyllabic) were followed by voiced segments, eight (four monosyllabic, four disyllabic) by voiceless segments; see (3) for examples. Sixteen sentences had the target words in XP-final position, with the same distribution regarding stress and following segments as in the clause-final condition (see (4)), and sixteen sentences had the target word in XP-internal position, specifically in NP-internal position (see (5)). The sentences were pseudorandomised according to the usual restrictions. Note that the voicing condition only applies to three positions; in utterance-final position, no segment follows the target word ending in /l/.

(2) Target word utterance(U)-final

a. Í gær borðuðum við svínakjöt, kartöflur og kál.
Yesterday we at pork, potatoes and cabbage.
b. Einu sinni eldaði mamma mín oft blómkál.
In the past my mum cooked cauliflower often.

(3) Target word clause(Cl)-final

a. [Í gær borðuðum við svínakjöt, kartöflur og kál,]$_{clause}$
[en í dag borðum við fiskisúpu]$_{clause}$
Yesterday we ate pork, potatoes and cabbage,
and today we ate fish soup.
b. [Í gær borðuðum við svínakjöt, kartöflur og kál,]$_{clause}$
[sem bróðir minn og kærasta hans elduðu fyrir okkur]$_{clause}$
Yesterday we ate pork, potatoes and cabbage,
which my brother and his fiancé cooked for us.
c. [Einu sinni eldaði mamma mín oft blómkál,]$_{clause}$
[en nú á dögum eldar hún ekki neitt]$_{clause}$
In the past my mum often cooked cauliflower,
and today she does not cook anything.
d. [Einu sinni eldaði mamma mín oft blómkál,]$_{clause}$
[sem hún keypti á markaðnum í hverri viku]$_{clause}$
In the past my mum often cooked cauliflower,
which she bought in the market every week.

(4) Target word XP-final

a. Einu sinni eldaðum við [kartöflur og kál]$_{NP}$ [á hverjum degi]$_{PP}$
In the past we ate pork, potatoes and cabbage every day.
b. Á morgun þarf ég að kaupa [kál]$_{NP}$ [fyrir kjötsúpuna]$_{PP}$.
Tomorrow I have to buy cabbage for the meat soup.
c. Í morgun keypti sambýlismaður minn [blómkál]$_{NP}$ [í Bónus]$_{PP}$
This morning my flat mate bought cauliflower in Bónus.
d. Í Bónus keypti sambýliskona mín [blómkál]$_{NP}$ [frá Spáni]$_{PP}$
In Bónus my flat mate bought cauliflower from Spain.

(5) Target word XP-internal

a. Mér líkar [kál ömmu minnar]$_{NP}$ sem hún eldar.
I like my grandmother's cabbage which she cooks.
b. Mér líkar [kál frænku minnar]$_{NP}$ sem hún ræktar.
I like my cousin's cabbage which she grows.
c. Okkur þykir [súrkál ömmu okkar]$_{NP}$ frábært.
We think that our grandmother's sauerkraut is great.
d. Okkur þykir [súrkál systur okkar]$_{NP}$ rosalega gott.
We think that our sister's sauerkraut is very good.

2.2. Participants, apparatus and procedure

The recordings took place in November and December 2013 in a quiet closed room at the University of Iceland in Reykjavík. The results reported here are based on the recordings of twelve female native speakers of Icelandic. All speakers were from Reykjavík or the greater capital area or had lived there most of their lives. They were between 19 and 35 years of age and volunteered their participation. The participants were seated in front of a laptop computer. The sentences were presented one at a time on the computer screen using Microsoft PowerPoint. Sentences were presented on one line, except for the clause-final condition, where a comma was placed after the target word and a new line was started after the comma to help elicit an IP-boundary. The participants read the sentences at a normal speech rate. All utterances were recorded at a sampling rate of 44100 Hz using a Microtrack II (M-Audio) recorder and Rode NT-5 condenser microphone. The recordings were then edited into individual sound files.

2.3. Data treatment

Overall, the 12 participants produced 672 target sentences (96 utterance-final, 192 clause-final, 192 XP-final, 192 XP-internal). All targets were annotated in Praat ([13]) based on careful inspection of waveform, spectrogram and F0 contour and on perception. In the U-final, XP-final and XP-internal conditions, all utterances were annotated on at least a segmental and a text tier; in the clause-final condition all utterances were additionally annotated on a tone tier to identify boundary tones (T%) at IP-edges in target position (e.g. Figure 3). Boundary tones (L% or H%) occurred in target position in all 192 target sentences produced in the clause-final condition.

As for /l/, three realizations occurred in the data: [l], [ɬ], and [l ɬ], the latter being infrequent (N=14), and mostly produced at a clause boundary (N=11). Based on native speaker perception and articulatory differences between [ɬ] on its own and [ɬ] in an [l ɬ] sequence, [l ɬ] was counted as [l]. The realizations of /l/ as [l] and [ɬ] are illustrated in Figures 1 and 2, respectively, zooming in to the target area.

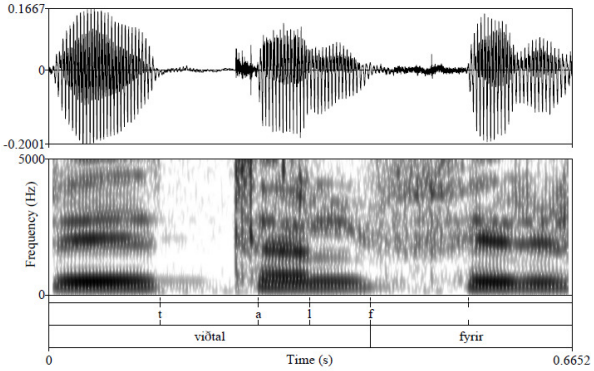

Figure 1: *No devoicing: /l/; Sentence: Blaðamaðurinn tók áhugavert viðtal fyrir Fréttablaðið ('The journalist took an interesting interview for Fréttablaðið.').*

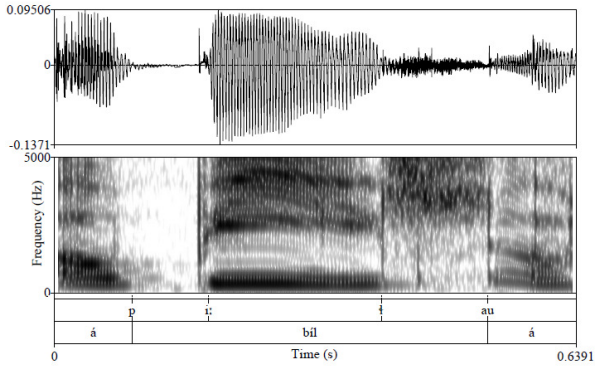

Figure 2: *Devoicing applied: /l̥/; Sentence: Venjulega eru Jón og Brynja á bíl á sunnudögum. ('Normally Jón and Brynja take the car on Sundays.')*

2.4. Results

The results by position are as follows. First, all 96 final /l/ in utterance-final position (see (2)) were devoiced, i.e. realized as [l̥]. Second, 126 (66%) final /l/ in clause-final position (see (3)) were devoiced, i.e. realized as [l̥], 62 (32%) were voiced [l], and four (2%) were unclear. Third, 164 (85%) final /l/ in XP-final position were realized as voiced [l], 22 (12%) were realized as [l̥], and 6 (3%) were unclear. Finally, XP-internally, 182 (95%) final /l/ were realized as [l], only 6 (3%) were realized as [l̥] and 4 (2%) were unclear or not realized at all. These results are summarized in Figure 3 and Table 3 below, excluding the unclear cases.

In order to test whether these differences between positions were significant and whether stress on the syllable ending in /l/ and voicing of the following segment also affected devoicing of /l/, the data were analysed statistically. They were coded by position (as in (2)-(5)), stress on the target syllable (stressed, unstressed) and voicing of the following segment (voiced, voiceless). All unclear cases (N = 14) were discarded from the analysis. The data were aggregated by participants and analyzed using a binomial logistic regression model with devoicing ([l] vs. [l̥]) as the dependent variable and the above-mentioned factors as fixed factors. The analysis showed no effects of stress ($p > 0.2$, see Table 4) and no effect of voicing of the following segment ($p > 0.12$, see Table 5), but a main effect for position. Specifically, there were significantly more [l̥]-realizations at the end of the utterance compared to the end of the clause ($ß = 0.35$, $SE = 0.15$, $p < 0.05$), which again had significantly more [l̥]-realizations than target words produced at the end of XPs ($ß = -1.90$, $SE = 0.27$, $p < 0.0001$), which again had significantly more [l̥]-realizations than target words that occurred within an XP ($ß = -0.94$, $SE = 0.46$, $p < 0.05$). There were no significant interactions between factors.

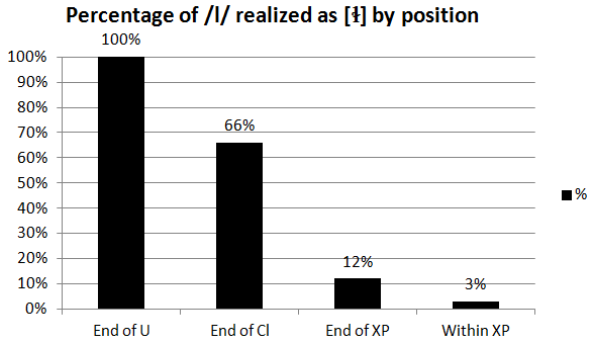

Figure 3: *Results by position*

position	[l]	[l̥]
1 (U-final)	0	96
2 (Clause-final)	62	126
3 (XP-final)	164	22
4 (XP-internal)	182	6

Table 3. *Cross-tabulation of /l/ according to position and (de)voicing*

	stressed (mono-syllabic)		unstressed (disyllabic)	
position	[l]	[l̥]	[l]	[l̥]
1 (U-final)	0	48	0	48

3 (XP-final)	84	10	80	12
4 (XP-internal)	89	6	92	1

Table 5. *Cross-tabulation of /l/ according to position, voicing of the following segment and (de)voicing*

3. Discussion

Final devoicing of /l/ in Reykjavík Icelandic obligatorily marks the end of the utterance (U). It is thus a U limit rule in Nespor & Vogel's [10] sense and seems to resemble in its

distribution other phonological rules which mark the end of a phonological utterance, such as final devoicing in Spanish (see [10]) and in the Chadic language Angas (see [14]), as well as Visarga in Sanskrit (see [9]), although not all of these have been experimentally studied.

The process is frequent but not obligatory at the end of the IP, thus it does not necessarily co-occur with other IP-boundary markers such as boundary tones. To illustrate this, Figure 4 shows an example of [l] produced at the end of IP, clearly co-occurring with H%, a short break of roughly 50 ms, and followed by pitch reset in the following IP, serving as additional evidence for a new IP, given that the IP has been identified as the domain for declination in Icelandic ([5], [6]).

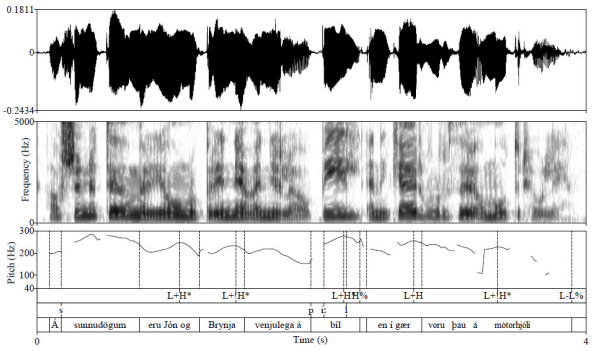

Figure 4: *[l] at IP-boundary; Sentence: Á sunnudögum eru Jón og Brynja venjulega á bíl, en í gær voru þau á mótorhjóli. ('On Sundays Jón and Brynja normally take the car, but today they were by motorbike.')*

Given the statistically significant difference between end of utterance (obligatory application of devoicing) and end of IP (optional application of devoicing, no obligatory co-occurrence with other IP-boundary markers), final devoicing in Icelandic may be taken as evidence for the level of the prosodic utterance in the prosodic hierarchy. Without this level, the difference between the two positions found in the present study cannot be accounted for.

Devoicing of /l/ is clearly disfavored, i.e. does not normally apply, within IP. If there is a level between PWd and IP in the prosodic hierarchy of Icelandic, it does not seem to affect devoicing of /l/. Note that of the 22 /l/ realized as [ɬ] at an XP-boundary, 10 are in the sequence <*bíl til*> ('car to') in the sentence <*Á síðasta ári förum við í bíl til Akureyrar*> ('Last year we drove by car to Akureyri'). Given the sequence /l t/, it is possible that even across a syntactic XP-boundary, it behaves in the same way as the same sequence of sounds word-internally, e.g. in adjectives marked for neuter on a stem ending in –l, cf. *kalt* ('cold', neuter of *kaldur*, stem *kal-*) and *gult* ('yellow', neuter of *gulur*, stem *gul-*), pronounced with devoiced /l/ before /t/ (e.g. [15]). Within XP, devoicing applies even less frequently. However, if the item involving the sequence [*bíl*]$_{NP}$ [*til Akureyrar*]$_{PP}$ is removed from the statistical analysis, the difference between position 3 (XP-final) and position 4 (XP-internal) is not significant anymore ($p > 0.9$). The few remaining instances of [ɬ] at an XP-boundary may be put down to careful articulation or promotion of the prosodic boundary at an XP-edge to IP-level.

The most interesting result is clearly the significant difference between positions 1 (U-final) and 2 (clause/IP-final), given that within IP devoicing is clearly disfavored, and given that the predictions were identical for positions 1 and 2. A factor not included in the experimental design is information structure. All utterances were produced with wide focus. Icelandic has right-most prominence at IP-level (e.g. [5], [16]), thus target words bear nuclear prominence in positions 1 and 2, and prenuclear prominence in positions 3 (XP-final) and 4 (XP-internal), but are never located in post-nuclear position. Given that stress on the target syllable turned out not to be significant, I would not expect the difference between nuclear and prenuclear prominence to be responsible for the clear position effect, and at any rate, it would not explain the significant difference between positions 1 and 2, which are both nuclear. Perhaps the size of the prosodic constituent including the target word may be another factor. However, again, this would not explain the difference between positions 1 and 2, because the size of the target constituents (U, IP) was identical; compare (2) and (3). For the time being, I thus conclude that it is the category of the prosodic constituent (U vs. IP) which is responsible for the obtained effect.

4. Concluding remarks

This paper has shown that final devoicing of /l/ (i.e. realization of final /l/ as [ɬ]) obligatorily marks the end of an utterance in Icelandic and provides evidence for utterance level in the prosodic hierarchy. It is still frequent but not obligatory at the end of an IP. If the prosodic hierarchy of Icelandic has a level between IP and the prosodic word, final devoicing of /l/ is not the process to establish this level, because its application is very infrequent within IP at potential lower level boundaries; the difference between XP-final /l/ and XP-internal /l/ is only marginally significant and disappears when one particular item is removed which may lead to devoicing of /l/ for independent reasons. Future research will have to show whether other phonological processes may help to establish more levels in a prosodic hierarchy for Icelandic. Moreover, it will show whether the results reported here extend to other sonorants which undergo devoicing in word-final position in Icelandic, e.g. /ð, r, ɣ/, and whether utterances in context (e.g. in turn-final position) will behave in the same way as utterances in isolation. Furthermore, only the results for Reykjavík Icelandic have been reported on here, thus future results may reveal regional variation in final sonorant devoicing. Given that Icelandic has phonological dialects (see [17]) and that the voiced vs. voiceless pronunciation of word-internal sonorants (e.g., /l, m, n/ before stops /p, t, k/) is one dialectal feature, it is at least conceivable that dialectal variation extends to final devoicing, too.

5. Acknowledgements

I am grateful to Ari Páll Kristinsson, Aðalsteinn Hákonarson, Haukur Þorgeirsson, Kristján Árnason and Élisabeth Delais-Roussarie for valuable comments and discussion, to Nanna Kristjánsdóttir and Þorbjörg Þorvaldsdóttir for help with the experimental data, and to Bettina Braun for discussion and help with the statistical analysis. This piece of research was supported by a Snorri Sturluson Fellowship from the Árni Magnússon Institute for Icelandic Studies, University of Iceland, to the author.

The Realization of French Rising Intonation by Speakers of American English

Scott Lee

[1] Program in Linguistics, University of Georgia, Athens, Georgia, United States

gte577z@uga.edu

Abstract

This study examines the realization of French intonational rises by adult native speakers of American English. Production data were gathered using a discourse completion task and a storytelling task from eight American college students beginning a semester-long study abroad program in Southern France. Results suggest that speakers struggled with two particular aspects of French intonation: the grouping of words into Accentual Phrases, and the phonetic realization of phrase-final rises. In particular, the probability distribution for the alignment of the late L elbow was bimodal for L2 speakers but unimodal for L1 speakers, suggesting the use in the learner speech of two distinct tonal patterns instead of the single French LH*. Mean values for overall pitch range and the scaling of continuative rises were significantly lower and less variable than French L1 values as well.

Index Terms: intonation, L2 prosody, French

1. Introduction

Most studies on second language acquisition have focused on the production and perception of segmental material [see e.g. 1, 2, 3]. To gain a better understanding of the phonetic characteristics of foreign accent, though, it is necessary to explore prosodic as well as segmental characteristics of learner speech. A number of recent studies have addressed this issue, exploring features like tonal alignment [4], tonal phrasing [5], and pitch scaling [6]. This study continues this trend by exploring the intonational characteristics of L2 French spoken by native speakers of American English. In prosodic terms, the two languages have a number of important differences, notably that stress is distinctive in English but not in French, and that intonation phrases (IPs) are built from accentual phrases (APs) with a default tonal pattern in French, instead of from a series of pitch accents as they are in English. The main goal of this study is to examine how L1 English speakers navigate these differences in their spoken L2 French, which will hopefully lend support to previous research findings, as well as shed light on interesting directions for future research on the acquisition of L2 prosody.

1.1. Intonation models

Although the scope of this paper is primarily phonetic, it is informed by the intonational phonologies of the languages under investigation. The models of intonation assumed by this paper are the Autosegmental Metrical (AM) systems developed for English by Pierrehumbert and Beckman [7] and for French by Jun and Fougeron [8, 9]. The two systems have a few structural differences that are relevant to this study. First, IPs in French are built from APs, which have a default /LHiLH*/ tonal sequence. The phonetic realization of this sequence depends on a number of factors, like speech rate, speech style, and how many syllables are in the phrase. By contrast, IPs in English are built from a sequence of pitch accents on stressed syllables, with nuclear or phrase-final accents being followed by a phrase accent and boundary tone. A second important difference is that English has two bitonal pitch accents, while French only has one. A second rise has been proposed for French [10], but the accent spans two syllables, with the L target appearing on the penultimate syllable and the H target on the final syllable. In English, however, the targets for both pitch accents may associate with a single stressed syllable, producing a contour that is sometimes similar to the French contour (in the case of L+H*) but sometimes not (in the case of L*+H). For the latter, the L target aligns with the stressed syllable, and the H target is realized somewhere near the following syllable boundary, producing a "scooped" shape with a relatively pronounced dip in f_0.

1.1.1. Alignment of the late rise in French

In her study of French tonal structure, Welby [11] reported values for the alignment of tonal targets in the early and late rises. In general, late H* was aligned with the last full syllable of the phrase, and the late L was realized close to the preceding syllable boundary. The position of the late L was not correlated with the duration of either syllable (penultimate or final), but it appeared in the final syllable 82% of the time. Her conclusions support an AM analysis of French intonation, and they support earlier analyses [see e.g. 12] of the late rise as a bitonal pitch accent.

1.2. Previous research

1.2.1. Korean and English

Jun and Oh [5] looked at how native speakers of American English acquired the phonology and phonetics of Korean intonation, which shares important phonological characteristics with French intonation. As in French, Korean IPs are built from APs, and the APs are built from rising sequences of L and H tones, with the exact tonal specification depending on the number of syllables in the phrase. To explore the relationship between the speakers' level of experience with Korean and their spoken proficiency, Jun and Oh designed a set of 40 sentences to test two main intonational features: the grouping of words into APs, and the phonetic realization of tone sequences. Interestingly, their results show that although advanced speakers produced more correct phrasings than intermediate and beginning speakers, they were generally not more successful at realizing the underlying tonal sequences phonetically. Specifically, they found that pitch range in AP-initial HL sequences was significantly smaller for learners than for native speakers, and that AP-final H tones were easier for learners to accurately produce than those elsewhere in the phrase, presumably because they are produced more regularly in L1 Korean and are thus more perceptually salient.

1.2.2. Dutch and Greek

Mennen [1] examined bi-directional intonational transfer in Dutch non-native speakers of Greek. Prenuclear or non-final rises have the same phonological structure in both languages, but they differ in their phonetic realization, with peak alignment not only occurring earlier but also being affected by vowel length in Dutch. The study consisted of two experiments, one looking for transfer from the L1 to the L2, and one looking for transfer from the L2 to the L1. Results for the first experiment showed that only one of the speakers was able to produce native-like L2 rises; the remaining four speakers produced L2 rises with alignment patterns from the L1. Results for the second experiment showed that the same four speakers produced L1 alignment patterns that were significantly different from those produced by monolingual L1 speakers, indicating an effect of exposure to the L2. Together, the experiments support the claim that intonational transfer can go both ways, i.e. from the L1 to the L2 and from the L2 to the L1. Crucially, they also support Jun and Oh's findings that the phonetics of L2 intonation are difficult for speakers to acquire.

1.3. Research questions

Using AP-final rises in French as a test case, the production experiment was designed to answer a number of questions raised by previous studies about the acquisition of L2 intonation. First, do learners acquire some aspects of L2 intonation (e.g. phrasing) more easily than others, and if so, which ones? If Jun and Oh's results hold true for the speakers in this study, then we would expect them to have more success grouping words into APs than realizing tonal sequences with native-like phonetics. Second, are phonologically similar tonal sequences realized differently in the learners' L2 than they are in their L1, and if so, how? French provides a good platform for testing both of these questions, since it is phonologically and phonetically different from English in terms of its intonation.

2. Methods

2.1. Participants

Production data were gathered from eight adult native speakers of American English participating in a study abroad program in Montpellier, France. This paper reports the results of the pre-departure pilot study that was conducted immediately before the participants left. Although their proficiency with spoken French varied, all speakers had completed the equivalent of four semesters' (i.e. two years') worth of undergraduate French. Their language backgrounds also varied, with two speakers having completed the same level of coursework or higher in Spanish, and one having working knowledge of Spanish, Italian, and Portuguese; the remaining five had only French as their L2. Production data were then gathered from four of the participants' native French host families for comparison.

2.2. Materials

All participants were asked to complete two tasks: a storytelling task, and a discourse completion task (DCT) as outlined by Prieto [13]. The DCT consisted of 31 scripted sentences elicited from the participants, which they read in response to situational prompts described to them by the interviewer. A sample item is given in (1), where the response is italicized and bolded.

(1) Tu as acheté de la glace à la vanilla et à la noisette pour ta fête. Demande aux invités s'ils veulent de la glace à la vanilla ou à la noisette.

Vous voulez de la glace à la vanilla ou à la noisette?

'You bought two flavors of ice cream for your party, but you're not sure which flavor to serve. Ask the guests at your party which flavor ice cream they'd prefer.

Do you all want chocolate or vanilla?'

31 sentences were recorded per speaker in the first task and approximately two minutes of extemporaneous speech in the second. Learners completed the tasks in both languages, while the host families completed them only in French.

2.3. Procedures

For the discourse completion task, the interviewer read the situational prompt for each item, and the participants read the target sentence in response. For the storytelling task, participants were asked to tell a story about a social event they recently attended, like a family gathering or party. The tasks were completed during a single interview session and were separated by approximately five minutes of time during which the participants could review the instructions for the upcoming task. Instructions for both tasks were printed on a prompt sheet and were explained by the interviewer at the beginning of the session.

2.3.1. Data analysis

Speaker responses to both tasks were recorded using a Shure SM51 condenser microphone and digitized at a sampling rate of 44.1khz and a depth of 24kbit/s. Responses to the DCT were segmented by hand and saved as separate files, yielding a total of 496 (16 x 31) phrases of varying length and tonal structure. Responses to the storytelling task were saved as a single wav file. Sound files for both tasks were then loaded into Praat [14] and segmented into phrases, words, syllables, and phones. Praat scripts were used to align phone boundaries to the text, and the boundaries were adjusted by hand to ensure accuracy.

Pitch curves were generated using Praat's built-in pitch tracker, and files containing f_0 perturbations or disfluencies were discarded. Several intonational features were then labeled by hand for each phrase, including f_0 minima and maxima, position of the late H, and position of the late L elbow. AP and IP boundaries were also marked in the French data to allow for the comparison of L1 and L2 phrasing. For the L2 speech, boundaries were marked both when speakers produced grammatical phrase-final pitch accents, and when they produced ungrammatical phrase-medial pitch accents.

Numerical data were exported to a spreadsheet and then analyzed using the R statistical package [15].

2.3.2. ToBI labeling

Learner varieties of intonation have been shown to be phonologically distinct from native varieties [16]. In this study, the speakers produced rises in the L2 that were sometimes phonetically similar to analogous rises in an L1, but sometimes not. Because of this ambiguity, tonal categories were not labeled in the L2 and were analyzed phonetically instead.

3. Results

3.1. Phrasing

Data from the discourse completion task show that learners produced more sentence-medial AP boundaries than native speakers. Mean counts for both boundary types are presented in the table below and organized by speaker group. Values for the French L1 speakers were tightly clustered (σ=3.7) and are thus reported as an aggregate mean, but values for the L2 speakers were more widely dispersed (σ=11.38). A Welch's *t*-test indicated that the difference between the means was statistically significant ($p<0.0002$), supporting Jun and Oh's findings for Korean that non-native speakers of French are generally less successful than native speakers at grouping words into phrases.

Speaker	French L1	French L2
1	78	85
2	77	117
3	80	108
4	73	115
5	74	96
6	82	94
7	75	100
8	71	112
	μ=76.3 σ=3.7	μ=103.4 σ=11.38

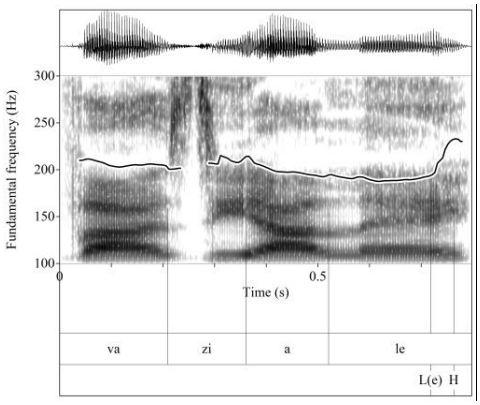
Table 1. *Number of sentence-medial APs produced by native and non-native speakers in the DCT.*

These results are likely due to two factors: the tendency for the non-native speakers to produce ungrammatical phrase-medial pitch accents, and their tendency to speak slower and with more disfluencies than the native speakers.

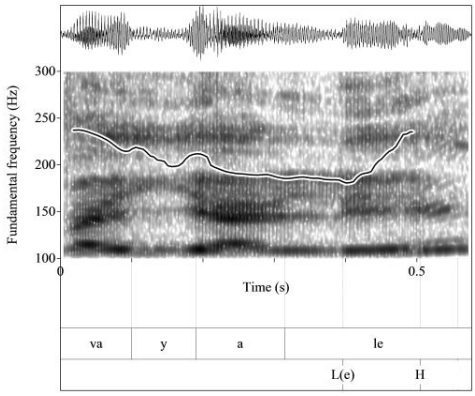
3.2. Tonal alignment

Results from both tasks show significant differences in the phonetic realization of rising tone sequences between the native and non-native speakers. In general, the L2 speakers realized the elbow in the late rise later than the L1 speakers. The placement of this elbow was also more variable. Figure 1 shows a spectrogram and pitch curve for the final four syllables of a sentence-medial AP in the phrase *Comment tu vas y aller* 'How are you getting there?' produced by a native (a) and a non-native (b) speaker. The low elbow in each figure is marked by an L(e), and f_0 is shown in hertz (Hz).

Figure 1. *Alignment of late rises in L1 and L2 French speech.*
a.



b.



The pitch curve in (b) is representative of a typical alignment pattern for late rises reported in [11], with the L elbow being located near the onset of the final syllable and the H target being reached near its end. The slope of the curve increases sharply about halfway through the syllable, but it is clearly rising throughout. By contrast, the pitch curve in (a) is marked by a much later rise in the final syllable, with the L elbow falling close to the H targetr near the end of the syllable. This pattern was common in the L2 speech, accounting for 45% of the total rises, and was in many cases produced with an even more pronounced delay.

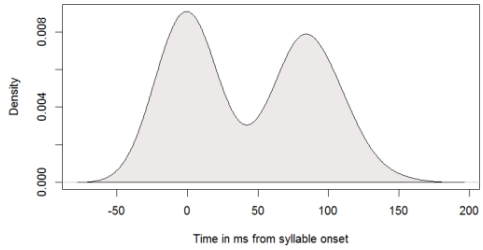
Table 2 presents the mean alignment in ms of the late elbow relative to the onset of the accented syllable. In calculating the means, positive values were entered for positions in the target syllable and negative values for positions in the preceding syllable. The French L2 values show late mean alignment relative to the French L1 values, which are closer to the syllable onset and similar to those reported by Welby [11].

Speaker	French L2 (μ, σ)		French L1 (μ, σ)	
1	32.1	39.3	10.5	8.3
2	51.6	58.6	15.6	10.3
3	45.3	33.2	8.5	9.6
4	39.8	37.4	21.3	11.4
5	52.5	49.3	12.3	9.3
6	61.8	56.7	11.2	14.2
7	33.1	36.5	9.3	16.3
8	71.0	58.8	18.1	15.8
All	48.4	46.3	13.35	11.9

Table 2. *Alignment in* ms *of the L-elbow in AP-final rises for French L2 and L1 speakers.*

The trend that emerges from these data is the close relationship between the mean and standard deviation for the L2 speakers' alignment patterns. In effect, the distribution was approximately bimodal, suggesting the speakers chose one of two options when realizing the rise: early alignment of the L, or late alignment of the L. In cases of early alignment, the elbow most often fell and occasionally before the syllable boundary. The alignment of the late H was relatively invariable, almost always occurring near the syllable boundary (mean latency from the right edge of the phrase was 1.2ms for all speakers, with σ =.53). A kernel estimation was used to calculate the probability distribution function for the alignment of the late L, shown in Figure 2. In addition to the bimodality, the distribution highlights the fact that the speakers tended to produce more early- than late-aligned L targets, on the whole.

Figure 2. *Probability density function for the alignment of the late L elbow in L2 speech.*



3.3. Pitch scaling

Overall pitch range, measured as 80% quantal range in Equivalent Rectangular Bandwidths (ERB) was lower for the learners (μ=2.1ERB) than for the native speakers (μ=4.3ERB); the difference was statistically significant (p=0.002). After z-score normalization, average values for the scaling of the late rises were shown to be significantly less variable for the learners as well, perhaps indicating a restriction in expressivity caused by a general processing constraint limiting the complexity of syntactic and pragmatic information that they can prosodically code.

4. Discussion and conclusion

The production data gathered for this study clearly suggest the presence of interlanguage effects in the non-native speakers' French intonation. In particular, the alignment and scaling of L2 AP-final rises differs significantly from that of the same rises in L1 French. One potential explanation for this difference is phonological. The L2 speakers essentially had two categorical choices when producing the AP-final rise: the scooped bitonal accent L*+H, and either the LH* or the L+H* (the phonetic distinction between these two was not clear in the data). If adult speakers can acquire L2 intonational phonetics, then we would expect advanced learners to produce mostly LH* and intermediate and beginning learners to alternate between the LH* and the L*+H. The results give some support to this hypothesis, with the learners, who self-rated their spoken proficiency in French as intermediate, producing the two contours fairly evenly.

The factors underlying this phonological interference are likely complex. Perceptual factors may play a role if the learners hear the French contour as a generic rise without perceiving (or perhaps recognizing as linguistically relevant) how consistently the tonal targets are aligned in L1 speech. However, pragmatic factors may also be involved, since the two pitch accents are generally assumed to have distinct meanings in English, with the scooped accent in particular signaling uncertainty or hesitation [see e.g. 17,18]; although the alignment of the late L elbow is potentially influenced by pragmatic factors [19], the variation does not appear to be as clearly categorical as it is in English. Perceptual and pragmatic factors are of course not mutually exclusive, and more investigation is needed to determine to what extent they both contribute to the phonological and phonetic characteristics of the learners' L2 intonation.

The findings suggest a number of directions for future research. First, production data from English are needed to determine whether rising intonation in the learners' L1 is affected by their exposure to the L2. Second, perception experiments are needed to look for interference between the learners' L1 and L2, e.g. whether they perceive L2 rises as distinct from L1 rises. Production data from the participants in this study will be gathered after they return from France to examine the effects of prolonged exposure to the L2 on their speech and add to the growing body of longitudinal research on prosodic acquisition. Based on the findings in [5] and [16], the expected result is for the speakers to make improvements to their phrasing, but not necessarily to the realization of the tone sequences. This last component also has the benefit of indirectly testing the effectiveness of language immersion as a pedagogical technique for improving L2 prosody, which is a relatively under-researched area of second language acquisition.

5. Acknowledgements

I would like to thank Meghan Armstrong and Keith Langston for their guidance and patience in helping me design the experiments for this study. I would also like to thank Diana Ranson for nurturing my interest in French, and the University of Georgia Graduate School and Office for the Vice President of Research for their generous financial support. Finally, thanks to Pauline Welby for creating the Praat script used to draw the pitch tracks in this paper.

Monosyllabic Lexical Pitch Contrasts in Norwegian

Niamh Kelly[1], *Rajka Smiljanić*[2]

[1,2]Department of Linguistics, The University of Texas at Austin, USA

niamh.kelly@utexas.edu, rajka@austin.utexas.edu

Abstract

This paper examines the lexical tonal accent contrast in monosyllabic words in the Trøndersk dialect of Norwegian. The results of a production experiment in which speakers produced the unmarked accent and the circumflex accent showed that the tonal distinction is characterised by a difference in f0 maximum, f0 height at onset, f0 minimum and its timing, and height of the final Accent Phrase H tone. The presence of the tonal accent contrast on monosyllabic words is unusual among dialects of Norwegian and Swedish.

Index Terms: lexical pitch accent, Norwegian, monosyllabic

1. Introduction

Scandinavian tonal accent contrasts have been described extensively, both impressionistically and experimentally [1–10]. The two contrasting tonal accents in Norwegian and Swedish are referred to as accent 1 and accent 2 [11]. Depending on the variety in question, the tonal contours of the two contrastive accents of Swedish and Norwegian may differ in their tonal makeup (e.g., LH vs HLH) or they may have the same tones but different timing in relation to the segmental string (e.g., both HLH) [12]. An example from the Oslo variety of Norwegian of words distinguished only by the tonal accent is *bønder* "farmers" (accent 1, LH) and *bønner* "beans" (accent 2, HLH) (the segments of both words are pronounced /ˈbønːər/).

Researchers agree that the Scandinavian accent contrast is generally only found on polysyllabic words [6, 13, 14] and some regard all monosyllabic words as having accent 1 [15, 16]. One explanation for this difference - likely related to the origin of the contrast - is that since accent 2 has a later timing, it needs a second syllable in order for the later tones to surface [13]. This is in contrast with tonal languages from a wide variety of language groups such as Burmese, Mandarin, !Xoo or Mixtec, where each syllable can bear a tone [17], but similar to other pitch accent languages such as Basque [18, 19] or Serbo-Croatian [20]. However, a small number of dialects of Norwegian and Swedish, including some of the Trøndersk dialects, have been described as having a tonal contrast surfacing on monosyllabic words, due to apocope, final vowel deletion [21–23]. This is referred to as a contrast between the unmarked monosyllabic accent and the circumflex accent and describes a difference in the shape of the contour between the accents. While previous research focused on the characteristics of the lexical contrast in polysyllabic words, only few acoustic studies examined in detail the nature of the contrast in monosyllabic words [23, 24]. Furthermore, even within the Trøndelag dialectal region, not all varieties (e.g., the city of Trondheim) have the contrast on monosyllabic words (Gjert Kristoffersen, p.c.). Given the rather limited number of monosyllabic minimal pairs that differ only in the accent feature, it is possible that this phenomenon will disappear. One aim of this study was thus to document this prosodically unusual variety.

The major goal of this work was to investigate whether the lexical tonal accent contrast surfaces on monosyllabic words in the Trøndersk dialect and, furthermore, what the exact acoustic correlates of the contrast are. This dialect is spoken in the Trøndelag region, a variety of East Norwegian spoken in central Norway.

In the Trøndersk dialect, disyllabic words with accent 1 or accent 2 both have the same shape (previously described as HLH [2, 25, 26]) with the tonal contour aligned later in accent 2 words. The circumflex accent occurs on words that are disyllabic in other varieties of Norwegian, such as infinitive forms of verbs [22], for example *å glimte* 'to gleam'. Although the circumflex accent most commonly occurs on words that originally had accent 2, they can also form from accent 1 words [24]. In the Trøndersk variety, these words are generally pronounced without the final (unstressed) vowel, reducing them to monosyllabic words which retain the underlying tones.

A small scale acoustic analysis of a different Trøndersk dialect, that of Ålvundeid, found that the circumflex accent is characterised by a longer vowel and a higher f0 onset than the unmarked monosyllabic accent [24]. In comparison, the unmarked monosyllabic accent is simply an L tone in East Norwegian (Gjert Kristoffersen, p.c.). In the Ålvundeid study, all target words were focused by elicitation. It is therefore not clear which tonal events characterise the accent contrast itself (if any) and which arise due to pragmatic focus. In addition, the Ålvundeid study examined only two male speakers from each of three age groups ('old' (over 70), 'mid' (38 and 50), and 'young' (20/21)). The current study aims to separate the effect of sentence intonation from the lexical tonal accent in order to examine the features that characterise the contrast on monosyllabic words in ten speakers of the Trøndersk dialect. Specifically, recordings were made of native speakers of the Trøndersk dialect reading sentences containing monosyllabic words with either the unmarked accent or the circumflex accent, in neutral (non-focused) intonation.

It was expected that the circumflex accent would have a longer vowel, higher f0 at vowel onset and later alignment of tones than the unmarked monosyllabic words.

2. Methods

2.1. Speakers

Ten native speakers (four males, six females) aged 18-45 of Trøndersk were recorded reading sentences containing the target words. The speakers were from a variety of towns south and west of Trondheim, where the circumflex accent is known to occur (Stian Hårstad and Jørn Almberg, p.c.), such as Tingvoll, Oppdal, Rennebu, Surnadal, Sunndal.

2.2. Stimuli

Target words contained only voiced sonorant consonants next to the vowel, such as *smil* "smile" (unmarked) and *'smile* "to smile" (circumflex). (Recall that, in this dialect, the final *e* is apocopated.) The words all contained the vowel /i/.

In Norwegian, the accent phrase (AP) high boundary tone (H%) [13, 27–29] is associated with the final unstressed syllable in the AP [29]. In order to control for the effect of this H%, the target word was always two unstressed syllables before the end of an AP. The target word also followed two or three unstressed syllables at the beginning of the sentence, which were AP-external [26]. In this way, the accent of the target word avoided being affected by either the accent or the final H% of a preceding AP [27]. The target word was always followed by a contrastively focused word in the following AP, in order to ensure that the target word did not receive narrow focus.

Examples (with target words in bold): (AP = accent phrase, IP = intonational phrase, IU = intonational utterance)

Unmarked:
Det var et lim i en film, men ikke i et stykke.
((Det var et (**lim** i en)$_{AP}$ (film,)$_{AP}$)$_{IP}$, (men ikke i et (stykke)$_{AP}$)$_{IP}$)$_{IU}$
"There was glue in a film, but not in a play."

Circumflex:
Jeg vil smile i en film, men ikke i et bilde.
((Jeg vil (**smile** i en)$_{AP}$ (film)$_{AP}$)$_{IP}$, (men ikke (i et bilde)$_{AP}$)$_{IP}$)$_{IU}$
"I want to smile in a film, but not in a photo."

For each accent there were five target words, each produced three times, giving 15 tokens per accent per speaker, a total of 300 tokens (15 tokens x 2 accents x 10 speakers). The words of the different accents were minimal pairs, where the accent was the only difference between the words.

2.3. Procedure

Speakers were recorded in the phonetics studio at the National University of Science and Technology (NTNU) in Trondheim, Norway. The experimenter was the first author. The sentences were presented one by one on powerpoint slides, with the speaker in control of when to move to the next sentence. The sentences were randomised and interspersed with sentences containing disyllabic target words. The sentences were in the same order for all speakers. They were written in the standard Bokmål orthography and also in a transcription of Trøndersk. Speakers were asked to speak as they would at home. None of the speakers had difficulty following the instructions.

2.4. Measurements and Analysis

In order to fully examine the F0 contour and its alignment with the segmental string, the following measurements were obtained (Figure 1 depicts and defines all the labelled landmarks):

1. F0 maximum (H)
2. F0 minimum (L)
3. F0 maximum timing ((H-V1)/(Vowel duration))
4. F0 minimum timing ((L-V1)/(Vowel duration))
5. F0 height at vowel onset (V1)
6. Vowel duration (C3-V1)
7. AP H% tone height (APH)
8. Boundary slope ((APH-LTP)f0/(APH-LTP)time)

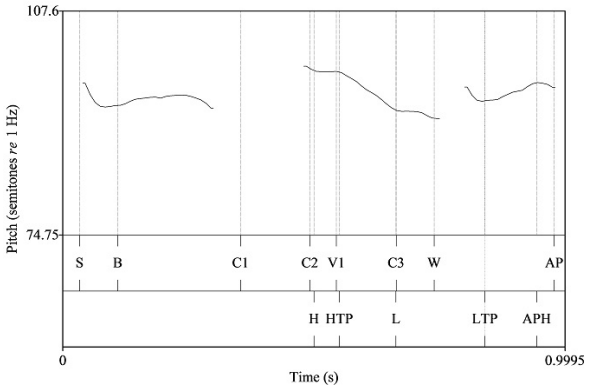

Figure 1: *Circumflex f0 contour of the word 'smile' showing measurement points.* S = beginning of the sentence; B = beginning of f0 rise; C1 = onset of target word; C2 = onset of second consonant (if present); V1 = vowel onset; C3 = onset of post-vocalic consonant; W = end of target word; AP = end of AP; H = f0 maximum, HTP = turning point from f0 maximum; L = f0 minimum; LTP = turning point from f0 minimum; APH = AP boundary tone.

All measurements were made on the target word. Duration was measured in milliseconds and f0 was measured in semitones in Praat [30]. Timing of f0 maximum and minimum were measured in milliseconds relative to vowel onset. These timings were then divided by the duration of the vowel, to get relative timing. This controlled for speaking rate differences. Boundary slope was measured as the difference in pitch between the turning point of the f0 minimum and the following AP boundary H%, divided by the duration between these two points.

Statistical tests consisted of a mixed model multiple linear regression analysis, conducted using the lme4 package in R [31]. The independent variable was accent and the dependent variables were the measures (f0 maximum and minimum and their timing, f0 at vowel onset, vowel duration, AP H% height, and slope of the rise to the AP-boundary tone). Speaker was included as a random effect. The reference level for accent was the unmarked accent. Since linear regressions do not produce *p*-values, the significance of accent as a predictor of each measure was calculated by a likelihood ratio test comparing a model that included accent as a predictor and one that did not [32]. This was conducted using the anova function in R, a likelihood ratio test for nested models.

3. Results

An average, time-normalised pitch track [33] for all target word productions by one female speaker (S16F) for the two accents is shown in Figure 2. This is representative of the other speakers. From this figure, it can be seen that the two accents are distinct. They differ in shape with the circumflex (blue line) having a higher f0 maximum and later f0 minimum timing than the unmarked accent. Furthermore, the circumflex accent has a higher f0 at onset.

Table 1 shows the statistical test results for each measure. The coefficient and t-values are from the linear regression tests

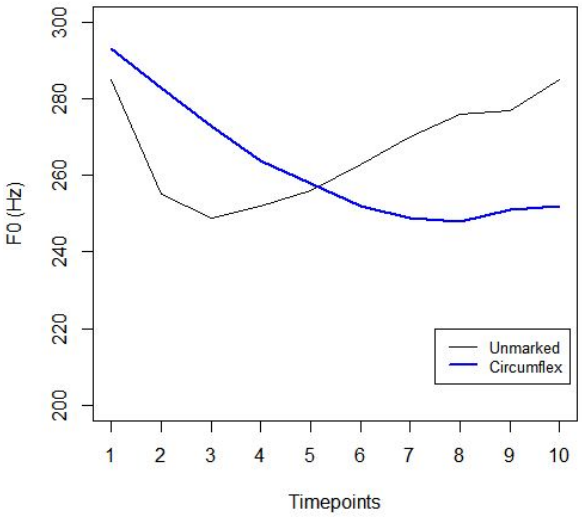

Figure 2: *Average, time-normalised f0 contour for one speaker.*

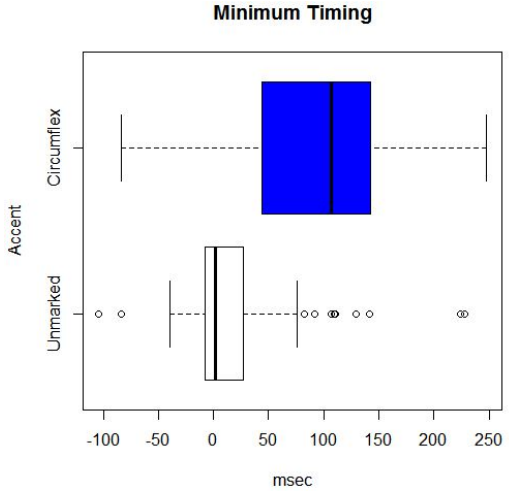

Figure 3: *F0 minimum timing by accent (unmarked in white, circumflex in blue).*

and the *p*-value is from the likelihood ratio test. A significant result (*) indicates that accent is a significant predictor of the measure. The sign of the coefficient tells the direction of the difference. Since the unmarked accent was the reference level, a positive coefficient means that for that measure, the circumflex accent has a higher average value than the unmarked accent, and a negative coefficient means the circumflex accent has a lower average value than the unmarked accent. For example, f0 minimum has a negative coefficient, meaning that the circumflex accent has a lower average f0 minimum than the unmarked accent.

Table 1: *Regression and likelihood ratio test results for each measure.*

Measure	Coef.	t-value	*p*-value
Vowel duration (msec)	-0.67	-0.12	0.906
F0 Maximum (st)	1.41	8.5	p<0.001*
F0 Minimum (st)	-0.47	-2.8	p<0.01*
F0 vowel onset (st)	1.71	9.9	p<0.001*
F0 max timing	-0.004	-0.07	0.956
F0 min timing	0.54	5.2	p<0.001*
Boundary slope	0.002	1.1	0.256
AP H% height	-0.5	3.3	p<0.01*

The results revealed that the two accents are differentiated by f0 maximum and f0 minimum height, f0 height at vowel onset, timing of f0 minimum (relative to vowel onset) and AP H% height. Table 2 shows the averages and standard deviations for each of these measures by speaker. (A negative number for timing means the f0 minimum occurred before vowel onset.)

The circumflex accent has a higher f0 maximum and f0 height at vowel onset, lower f0 minimum and AP H% tone, and later f0 minimum timing than the unmarked accent. Figure 3 shows the raw f0 minimum timing results pooled across speakers. The average f0 minimum timing for the unmarked accent is just after vowel onset, while that for the circumflex accent is over 100 milliseconds into the vowel.

4. Discussion

The results of this experiment confirmed that differences between the unmarked monosyllabic accent and the circumflex accent are present in Trøndersk. This is unlike many other varieties of Norwegian and Swedish in which this contrast is not found on monosyllabic words. The circumflex accent has a higher f0 maximum and onset, lower f0 minimum, later f0 minimum timing and lower AP H% tone than the unmarked monosyllabic accent. This indicates a wider pitch range and later timing for the circumflex accent. It should be noted that the height of the f0 maximum was not consistently found for all speakers and all words, and further testing showed that there were significant differences among the speakers for this measure. This suggests that this may not be as reliable a cue as the others for signalling the contrast. One reason for this was that for many tokens of the unmarked monosyllabic accent, there was no consistent point at which to mark the f0 maximum. The difficulty in reliably identifying the f0 maximum is consistent with the description of this accent as being just an L tone in this dialect.

While a previous acoustic study on the monosyllabic contrast [24] found vowel duration differences for the two accent types, speakers in this study did not use temporal cues to implement the lexical contrast. In the Oppdal dialect, there is a longer vowel in the circumflex accent, leading to an analysis of these syllables as being trimoraic [23]. The results from the current study suggest that this is not the case for all dialects of Trøndersk. The current results demonstrate that the circumflex accent can be realised without increasing vowel length.

It was also expected that the circumflex accent should have a steeper slope from the f0 minimum to the AP H% tone, due to the later timing of the f0 minimum for this accent; however, this was not found. The results instead revealed that the circumflex accent has a lower phrase boundary tone (H%) which in turn affected the slope. The circumflex accent thus has a later timing, lower f0 minimum and a lower AP H% tone. The lower AP H% tone could be due to the fact that the speaker simply does not have time to reach the natural H% target for the circumflex accent; however, this explanation seems unlikely, since the two

following syllables should be enough to reach this target, and the f0 contour did not reach any higher point after the AP.

The work presented here offers evidence of the lexical tonal accent contrast in monosyllabic words in Trøndersk. Future research will examine the realisation of both the unmarked monosyllabic accent and the circumflex accent in AP-final position and in a focus context, to determine how the contour is affected by sentence intonation and pragmatic factors. A comparison of those results with the findings of the current study will also indicate which cues are the most consistent in realising the monosyllabic contrast. Another direction of future research could be to compare the circumflex contour with that of accent 1 and 2 disyllabic words (depending on the accent of the word before apocopation), to examine whether the circumflex accent is indeed realised as a compressed form of the disyllabic tonal contour. This type of comparison could help to further elucidate the features that characterise the circumflex accent.

5. Conclusion

This investigation has shown that the circumflex accent is significantly different from the unmarked accent in monosyllabic words in the Trøndersk dialect of Norwegian. The acoustic analysis provides evidence that there is in fact a tonal accent contrast on monosyllabic words in this variety, at least in production. It remains to be determined whether listeners can perceive this tonal contrast on monosyllabic words and, furthermore, which of the cues indicated here are most salient for differentiating the accents.

This work provides an acoustic analysis of an unusual monosyllabic contrast in Scandinavian. Future work will examine how this contrast is affected by sentence intonation, thereby adding insight to how the lexical and phrasal levels of intonation interact.

6. Acknowledgements

We would like to thank Gjert Kristoffersen and his collaborators for their huge assistance in choosing target words and to Gjert for proof-reading the sentences and transcribing them into the dialect, as well as for comments on this paper. Special thanks to Wim van Dommelen for the use of the recording studio at NTNU, Trondheim. We also thank the anonymous reviewers for their helpful comments. The research used for this investigation was conducted with the support of the National Science Foundation Doctoral Dissertation Research Improvement Grant No. 1322700.
