Abstract

In this paper, we examined different methods of modeling prosodic features of tones, and their effects on a speaker-independent Taiwanese tone recognition system. Tones can be modeled either by plain or curve-fitted features. Plain features represent the original curve faithfully using pitch values, while curve-fitted features can be thought of as an approximation to the values using mathematical functions, such as a Legendre polynomial. In addition, durational information of tones was also proven effective in previous researches. Thus, we proposed a new approach of modeling Taiwanese tones using curve-fitted features extracted from fractions of the pitch curve, along with duration as an additional prosodic feature. Our experimental results showed that using these features in an SVM classifier could substantially improve the accuracy of tone recognition in Taiwanese. Besides, we provided an empirical perspective for theoretic studies on tonal neutralization.

Index Terms: Taiwanese, tone recognition, prosodic feature

1. Introduction

Sinitic languages such as Mandarin and Taiwanese are famous for their syllabic and tonal characteristic, which is different from western languages, such as English. The same syllable structure can carry different lexical tones to indicate different meanings. Tones provide critical information in speech recognition. It was argued that articulatory features such as segmental information, syllable structures and prosodic features may play an important role in tonal recognition in Mandarin [1].

Taiwanese, a relatively understudied language with fewer resources, is a dialect of the Southern Min languages widely spoken in Taiwan. Generally speaking, the structure of Taiwanese syllables is of the form 'CGVC', where 'C' stands for consonants, 'G' for glides, and 'V' for vowels [2]. Compared to Mandarin, Taiwanese has a more complicated tonal system. It has three tonal height contrasts, while Mandarin, on the other hand, only has two. There are seven tones in Taiwanese. Note that Tone 4 (or the *Yangshang* tone in traditional Chinese phonology terms) is missing because it was diachronically merged with Tones 3 or 6. The corresponding F0 curves of Tone 1 through 3 and 5 through 8, after normalizing the duration of the syllable, are shown in Figure 1.

Among them, Tone 7 and 8 are comprised of a stop consonant coda /p, t, k, ?/, and are called 'checked tones' or 'entering tones'. Durational differences between checked tones and other tones are significant, with checked tones being shorter. Furthermore, it was observed that the duration of a syllable might change drastically depending on different syllable structures. Duration is argued to be an important phonetic cue even in discourse [3]. Therefore, in order to characterize the tonal structure of Taiwanese, one has to consider not only the pitch curve but also other prosodic qualities such as duration. Moreover, the pronunciations of tones in Taiwanese were under the influence of tone sandhi, in which a citation tone changes to a sandhi tone according to its syntactic position. The details of this phenomenon were described in [4], but they are beyond the scope of this research.

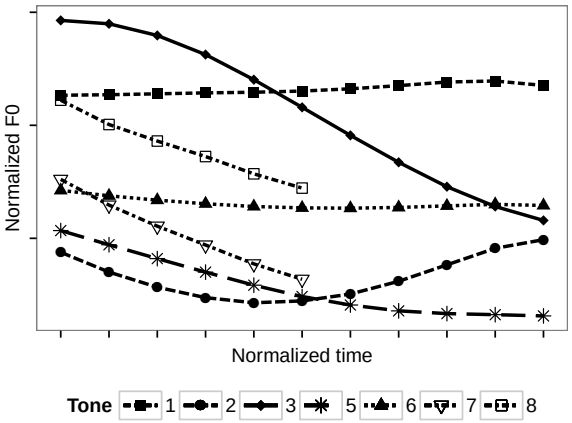

Figure 1: *Mean normalized F0 contour of seven Taiwanese tones.*

In the interest of comprehensive studies of the phonetics and phonology of Taiwanese language, a large speech corpus is required. However, a sizable Taiwanese speech database with accurate labeling is hard to come by. During the collection of such data by hand, one can find it to be time-consuming and error-prone. Thus, an automatic recognition system is crucial for building a large corpus for further studies.

Several researches have focused on different aspects of automatic processing of Taiwanese speech data. For example, in [5], a large vocabulary Taiwanese speech recognizer is built using HMM with raw pitch features in addition to a multiple pronunciation lexicon for sandhi tones. Specifically, two pitch smoothing techniques of the unvoiced regions, namely, random padding and exponential function linking between two consecutive pitch values, were compared to examine their abil-

ity to lower the character and utterance errors. Their results showed that using pitch information with exponential function for smoothing, in addition to the multiple pronunciation model, could significantly decrease the error rates in speech recognition. Another research focused on tone labeling of Taiwanese [6], in which both the citation and sandhi tones were jointly represented using statistical pitch contour models in order to eliminate contextual effects. It was proven to outperform the vector quantization method.

In this research, we want to focus on the recognition of Taiwanese tones using plain or curve-fitted features of the pitch contour along with durational feature. Following a similar approach in [7], we adopted the sub-sectioning method of splitting a pitch contour into different numbers of sections, and modeling them separately as our curve-fitted features. Also, the duration of a tone was included as an additional prosodic feature. We want to examine the effect of plain versus curve-fitted modeling of the F0 contour, as well as the effect of the number of sections and durational feature on tone recognition.

This paper is organized as follows. Section 2 describes our method of modeling and recognizing Taiwanese tones. Section 3 presents the experimental results along with some discussions. Finally, Section 4 concludes this paper.

2. Methods

We implemented several methods of extracting features from the F0 contour in order to compare the effect of them. First, raw F0 values were extracted by a Praat [8] script provided by [9]. Then, three types of feature sets, namely, plain, curve-fitted, and duration, were obtained from the raw F0 values to model different aspects of a tone. Plain and curve-fitted features were intended to capture the shape of the pitch curve, while the duration feature was included to describe the time-domain information. The following sections explain the definitions and extraction methods of these feature sets. Both the detailed and curve-fitted features were then paired with the duration features to train SVM classifiers and evaluation their performance on tone recognition.

2.1. Plain features

Plain features were simply the raw pitch values, in Hertz, computed from the audio. They precisely represent the original form of tones. There are 11 pitch values from equally-spaced points for each rhyme part of the syllable. The purpose of using these features is to provide fine-grained information of the pitch curve for tone model training.

2.2. Curve-fitted features

On the other hand, curve-fitted features were statistical pitch contour models used to capture the general characteristic of F0 variation within a tone. They can be further divided into two kinds. One is the method proposed by [10], in which a 3rd order orthogonal polynomial was used to represent the entire F0 contour. The basis polynomials, which are discrete Legendre polynomials, were normalized to the interval between 0 and 1. The detailed formulation is as expressed in (1).

$$
\begin{aligned}
\Phi_0(\frac{i}{N}) =& 1, \\
\Phi_1(\frac{i}{N}) =& \sqrt{\frac{12 \cdot N}{N+2}} \left(\frac{i}{N} - \frac{1}{2} \right), \\
\Phi_2(\frac{i}{N}) =& \sqrt{\frac{180 \cdot N^3}{(N-1)(N+2)(N+3)}} \cdot \\
& \left[\left(\frac{i}{N} \right)^2 - \frac{i}{N} + \frac{N-1}{6 \cdot N} \right], \\
\Phi_3(\frac{i}{N}) =& \sqrt{\frac{2800 \cdot N^5}{(N-1)(N-2)(N+2)(N+3)(N+4)}} \cdot \\
& \left[\left(\frac{i}{N} \right)^3 - \frac{3}{2} \left(\frac{i}{N} \right)^2 \right. \\
& + \frac{6 \cdot N^2 - 3 \cdot N + 2}{10 \cdot N^2} \left(\frac{i}{N} \right) \\
& \left. - \frac{(N-1)(N-2)}{20 \cdot N^2} \right]
\end{aligned}
\tag{1}
$$

for $0 \leq i \leq N$ where $N+1$ is the number of samples in the pitch contour. In this way, the original pitch values $\hat{f}\left(\frac{i}{N}\right)$ can be approximated by (2)

$$
\hat{f} = \left(\frac{i}{N} \right) \sum_{j=0}^{3} \alpha_j \cdot \Phi_j \left(\frac{i}{N} \right), 0 \leq i \leq N \tag{2}
$$

where

$$
\alpha_j = \frac{1}{N+1} \sum_{i=0}^{N} f \left(\frac{i}{N} \right) \cdot \Phi_j \frac{i}{N} \tag{3}
$$

Afterwards, the four coefficients $[\alpha_0, \alpha_1, \alpha_2, \alpha_3]$ from (3) were kept as one type of the curve-fitted features.

The other kind is a fractionalized fitting method similar to [7], in which the F0 curve was divided into four sections, and each section was represented by various parameters. Following this angle of approach, we used the 2nd order polynomial with the first three of the coefficients in (3). The F0 curve was first split into different numbers of equal-length sections, and each section was fitted separately. Figure 2 illustrates the difference between using a 3rd order polynomial to fit the entire curve, and fitting four sections separately using a 2nd order polynomial. We can see that a fractionalized fitting is more faithful to the original curve, while the higher order polynomial can capture the general shape of the curve. The resulting coefficients of the fitted functions were used as another set of curve-fitted features. The number of sections in a tone is another variable that we want to examine in this research.

2.3. Duration features

Lastly, the durations of each rhyme was used as another prosodic feature. As mentioned in Section 1, the duration information may be useful in distinguishing tones, especially the checked ones. We want to examine its effectiveness in distinguishing checked and non-checked tones, as well as other tones that were reported to have durational differences.

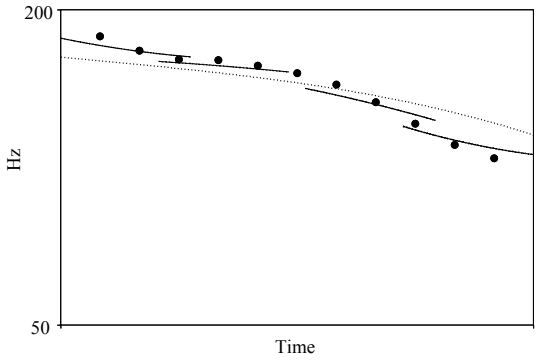

Figure 2: *Illustration of different curve-fitting methods on a series of samples of Tone 3. The dotted line represents using the whole series for fitting, and the solid lines represent fitting four sections separately.*

3. Experiments and Analysis

3.1. Experimental setup

We compiled a Taiwanese read speech corpus containing a total of 11,352 syllables from 10 different native speakers of Taiwanese. The recordings were conducted in a quiet room with a sampling rate of 44.1K and a background noise level lower than 30 dB. The wordlist consists of various categories of CVC combinations as described in Table 1, in which syllables with a stop coda were all carrying checked tones. The syllables represent real Taiwanese monosyllabic words, and were embedded in a carrier sentence to prevent influence from syntactic structures. Note that not all consonants and vowels in Taiwanese were included, as we are still in the process of building a comprehensive inventory now.

Table 1: *Inventory of our Taiwanese speech corpus.*

Position	Category	Inventory
Onset	Stop	p, t, k, ʔ, g
	Fricative	s
	Affricate	ts
	Liquid	l
	Nasal	m, n, ŋ
Vowel	Oral	i, e, a, ə, u, o, ɔ, ɤ
	Nasal	ã, ĩ
Coda	Stop	p, t, k, ʔ
	Nasal	m, n, ŋ

The total duration is about 11 hours. Since durational information may be used in training our tone models, the average duration is also reported in Table 2. The wave files were labeled by trained phoneticians using IPA symbols and numbers that denote surface tones. Pitch values from the rhyme part of the syllable were extracted using a Praat script "TimeNormalizedF0.praat" [9] from 11 equally spaced points. Then, different features described in Section 2 were obtained and used to train speaker-independent SVM classifiers using LibSVM [11], for comparing the effectiveness of our modeling methods.

Table 2: *Mean duration of seven Taiwanese tones in the corpus.*

Tone	Duration (ms)
1	202
2	233
3	183
5	180
6	209
7	122
8	107

3.2. Results and discussion

As shown in Table 3, the five-fold cross-validation accuracies of different feature sets were computed to evaluate the overall performance of our system. A few observations can be made from the results.

First, including the duration feature can indeed assist in identifying tones, with a 3% improvement in accuracy. It indicated that both frequency domain and time domain information are essential in the modeling of tones. Secondly, using curve-fitted features of the F0 curve outperforms using the plain features of the raw F0 values, which conforms to previous researches of tone modeling. The technique of dividing the curve into a number of sections was proven effective as well. By just splitting the curve into two sections, we can achieve a 0.5% increase of accuracy.

Table 3: *A comparison of tone recognition accuracy between different feature sets.*

Type	Feature	Accuracy (%)
Plain Features	Raw F0	77.10
	Raw F0 + duration	80.02
Curve-fitted Features	Entire curve fit + duration	80.08
	2-section fit + duration	80.51
	3-section fit + duration	80.32
	4-section fit + duration	**80.75**
	5-section fit + duration	80.60

The best performance was found in the feature set of 4-section polynomial fitting plus duration, with the accuracy of 80.75%. Notably, a higher partitioning of the F0 contour, i.e. 5-sections, resulted in a lower accuracy. It showed that the number of features is not positively related to accuracy, as the separation of a tone contour into too many sections might cause an overfitting effect that compromised the robustness of a model and its ability to identify the general characteristics of a tone. A 4-section method may be appropriate in that it can capture the left and right contextual variations resulting from neighboring segments using the two boundary sections, while the fluctuations in the center regions of a tone were well-represented by the remaining two sections. It has also been proven successful in [7], in which the language being studied is Mandarin. On the other hand, fitting the whole curve with a higher-order polynomial function is too coarse to be effective in representing a tone, and thus resulting in a lower accuracy.

In order to further analyze the effectiveness of our model on each of the seven tones, we trained the model using the complete set of F0 and duration data with the 4-section plus duration feature set, and then computed the accuracy for each tone. The results were shown in Table 4. As we can see, Tone 7 and 8

have considerably lower accuracies than others. It may simply be due to the fact that the sample size is too small for generating a robust model. However, there are in fact two kinds of checked tones in Taiwanese, one ending with /p, t, k/ and the other with /ʔ/. Previous studies showed that the realizations of them are slightly different [4]. For a deeper understanding and modeling of these two checked tones, additional data as well as research on the modeling techniques are required.

Table 4: *Recognition accuracy grouped by tone types.*

Tone	Number of correct/total syllables	Accuracy (%)
1	2204/2525	87.29
2	805/939	85.73
3	2033/2193	**92.70**
5	1737/2117	82.05
6	2200/2645	83.18
7	441/588	75.00
8	154/344	44.77

Nonetheless, for the non-checked Tone 1 to 6, the best performance was found on Tone 3. It could be attributed to the unique shape and range of the F0 curve, as depicted in Figure 1, along with a shorter duration that gave rise to a more distinctive tone model. Contrastively, the relatively lower accuracy of less than 85% occurred in Tone 5 and 6. It could be accounted for if we look at the wrong predictions of the classifier, as explained separately below.

- For Tone 5, we found that the most common mistakes were Tone 3 and 6, each occurred about 140 times. The similar pitch height of Tone 5 and 6 might have caused a confusion for the recognizer. As for the other two tones with comparable pitch height, namely, Tone 7 and 8, they can be easily distinguished by duration. Meanwhile, Tone 5 and 3 may have been indivisible because they were alike in both shape and durational feature.
- For Tone 6, the most common errors were Tone 1 and 5, with around 260 and 140 occurrences, respectively. The analogous reasoning above could be applied to explain the indistinguishability between Tone 6 and 1, in that their shape, height, and duration were all comparable. The multiple resemblances between them could have contributed to the errors.

Another perspective on the lower accuracy group is that there may be mutual affinity among them. In fact, previous study [12] showed that, in some dialects of Southern Min, Tone 5 and 6 were merged or 'neutralized'. Our findings could lend support to the theory that tonal neutralization is the result of the similarity and difficulty in maintaining contrast between tones.

In sum, a more robust model with the capability to tackle with these problems is required to improve the accuracy of our system. Moreover, a full-fledged Taiwanese tone recognition system must be able to distinguish sandhi tones from surface tones, and our system is yet to achieve this goal. A more sophisticated modeling scheme is necessary to incorporate such complications.

4. Conclusions

In this paper, we examined the effect of fractionalizing prosodic features on Taiwanese tone recognition, and proposed a new approach to modeling Taiwanese tones. Our results showed that using curve-fitting of four fractions of F0 values, and including the duration feature into model training were useful means of improving the accuracy of tone recognition. By further analyzing the outcomes, we provided an empirical point of view for theoretic studies on tonal neutralization. Future work can be done on investigating the effect of other prosodic and articulatory features, such as consonant context or energy. Since previous research suggests that these factors may play a role in tone recognition [1], incorporating them into Taiwanese speech recognition systems could be fruitful. In addition, expanding our corpus to include more tokens of checked tones is necessary for improving the accuracy. Furthermore, the current system only dealt with the surface tones. We will have to derive a more extensive model to resolve the problem of recognizing sandhi tones in Taiwanese.

5. Acknowledgments

The Taiwanese recording corpus was provided by the National Tsing Hua University Phonetics Lab, and was supported in part by the National Science Council grant of Taiwan (NSC 97-2410-H-007-025 and NSC 99-2410-H-007-050). The authors would like to thank Dr. Yu Tsao for insightful remarks and assistance, as well as comments from two anonymous reviewers.

Abstract

This study presents the results of a large-scale comparison of various measures of pitch range and pitch variation in two Slavic (Bulgarian and Polish) and two Germanic (German and British English) languages. The productions of twenty-two speakers per language (eleven male and eleven female) in two different tasks (read passages and number sets) are compared. Significant differences between the language groups are found: German and English speakers use lower pitch maxima, narrower pitch span, and generally less variable pitch than Bulgarian and Polish speakers. These findings support the hypothesis that linguistic communities tend to be characterized by particular pitch profiles.

Index Terms: pitch range, pitch variation, cross-language differences, Bulgarian, Polish, German, British English

1. Introduction

Several studies over the past decades have shown that linguistic communities (different social groups within a single language or speakers of different languages) tend to be characterized by particular pitch profiles (pitch range and pitch variation, see [7] for a review). Luchsinger and Arnold [14] found that Puerto Rican girls in New York City and native American women use fundamental frequency (*f0)* differently. While Puerto Rican girls tend to speak on a rather high pitch, many American women prefer to speak on a low pitch level. Dialects of a language can also differ with respect to the use of *f0* (e.g. [6, 29]). Various cross-linguistic studies also indicate language specific differences with respect to *f0*. Comparing typologically different languages (English, Spanish, Japanese, Tagalog), Hanley et al. [9] and Hanley and Snidecor [10] found that the fundamental frequency of English males had the lowest median *f0*. Later studies compared Polish vs. English [17], Mandarin vs. English [4, 11], British English vs. German [18, 19], or Russian vs. German [20]. Some studies showed that bilingual speakers differ when speaking their two languages. For example, bilingual English/Japanese speakers used a higher pitch in Japanese than in English [8, 28, 30]. These findings demonstrate that such differences need not be due to physiological differences between speakers of different languages.

Ohala and Gilbert's [21] report on experiments in which listeners can identify their own language (Japanese, Cantonese and English) based solely on prosodic cues (*f0*, amplitude and timing characteristics). It has further been found that some languages are discriminable purely by their fundamental frequency ([23] for English and Japanese, [15] and [16] for English and French and [5] for English and Dutch).

Language specific components have also been found to be important in the perception and production of paralinguistic aspects ([13] for politeness in Japanese and English, [3] for 'confident', 'friendly', 'emphatic' and 'surprised' in British English and Dutch).

However, it is difficult to compare the data reported in these publications, because most studies have been limited to either male or female (mostly small numbers of) speakers, the analyses were based on different discourse types, or the methods for *f0* estimation were different.

The aim of this study is to lay a foundation for a large-scale quantitative analysis of the fundamental frequency (level and span) of speakers of two typologically different language groups (Slavic: Bulgarian and Polish, and Germanic: German and (British) English). The analysis presented here is based on the assumption that pitch range and pitch variation in linguistically homogeneous communities will cluster within each community, but might differ across communities.

2. Material and Methods

Two Slavic (Bulgarian and Polish) and two Germanic (German and English) languages are in the focus of this study. The material analyzed is continuous read speech taken from two comparable multi-lingual speech databases, EUROM-1 (for German and English) [2] and BABEL (for Bulgarian and Polish) [25, 26]. We used a subset of the data, consisting of 3 blocks of 20 numbers (from 0 to 9999) and 3 cognitively linked short passages, containing 5 thematically connected sentences, read by 22 speakers (11 male and 11 female) per language. The passages were based on identical, real-life topics for the different languages, freely translated and adapted for Bulgarian, German and Polish from the original English texts. The overall length of the analyzed material per language is about 60 minutes.

3. f_0 Measures

Pitch values were collected at 0.01 seconds time steps for the male and 0.005 seconds time steps for the female speakers using the RAPT algorithm [27] implemented in the program 'get_f0' from the ESPS software package. The automatically extracted *f0* values were verified and manually corrected, if necessary. Irregular voiced stretches of speech due to laryngealization were excluded from further analyses.

According to Ladd [12], *f0* values can be attributed to two partially related but distinct characteristics of a speaker's performance: (a) pitch level, i.e. the overall height of the speaker's voice, and (b) pitch span, i.e. the range of frequencies covered by the speaker. To analyze the cross-language differences in pitch range and variation, the following distributional measures were calculated: mean and median *f0* values for level and interquartile range (IQR) and the simple pitch excursion for span, whereas the latter was simply computed as the difference between maximum and minimum pitch values over a passage or number block. The obtained Hertz measurements for span were additionally converted to semitones by means of the formula [24]:

39.863 * log10(Maximum/Minimum).

The measures describing the variation and shape of the *f0* distribution were standard deviation (SD), kurtosis and skewness (in Hz).

4. Results

Means and standard deviations for each of the distributional measures for pitch level and span are presented in Table 1, organized by language, speaker sex, and task.

As a first step towards determining the differences, linear mixed models with the respective measure as dependent variable, speaker as random factor, and native language (Bulgarian/Polish/English/German), gender (male/female) and task (passage/number set) as fixed factors, as well as all their possible interactions, were computed for each dependent variable in separate analyses. Separate Tukey post-hoc tests were carried out per variable, if appropriate. The confidence level was set at α=0.05.

4.1. Passages

Predictably, gender had a significant main effect on mean (F [1, 80] = 520.32, p<0.001) and median *f0* (F [1, 80] = 480.50, p<0.001), IQR (F [1, 80] = 70.47, p<0.001), minimum *f0* (F [1, 80] = 266.57, p<0.001), maximum *f0* (F [1, 80] = 341.84, p<0.001) and SD (F [1, 80] = 94.69, p<0.001), with females having significantly higher *f0* values (cf. Figure 1 for level measures). Gender did not differ in skewness, kurtosis and *f0* span measured in semitones.

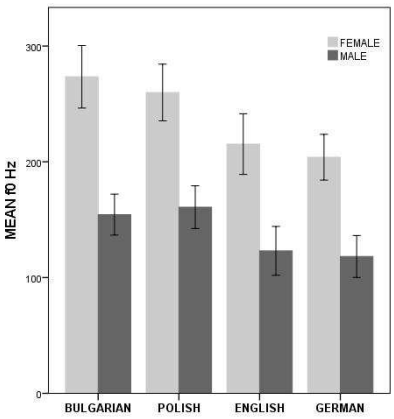

Figure 1: *Mean f0 pooled over all male and female speakers and all tasks.*

Table 1. Means and standard deviations for the distributional measures by language, speaker sex and task. The values for each measure are given in Hz except for the second span measure which is in semitones.

	measure	Passages		Numbers

However, over and above the expected gender effect, there was also a significant main effect of language on all measurements except on minimum *f0*, where the speakers are near the floor of their physiological *f0* range. Separate post-hoc tests showed that Bulgarian and Polish speakers had a significantly higher mean *f0* (F [3, 80] = 33.07, p<0.001), median *f0* (F [3, 80] = 32.60, p<0.001), IQR (F [3, 80] =

21.06, p<0.001), maximum *f0* (F [3, 80] = 33.29, p<0.001), *f0* span in semitones (F [3, 80] = 17.05, p<0.001) and SD (F [3, 80] = 26.96, p<0.001) than English and German speakers. We found a positively skewed *f0* distribution for the four languages. This implies that the most frequent *f0* observation occurs lower than the mean. The skewness values for English speakers were significantly higher than those for German, Polish and Bulgarian speakers (F [3, 80] = 11.51, p<0.001). English speakers also had a higher kurtosis than German and Bulgarian speakers, and Polish speakers had a higher kurtosis than Bulgarian speakers (F [3, 80] = 8.33, p<0.001). This reflects the fact that *f0* in Bulgarian and German is distributed over a narrower area (cf. Tables 1 and 2).

The statistical analysis revealed a significant interaction between language and gender for mean *f0* (F [3, 80] = 3.10, p<0.05), maximum *f0* (F [3, 80] = 6.15, p<0.001) and SD (F [3, 80] = 3.76, p<0.05). In the passages, the speakers of the Slavic group used higher average *f0* and higher maximum values and showed a larger SD (possibly indicating more liveliness) than the speakers in the Germanic group. The only exceptions to this finding are the English male speakers with respect to their maximum *f0* values and SD (cf. Figure 2a). Thus, the English male speakers used the same maximum *f0* values and had the same SD as the German male speakers and the male speakers from the Slavic group. Figures 2a and 2b display the mean and maximum pitch values as well as SD for male and female speakers in the four languages.

4.2. Number Blocks

In these analyses, as expected, we found again that women had a significantly higher mean *f0* (F [1, 80] = 424.13, p<0.001), median *f0* (F [1, 80] = 379.82, p<0.001), IQR (F [1, 80] = 43.09, p<0.001), maximum *f0* (F [1, 80] = 339.89, p<0.001), minimum *f0* (F [1, 80] = 315.98, p<0.001) and SD (F [1, 80] = 51.78, p<0.001) . In contrast to the findings for the passages, in the number task male speakers used a larger frequency range in semitones (F [1, 80] = 6.97, p<0.01) than females. This result may be partially attributed to the fact that speakers tend to use quite idiosyncratic intonation patterns for the number blocks: some speakers prefer continuation rises to separate the blocks, other speakers tend to use falling intonation to end a block. Gender was also significant for skewness (F [1, 80] = 8.32, p<0.05).

Table 2. *Language-group differences for the f0 measures on the basis of Tukey post-hoc comparisons.*

f0 measure	significant language-group differences	
	passages	number blocks
mean *f0*	BG = PL > EN = DE	BG = PL > EN = DE
median *f0*	BG = PL > EN = DE	BG = PL > EN = DE
min *f0*	N.S.	N.S.
IQR	BG = PL > EN = DE	PL > BG > EN = DE
max *f0*	PL = BG > EN = DE	PL > BG > EN > DE
span ST	PL = BG > EN = DE	PL = BG > BG = EN > DE
SD	BG = PL > EN = DE	PL > BG > EN = DE
skewness	EN > DE = PL = BG	EN > PL = DE > BG
kurtosis	EN = PL > PL = DE > DE = BG	BG = EN = DE > PL

Again, a significant main effect of language was found in all measures except *f0* minimum: mean *f0* (F [3, 80] = 37.75, p<0.001), median *f0* (F [3, 80] = 36.73, p<0.001), IQR (F [3, 80] = 44.68, p<0.001), maximum *f0* (F [3, 80] = 35.52, p<0.001), *f0* span in semitones (F [3, 80] = 16.27, p<0.001), SD (F [3, 80] = 42.57, p<0.001), skewness (F [3, 80] = 31.87, p<0.001) and kurtosis (F [3, 80] = 9.82, p<0.001). However, the post-hoc tests yielded different language groupings (cf. Table 2).

Significant interactions between gender and language were found for IQR (F [3, 80] = 3.30, p<0.05), SD (F [3, 80] = 3.71, p<0.05) and kurtosis (F [3, 80] = 2.99, p<0.05).

4.3. Level vs. Span

The scatter plots in Figures 3 and 4 provide a visual representation of *f0* span (in Hz) and level (mean *f0* Hz) for all speakers of the four languages. The figures show that some speakers have a wide span but differ in level or vice versa, i.e. some speakers have a similar level but differ in span. The English and German speakers cluster in the lower left corner of the level/span plane, while the Bulgarian and Polish speakers cluster mostly in the higher right sector, which indicate that Slavic speakers may are more expressive than Germanic speakers in terms of span and level. The scatter plots also illustrate the different strategies of some speakers with respect to task type.

5. Discussion and Conclusions

This paper contributes to the growing number of studies on cross-language differences in pitch range and pitch variation. Our results confirm the hypothesis that linguistic communities tend to be characterized by particular pitch profiles. German and English speakers use a considerably lower level, narrower span, and generally less variable pitch than Bulgarian and Polish speakers. Gender also plays a significant role in *f0* variation. In the present study a distinctive frequency region as well as different mean frequencies were found for male and female speakers (about 139 Hz and 238 Hz respectively). However, the differences in mean frequencies were on the average less than one octave: 10.14/9.72 semitones for Bulgarian, 8.63/7.86 semitones for Polish, 9.32/9.64 semitones for German and 9.51/10.11 semitones for English (first number for passages, second one for number blocks).

Systematic differences between tasks were observed which appear to be attributable to differing strategies that speakers employ when reading short stories versus lists of numbers. Inter-speaker variability was considerably greater for the number lists. The syntactic-semantic structure of the story seems to constrain the speakers' prosodic options.

Our results do not corroborate the results reported by Mennen and colleagues [18, 19]; the female English and German speakers do not differ with respect to level and span. But distributional measures may in fact not be able to capture significant cross-linguistic differences (cf. [1, 19, 22]). In future work we expect to refine our measures of pitch range, by including linguistically based measures which were found to be better predictors of differences in pitch range and pitch variation across speakers and languages, and also by adding data from more speakers, including Bulgarian and Polish L2 speakers of English, more languages, as well as spontaneous speech data.

6. Acknowledgements

This research was partially supported by Research Grant UMO-2012/04/M/HS2/00551 from the NCN (Polish National Research Center).

We would like to thank Ryszard Gubrynowicz (Speech Acoustics Laboratory, Institute of Fundamental Technology Research, Polish Academy of Science) and Snezhina Dimitrova (English Department, Sofia University “St. Kliment Ohridski”) for kindly providing the Babel databases for Polish and Bulgarian, respectively.

Silent reading and prosodic structure constraints

Philippe Martin

Abstract

Silent reading of written texts involves normally a process of subvocalization, i.e. the presence of a voice reading the text in the head of the reader speaking to her/himself. This process includes not only the sequences of syllables corresponding to the written material, but also sentence intonation. Since subvocalization cannot be eliminated other than by changing the status of each word into a pictographic function (as it may be the case for a STOP road panel sign for example), it is argued here that sentence intonation is essential to language comprehension, and more specifically to the conversion of sequences of syllables into higher order linguistic units (corresponding to accent phrases AP in the Autosegmental-Metrical model).

Consequently, reading and in particular silent reading is constrained by the same rules than the prosodic structure in general, and specifically to the minimal duration of accent phrases. This minimal value, occurring when AP's contain only one syllable, is about 250 ms, a value which corresponds to the minimal period value of Delta brain waves [4], [11]. Therefore, this AP minimal duration limits also the maximal number of AP that could be processed in silent reading, i.e. about 240 per minute, which corresponds to the maximal number of words per minutes experts in fast reading can process while keeping a reasonable level of comprehension, i.e. about 800 wpm.

Index Terms: silent reading, prosodic structure, subvocalization, Delta waves, Theta waves.

1. Introduction

When we read, either silently or aloud, we generate speech sounds according to the reduced information given in the written text. In this process, we also generate a prosodic structure, which hierarchically organizes accent phrases AP (minimal units of intonation containing a single lexical or group stress), into prosodic groups, called in the Autosegmental-Metrical model ip (intermediate intonative phrases) and at a higher level IP (Intonation Phrases), whose sequences in turn constitute the whole utterance intonation.

It is noticeable that this prosodic structure (re)generation is essential to help the reader to understand the text. Therefore, the whole reading process is constrained by the rules governing the elaboration of the sentence prosodic structure when speaking either silently or aloud, and in particular the minimal and maximal duration of accent phrases [11].

In silent reading, it is difficult to proceed without subvocalization, i.e. without hearing a voice in one's head that corresponds to a voice reading the text aloud. For this reason, silent reading may be subject to similar constraints than reading aloud (let aside articulatory constraints). These constraints may interact or even supersede constraints established for eye movement while reading. In particular, they may lead to a new explanation pertaining to the maximum number of words that can be processed in fast reading.

2. Eye movement

When reading, the eye proceeds in saccades (short rapid movements) to scan the text, jumping in steps varying from 1 to 20 characters with an average of 7 to 9 characters (forward and backward). In the process, the most frequent fixations are given by verbal forms and punctuation marks (dots, commas, semicolons, question marks, etc.). The eye jumps then constantly to spot these markers, which will constitute the bases for the prosodic structure to build [10].

Most of the laboratory speech research on sentence intonation actually investigate this process thoroughly on read speech, before considering spontaneous, non-prepared speech prosodic features. For example, if a dot normally ending written text sentences is associated with a falling conclusive prosodic marker, the correspondence of the other punctuation marks and the verbal forms must be dynamically associated with a proper prosodic contour (a Tone Boundary in the Autosegmental-Metrical model).

The saccades allows to eye to focus on fixation point in 20 ms to 40 ms, whereas the fixation point last between 100 ms and 500 ms [17]. The fixation state of the eye allows the fovea, the central part of the retina, to scan the selected written information with high resolution, whereas peripheral information is viewed with fewer details (Fig. 1).

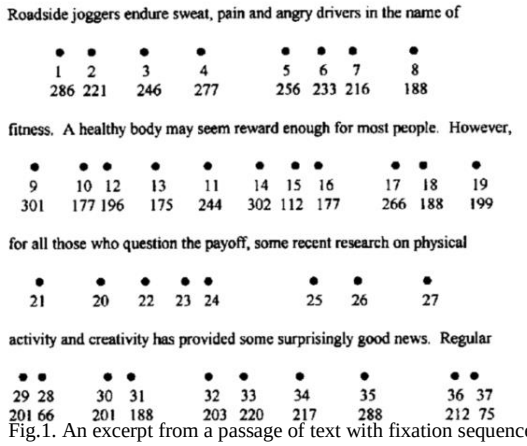

Fig.1. An excerpt from a passage of text with fixation sequence and fixation durations. The dots below the words indicate the fixation location, the first number below a dot its rank in the sequence, and the second number below a dot its duration of fixation (from [17]).

Due to the complex muscular mechanisms for speech generation, oral (i.e. aloud) reading is slower than silent reading. However, the puzzling aspect of silent reading lies in its limitations. Despite a number of questionable commercial claims stating that fast readers could read up to 3000 words per minute (about 50 words/sec…), the fast reading process is limited by subvocalization, the effect to hear a voice in one's head while reading silently (which was curiously attributed by some to the way we learn to read at school [13]).

3. Subvocalization

Subvocalization does not pertain to the mechanical control of articulators muscle control, but to the perception of the speech signal, which is recovered by reading. The invention of writing has precisely this function, allowing not only reading aloud but also silently, i.e. "to talk to oneself in silence". Indeed, writing is a shorthand notation system of speech sound and not of articulatory movements, contrary to what claim supporters of the motor theory of speech perception [8]. There is apparently no writing system (even API) referring directly to articulatory configurations.

Other systems such as pictograms bypass the generation of speech sounds by associating directly significant and signifier to access their signification without going through language units be syllables, words, prosodic words, syntagms, etc. A road STOP sign may indeed be read aloud or silently, but is more frequently directly associated with its meaning, i.e. to give way on the road.

Likewise, dates written with numbers, e.g. 1789, may be read as "seventeen hundred eighty nine", but the constant use of symbols not corresponding directly to syllables and words leads more frequently to a direct access to its signifier. The passage to the status of pictogram depends of course of the familiarity of the reader with the object and its frequency of occurrence.

Writing systems using ideograms, for example Mandarin, also involve subvocalization in silent reading. Learning Mandarin without being concerned by ideograms pronunciation would be difficult, as many words are plurisyllabic, implying for such reader to deal with combination of pictograms [9]. However, one could associate other sounds to ideograms, such as English words for example, but the mediation of some speech sound seems difficult to avoid, although not impossible in principle.

Commercial US based fast reading "schools" claim that they can remove subvocalization, or at least minimize it. The subliminal idea is to transform every word into a pictogram, so when read it will not be pronounced silently. Other techniques recommend to use a pencil to determine eye fixation targets and accelerate the number of saccades. An application even proposes to display only lexical words sequentially on a computer screen with a user adjustable speed (this approach incidentally corresponds to the definition of accent phrases in the autosegmental-metrical model, i.e. one lexical word for each accent phrase). Comprehension should then be achieved without any prosodic structure and no syntactic structure linking the read words together by simple concatenation and no hierarchical structure.

Faster readers claim speed from 400 wpm (words per minutes) to 800 wpm. With an average number of about 3 (written) words per accent phrase, 800 wpm convert into about 266 AP's per minute, or 266/60 = 4.4 AP's per second. So the minimal average duration between silently read AP's would be about 225 ms. 800 wpm for the best observed performance for speed readers [2].

4. Accent phrases

Recent studies on spontaneous speech show that we speak and read by accent phrases and not word by word [1]. Accent phrases (AP's, aka prosodic word, stress groups, temporal groups, etc.) are minimal units of prosody contain only one (lexical or group) stress. It is also claimed that accent phrases necessarily contain either a verb, a noun, an adjective or an adverb together with grammatical words, but the analysis of non-prepared speech (i.e. spontaneous) data invalidated this hypothesis [12].

Accent phrase duration measured on various styles of spontaneous speech show that the shortest values, corresponding to a single syllable accent phrase, is about 250 ms, even if the single syllable is reduced to a single vowel, which would otherwise take some 100 ms to 150 ms when unstressed [12]. This minimal duration seems to be a limit under which the syllable ceased to be perceived as prominent (i.e. stressed).

The longest duration of accent phrase is about 1200 ms, which corresponds to an average of 7 syllables. This implies that sequences of more than 7 syllables or so must contain more than one stressed syllable, as in the English word *paraskevidekatriafobia* (the fear of Friday 13) realized with two or three stressed syllables: *paraske'**vi**dekatriafo'**bi**a* or *pa'raskevide'katriafo'**bi**a* for example. The question is: why do we have these lower and upper duration limits for accent phrases?

5. Theta and Delta brain waves

In the years 1930-40, researchers observed that the human brain consisted of a very large number of neurons (in the order of 100 billions) interconnected in groups in specific regions of the brain mass. These interconnections allow a transfer of chemically stored information in each neuron. These transfers induce variations of a small electric potential (in the µV range), that can be observed through captors positioned on subjects skull (electroencephalography, or EEG). These electrical variations are called evoked potential as they result from a sensory stimulation, auditory, visual or other.

Electrical activity produced by transfers of group of neurons to other groups of neurons is not done haphazardly. First, they operate in specific frequency ranges linked to specific cognitive activities, and secondly they can be synchronized in phase in each frequency range. Greek letters designate specific frequency ranges: Alpha, Delta, Delta, Gamma… The range of interest here are Delta, varying from 1 to 4 Hz, and Theta, varying from 4 to 10 Hz.

Evoked potential is usually observed with a relatively large number of captors (from 32 to more than 256 today) placed around the subject skull according to location standards. EEG signals are stored in real time and analyzed into the frequency domain with either a (Fast) Fourier or Wavelet transform. The resulting representation is very similar to spectra obtained in frequency speech analysis, the frequency ranges being of course much lower.

The constraints governing temporal groups observed on prosodic structures of both read and spontaneous speech can find a justification – and an explanation – in recent neurophysiological research work on speech ([4], [5], [11]). These studies, based essentially on EEG, investigate the possible correlations that may exist between brain activity and the perception and linguistic treatment of the information by listeners.

Researchers in neurolinguistic for instance, demonstrated with this technique of investigation the precedence of prosodic over syntax treatment [19]. Experiments described in [14] and [4] showed that the speech flow was segmented thanks to prosodic tags and with direct identification of already

memorized units. Two complementary processes would explain the conversion of syllabic flow into higher order units, which would result preferential lateralization to the right hemisphere for the prosodic information, and the left hemisphere for language information already stored.

Following proposals put forward in [3], [4] and [5], these observations lead to the following hypothesis. We know that the waves of the cortex Theta and Delta (among others) govern the flow of information transfer between neuronal groups. Delta wave frequencies ranging from 1 to 4 Hz, while those of Theta waves range from 4 to 10 Hz. These values suggest that Delta waves are responsible for the timing of the transfer of syllabic sequences, the syllables storage in short-term memory being synchronized by Theta waves.

Figures 2 and 3 below illustrate the difference pertaining to EEG recordings resulting from a stimulus of unstructured pure tones (Fig. 1) and a structured sequence organized in 4 chunks of 3 pure tones, the last tone of each chunk with a longer duration (Fig. 2).

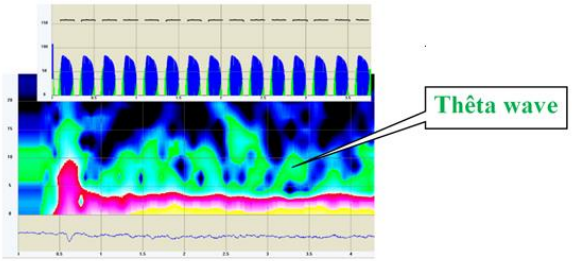

Fig. 2. Example of EEG spectral analysis (channel 28 or Pz) of evoked potential for a stimulus of a sequence of pure tones (top of the figure). Spectral analysis (bottom) shows Theta waves (in the range 4 Hz-10Hz) with no temporal structure [11].

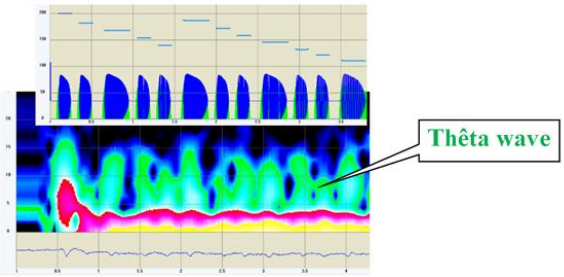

Fig. 3. Example of EEG spectral analysis (channel 28 or Pz) of evoked potential for a stimulus of a sequence of pure tones structured in groups of 3, the third tone being longer (top of the figure). Spectral analysis (bottom) shows Theta waves (in the range 4 Hz-10Hz) organized in a temporal structure corresponding to the stimulus structure [11].

Fig. 2 and 3 above suggest that temporal groups can only be perceived by the listener if their conversion is triggered by Delta waves (which may also synchronize Theta waves). This process is therefore constrained by the Delta wave properties, and in particular by its frequency properties. This hypothesis would account for 1) the extent of variation of the durations of stress groups, ranging from 250 ms to about 1200 ms (variation range of wave periods Delta) and 2) variation periods of Theta waves, from 100 ms to 250 ms.

6. Conclusion

Delta brain waves, whose periods vary from 250 ms to 1200 ms (about 1 Hz to 4 Hz), synchronize the conversion of sequences of syllables stored in short-term memory into higher linguistic units. This hypothesis is validated by the minimal and maximal duration of accent phrases (stress groups) which correspond to the Delta period variations. Furthermore, the average duration of syllables decreases linearly with their number in an accent phrase, from about 250 ms to 100 ms in accent groups of 1 to 7 syllables [11].

As no actual acoustical speech production is involved, silent reading is much faster than reading aloud, where multiple muscular command must be executed. Still, although eye saccade and eye fixation can operate much faster, for example in the reading of pictograms, subvocalization essential in silent reading limits the reading speed. Indeed, since subvocalization implies the generation of sentence prosodic structures as well as sequences of syllables, a prosodic constraint limiting the minimum duration of accent phrase to about 250 ms limits also the speed of the silent reading process, which has to go necessarily through this prosodic structure regeneration process. These values correspond tightly to the fastest reading performances cited in the literature [2], i.e. about 800 wpm or 4 AP per second.

Rising intonation in spontaneous French: how well can continuation statements and polar questions be distinguished?

Abstract

This study investigates whether a clear distinction can be made between the prosody of continuation statements and polar questions in conversational French, which are both typically produced with final rising intonation. We show that the two utterance types can be distinguished over chance level by several pitch, duration, and intensity cues. However, given the substantial amount of phonetic overlap and the nature of the observed differences between the two utterance types (i.e. overall F0 scaling, final intensity drop and degree of final lengthening), we propose that variability in the phonetic detail of intonation rises in French is due to the effects of interactional factors (e.g. turn-taking context, type of speech act) rather than to the existence of two distinct rising intonation contour types in this language.

Index Terms: rising intonation, question intonation, continuation intonation, polar questions, French

1. Introduction

One of the main challenges to the study of human communication is the lack of a one-to-one mapping between pragmatic function and linguistic form. In this study, we tackle this issue by investigating the prosody of continuation statements and polar questions in French, two utterance types that often exhibit a similar form (i.e. SVO word order and final rising intonation) in spite of their markedly different functions (e.g. keeping vs. yielding the floor, conveying vs. requesting information). Despite the syntactic and intonational similarities of these two utterance types, it is possible that their prosodic characteristics can distinguish them robustly, and that participants in a conversation do not need to rely solely on context in order to interpret their pragmatic function. Our aim in this study is to examine whether a clear distinction can be made between the prosody of the two kinds of utterances in a corpus of spontaneous French.

Several claims regarding the prosodic distinction between rising continuation statements and rising polar questions have been made in the French intonation literature. Based on introspection, [1] claimed that these two utterance types both have final rising pitch, but also that they are differentiated by the scaling and shape of the final pitch rise, with questions reaching a higher pitch maximum and exhibiting a more concave final pitch contour than continuation statements. Two later studies based on spontaneous and read speech [2, 3] supported this distinction in the scaling of the final pitch maximum, but did not find evidence for a distinction in terms of contour shape. Moreover, [3] found a different intensity profile and a shorter duration of the final vowel for continuation statements than for questions.

However, [4], based on the variability observed for both continuation statements and polar questions, claimed that a single underlying rising intonation pattern is compatible with both functions. The possibility that rising polar questions and continuation statements share the same phonological pattern has also been reflected in more recent accounts of French intonation within the Autosegmental-Metrical framework. It has been suggested that the final rise found in both major continuations and polar questions coincides with the end of the highest level of phrasing (i.e. the Intonation Phrase) [5], and that they both consist of the same tonal elements (H*H%) [6].

In summary, there is disagreement in the French intonation literature about the exact prosodic characteristics of rising continuation statements and rising polar questions, and about their possible phonological distinction. In this study, we assess the extent to which these two kinds of utterances can be distinguished phonetically on the basis of their prosody using data from a corpus of French spontaneous conversation.

2. Method

Our data come from the Nijmegen Corpus of Casual French [7], which consists of 23 casual conversations among groups of friends recorded with head-mounted microphones in a sound-attenuated room. We used the initial dyadic part of each conversation, which had a duration ranging from 4 to 40 minutes, and provided a total of around seven and a half hours of spontaneous conversation. Twelve dyads were composed by female speakers, and eleven by male speakers. All speakers originated from Central or Northern France, and were mostly university students, with ages from 18 to 27.

The two authors independently inspected all the conversations in the data and identified cases of rising intonation using Elan and Praat software [8, 9]. We only considered utterances with rising intonation, which were immediately followed by a pause. The reasons for this were to avoid the effects of tonal and segmental coarticulation in the utterance-final syllable, and to make sure that the final rises in our data were all produced in a comparable context in terms of prosodic phrasing. It should also be noted that we did not mark cases with final plateaus, which we observed in tag questions [5] and enumerations [10]. After finishing a first annotation pass, we created a final dataset including all cases of rising pre-pausal intonation that were identified by the two annotators (n = 320). Then, for each utterance, we annotated whether it was a question or a continuation statement in the context of the conversation. Questions typically involved knowledge within the listener's epistemic domain [11] (e.g. 'You went to Paris yesterday?') and were followed by a turn transition and an answer, whereas continuation statements involved knowledge within the speaker's epistemic domain (e.g. 'I went to Paris yesterday') and were usually not followed by a turn-transition. No ambiguous cases were observed when the conversational context was taken into account. In total, we included a total of 126 questions and 190 continuation statements in our dataset.

Several acoustic measurements were performed with Praat [9] in the final syllables of the utterances, where differences in

the final prosody of continuation statements and polar questions were likely to be observed according to previous studies [1,2,3]. We measured the minimum and maximum pitch values (semitones re 100 Hz) in the final vowel of the utterance, which was always present regardless of the structure of the final syllable (e.g. open or closed, with or without an onset). These pitch minimum and maximum values corresponded to the start and end of the intonation rise throughout the final vowel and can be used to investigate differences in scaling between the intonation rises of continuation statements and polar questions. As an estimate of the pitch register used prior to the rise, we measured the median pitch in the interval from the start of the utterance up to the start of the final syllable. In order to control for speaker-based variation in pitch, we normalised pitch values with reference to the median value calculated in an excerpt of ten minutes for every speaker. The shape of the pitch rise has been proposed as being important [1] as well as irrelevant [2, 3] for distinguishing between continuation statements and polar questions in French. In order to examine this feature, we took pitch measures every ten ms throughout the final vowel, and approximated these values with a quadratic equation using least-squares linear regression as in [12, 13, 14]. For each pitch rise, we fitted a linear model $y = a + bx + cx^2$, where a represents the initial pitch value, b the initial slope and c the curvature of the rise. Convex pitch rises are fitted by models with negative quadratic coefficients, whereas concave pitch rises are fitted by models with positive quadratic coefficients. In addition to the pitch measurements above, we calculated the final drop in intensity between the intensity peaks in the last two vowels. Furthermore, we also measured the duration of the final vowel, which was always present regardless of the structure of the final syllable (e.g. open or closed, with or without an onset). In order to control for variability in final vowel duration due to differences in speech rate across tokens, we also calculated the speech rate over the last intonational phrase up to the final syllable, so that it could be included as a covariate in our statistical analyses.

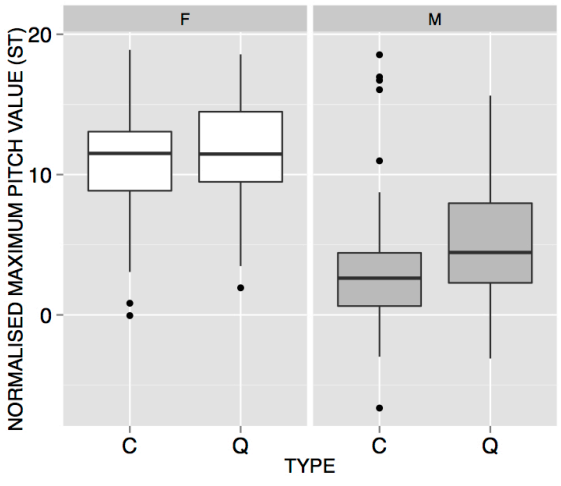

Figure 1: *Speaker-normalised maximum pitch in final vowel (semitones, re 100 Hz) for the two kinds of utterances (C = Continuation statement, Q = Question) for each gender (F = Female, M = Male).*

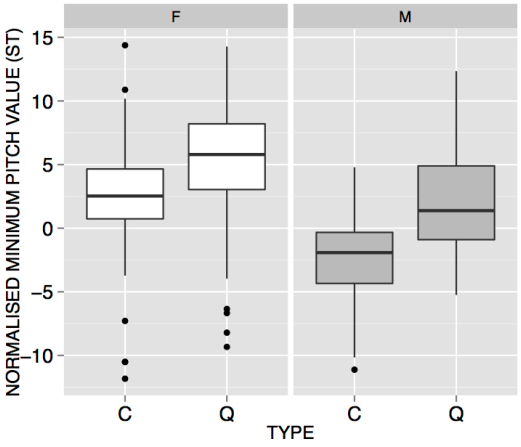

Figure 2: *Speaker-normalised minimum pitch in final vowel (semitones, re 100 Hz) for the two kinds of utterances (C = Continuation statement, Q = Question) for each gender (F = Female, M = Male).*

3. Results

We investigate whether the final prosody of continuation statements and rising polar questions can be clearly distinguished in spontaneous French. Using regression modelling, we first compare the pitch, duration and intensity characteristics between the two kinds of utterances. We focus on the final syllables of the utterances, where relevant differences are expected to occur according to previous literature. Following this, we evaluate the degree of overlap and separation between the two kinds of utterances using a leave-one-out cross-validation procedure.

3.1. Phonetic comparison

Figure 1 shows boxplots of maximum pitch values (i.e. the end of the pitch rise) as a function of utterance type, separated by speaker gender. This figure shows that, excepting a small number of outliers, questions tend to end in higher pitch compared to continuations for males, but not for females. It also shows a clear gender difference, with females having higher values in general. These differences were confirmed by a statistically significant interaction between utterance type and speaker gender in a regression model with maximum pitch as the dependent variable ($\beta = 1.7$, $t = 2.24$, $p < .05$).

Figure 2 shows boxplots of minimum pitch values in the final intonation rise as a function of utterance type, separated by speaker gender. As for maximum pitch, females appeared to have higher values than males in general. Regarding utterance type, questions appear to exhibit a higher minimum pitch value for both females and males. These differences were confirmed by a regression model with minimum pitch as the dependent variable, and utterance type and gender as predictors (utterance type: $\beta = 3.65$, $t = 7.52$, $p < .0001$; gender: $\beta = -4.47$, $t = -9.36$, $p < .0001$). Similarly to minimum pitch, the pitch median up to the final syllable of the utterance also exhibited a higher value for questions. A regression model with the same predictors as for minimum pitch supported this observation (utterance type: $\beta = 2.05$, $t = 6.50$, $p < .0001$; gender: $\beta = -4.39$, $t = -14.12$, $p < .0001$).

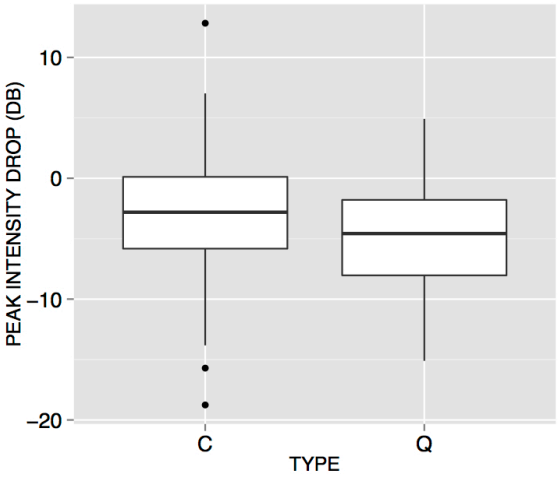

Figure 3: *Intensity drop in final vowel in seconds (dB) for the two kinds of utterances (C = Continuation statement, Q = Question).*

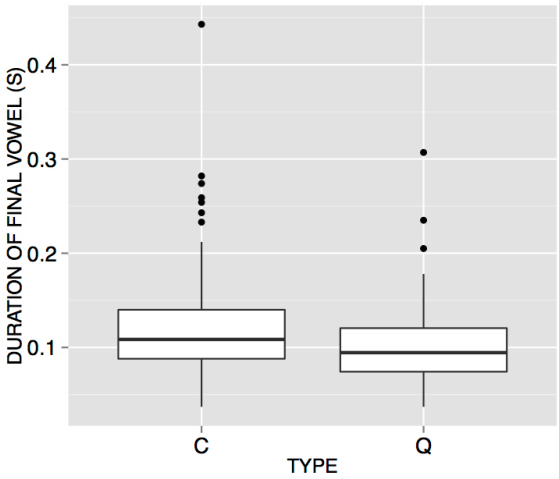

Figure 4: *Duration of the final vowel in seconds (s) for the two kinds of utterances (C = Continuation statement, Q = Question).*

In order to investigate the shape of the rise (i.e. convex vs. concave) we used quadratic equations modelling its trajectory as explained in the Methods section. We fitted a regression model with the quadratic coefficients of these equations, which capture the degree of curvature of pitch rises, as the dependent variable, and utterance type as predictor. The statistical analysis revealed that polar questions and continuation statements did not differ statistically in the curvature of their rises (p = .33). Inspection of the data revealed that the two utterance types could exhibit negative and positive curvature values, indicating that they could both have convex or concave final pitch rises.

Figure 3 displays boxplots of peak intensity in final syllable relative to the peak intensity in the previous syllable. The figure shows that questions tend to exhibit a lower final intensity peak compared to continuation statements. A regression analysis confirmed this difference (β = -1.89, t = -3.71, p < .001).

Finally, we investigated if the duration of the final vowel varies with utterance type. Figure 4 shows boxplots of final vowel duration for the two utterance types. We can see in this figure that questions tend to be produced with a slightly shorter final vowel in comparison to continuation statements. We fitted a regression model with duration as the response, utterance type as the main predictor, and also speech rate as a covariate, since we wanted to control for duration variability related to this factor. This model yielded a statistical difference of roughly 10 ms between continuation statements and polar questions (β = -0.012, t = -2.36, p < 0.05).

In summary, we have found differences between continuation statements and polar questions in terms of several pitch, duration and intensity measures. However, our data also indicate that these two utterance types overlap considerably in these prosodic features, in particular in the case of maximum pitch for females, and intensity and duration for both genders.

The question arises therefore how well the two utterance types can be distinguished on the basis of the several relevant phonetic features in the comparison. We address this question in the following subsection.

3.2. Cross-validation procedure

In order to estimate the degree to which continuation statements and polar questions can be separated on the basis of the cues identified in the previous subsection, we performed a leave-one-out cross-validation of the phonetic cues that appeared to be relevant with our data. This procedure simulated predicting new unseen data using our dataset in the following way: utterance type was predicted for each token in our dataset by means of logistic regression models trained on the rest of the dataset including several features, yielding a percentage of correct classifications for each different model. We used regression models that included several combinations distinguishing the two utterance types in the previous subsection. Models with pitch cues as predictors also included speaker gender as a covariate, whereas models including final vowel duration also included speech rate.

Our automatic classifications yielded different accuracy levels dependent on the model used. The minimum value of the pitch rise offered an accuracy of 72%, close to that of a model comprising all features (76%). The accuracy afforded by maximum pitch, on the other hand, was significantly lower (60%). Combining the two final pitch cues (i.e. minimum and maximum pitch) allowed for a marginal increase in accuracy over the model with minimum pitch alone (73%). Interestingly, the pitch median before the last syllable, which we used as an estimate of the pitch register of the utterance prior to the final syllable, was almost as good a predictor of utterance type as the final pitch cues, with an accuracy of 70%. Regarding non-pitch cues, intensity and duration both provided moderate improvements over chance level (61% for intensity, 67% for duration, and 67% for a model combining duration and intensity).

These results show that not all phonetic features are equally useful for distinguishing between the two utterance types. In particular, the minimum pitch value at the beginning of the pitch rise was the best cue for the contrast between continuation statements and polar questions, performing almost as well as a the full model with all cues, whereas the final pitch maximum only led to a moderate gain over chance level.

4. Discussion and conclusion

This study has investigated whether a clear distinction can be made between the prosody of French continuation statements and polar questions, which both exhibit rising intonation patterns previously claimed to be distinct or similar by different authors [1, 4]. Our comparative analysis in Section 3.1 has shown phonetic differences between the prosody of the two kinds of utterances in terms of several prosodic features. However, a great amount of phonetic overlap between the phonetic realizations of the two utterance types has been observed. This has been evidenced in Section 3.2 by the fact that roughly a quarter of the data was wrongly classified by a logistic regression model containing all relevant prosodic features identified in Section 3.1.

Regarding the phonetic differences, we have observed that the maximum pitch value in the final intonation rise tended to be higher for questions than for continuation statements, but only for male speakers. A more consistent difference was observed between the two utterance types in the minimum pitch value at the beginning of the rise, and in the pitch register prior to the final syllable of the utterance. As for the shape of the rise, we did not observe any differences between continuations and questions. On the other hand, the duration and peak drop intensity of the final vowel showed differences between the two utterance types. Questions tended to have a shorter final vowel and end in a lower peak intensity target than continuations.

Our findings therefore only partially agree with those from past studies. The higher maximum pitch in the rise for questions is in line with the findings of [1, 3], and the more pronounced final drop in intensity for questions agrees with the observations of [3]. Regarding the shape of the final pitch rise, which had been suggested as a relevant feature by [1], we did not observe any consistent differences between the two utterance types, in line with [2, 3]. In our data, final intonation rises in both continuation statements and polar questions could adopt slightly concave or convex shape.

On the other hand, the minimum pitch value in the intonation rise, a feature judged to be irrelevant by [1] and not investigated in detail by [3], clearly offered the best cue for distinguishing between continuation statements and polar questions. Our findings regarding the duration of the final vowel, which was the second-best cue to the contrast between continuations and questions, were also opposed to the previous literature [3]. In our study, polar questions exhibited shorter, not longer, final vowels than continuation statements.

These discrepancies between our findings and those of previous studies may be due to the fact that studies in the past were mostly based on introspection and read speech data, whereas ours used utterances extracted from spontaneous conversations more directly affected by the interaction between speakers. In our study, for instance, the fact that polar questions tended to have less final lengthening than continuation statements may be due to the fact that questions typically yield the floor to the interlocutor, and that their final part usually marks the end of the speaker's turn. This would be in line with observations from studies on English dialogue, which have shown that turn-final utterances tend to exhibit less final lengthening and a more marked final drop in intensity than turn-medial utterances [15, 16]. Since these differences in duration and intensity were observed in utterances with different intonation patterns, it can be concluded that they were not directly related to differences in intonation contour choice, but rather to differences in turn-taking actions (i.e. turn-yielding vs. turn-keeping). It is therefore likely that the observed differences in duration and intensity between continuation statements and polar questions in our French data are due to the different turn-taking contexts in which these utterances tend to occur.

Interactional factors may also be the reason why the minimum pitch value at the start of the rise and the pitch register at which the utterance was spoken before the final syllable, features neglected in previous research, provide the best cues in distinguishing continuation statements from polar questions in our corpus. It has often been proposed that questioning utterances in general, not only those with final rising intonation tend to exhibit higher pitch registers compared to assertive utterances [e.g. 17, 18, 19 among others]. Our finding that the minimum pitch at the start of the final rise and the pitch median before the final syllable were consistently different between continuation statements and polar questions is most likely due to the fact that the pitch register throughout the utterances is generally higher in questions than in continuations.

Our findings therefore appear to be in line with previous proposals [4, 6] that a single rising intonation pattern (e.g. H*H%) is compatible with both continuation statements and polar questions in French. We have observed an important amount of overlap in our data, showing that a clear phonetic distinction cannot be drawn between the prosody of rising continuation statements and polar questions in French. Moreover, we have argued that the phonetic differences observed between the two utterance types (i.e. overall F0 scaling, final intensity drop, degree of final lengthening), are likely to be due to the effects of interactional factors (i.e. turn-taking context). For these reasons, we conclude that continuation statements and polar questions in French both make use of the same rising contour type, and that this contour type is subject to contextual variation which may help cue different speech acts during conversation (signalling that one's turn is not complete vs. asking a question).

Intonation and focus marking in Ulyap Kabardian

Ludger Paschen[1]

[1] Department of Linguistics, Ruhr-University Bochum
ludger.paschen@rub.de

Abstract

This paper presents a pilot study that aims at establishing a model for the intonation of Ulyap Kabardian in the ToBI framework. On the basis of data gathered during a fieldtrip in 2012, it is suggested that four/three pitch accents and three boundary tones are needed to describe intonation in four communicative contexts. Additionally, it is shown that for focus marking in Ulyap Kabardian questions, a stress shifting rule dislocates word stress to a prosodically determined position. This shift rule is extraordinary in that it is insensitive to stress clashes. From a cross-linguistic perspective, the intonation system of Ulyap Kabardian bears a higher resemblance to the system of one of the Kabardian dialects spoken in Turkey than to Russian, the principal contact language.

Index Terms: Kabardian, intonation, focus, ToBI, polysynthetism, prominence

1. Introduction

The Kabardian language belongs to the Circassian branch of the North Western Caucasian family. The most characteristic typological features of all Circassian dialects are an abundance of consonant phonemes as opposed to only three vowel phonemes, a lack of lexical tones, a highly polysynthetic verb morphology and an ergative/absolutive case marking. There are about 360,000 speakers of Kabardian in Russia [5] and about 1,000,000 speakers in Turkey [11], all of whom are at least bilingual. It is important to note that the Circassian dialects spoken in Turkey differ substantially from those spoken in Russia due to a higher degree of exposure to the contact language [8]. The village of Ulyap (Улы́п) is located in the eastern part of the Republic of Adygeya in Russia. The Ulyap vernacular is a unique idiom in the Circassian family; its status as Besleney dialect, as postulated by [2], is highly questionable.

The aim of this paper is to provide a description of Ulyap Kabardian intonation used in neutral statements, wh-questions, lists and focus constructions. The study will include a prosodic description in the ToBI framework, phonetic measurements and a comparison to related languages and contact languages.

2. Methodology

Five adult female informants with permanent residence in Ulyap were recorded during multiple sessions using a hama EL-80 headset attached to an Olympus LS-5. The recordings were stored as wav-files (44.1 kHz, stereo, 16 kbit/s) and analysed using Praat [4]. The informants were asked to read out loud the sentences given in (1) – (4). The stimuli served to elicit the intonation patterns of neutral statements (1), wh-questions (2)[1], enumerations (3) and questions with narrow focus (4). There are several versions of (4) due to alternations of the verbal prefixes depending on the grammatical role of the focussed phrase; for the sake of simplicity, only two (A and DO focus) will be discussed here.

(1) *se* *s-jə-dze* *me-wəz*
1SG 1SG-POSS-tooth DYN-hurt
'My tooth hurts.'

(2) *sjə* *we* *q'-w-e-wəzə-r*
what 2SG DIR-2SG-DYN-hurt-ABS
'Where is the pain?' (lit: What is it that hurts you?)

(3) *babəʃʲ-əm* *ŝħe* *dame* *q'amzjə-xe-r* *jə-ʔa-xe*
duck-OBL head wing feather-PL-ABS POSS-have-PL
'Ducks have a head, wings and feathers.'

(4) a. AGENS focus:
fatjəme *asłen* *adəɣa+bze* *mə* *kabjənet-əm*
Fatima Aslan Adyghe+language PROX classroom-OBL
ʃʲ-j-e-z-ʁa-ŝ'e-te-r
LOC-IO-APPL-REL.A-CAUS-know-IPFV-ABS
'Was it Fatima who taught Aslan Adyghe in this classroom?'

b. DO focus:
fatjəme *asłen* ***adəɣa+bze*** *mə* *kabjənet-əm*
Fatima Aslan **Adyghe+language** PROX classroom-OBL
ʃʲə-r-jə-ʁa-ŝ'e-te-r
LOC-IO.APPL-3SG.A-CAUS-know-IPFV-ABS
'Was it Adyghe that Fatima taught Aslan in this classroom?'

3. Results

The model for the description of Ulyap Kabardian intonation follows the ToBI convention [3]. Based on the examples that will be discussed in this section, the intonation model for Ulyap Kabardian consists of the following components.

Tiers:

1. *tone* (T): pitch accents, boundary tones and prosodic boundaries
2. *Ulyap* (U): (phonemic) transcription of the Ulyap Kabardian speech sample on the word level
3. *English* (E): translation on the word level

[1] (1) and (2) were presented separately and did not form a dialogue-like sequence.

4. *break indices* (B): numeric values, perceived breaks
5. *word stress* (S): the syllable that has the lexical word stress; also used to indicate stress movement (applicable only in special focus constructions)
6. *misc* (M): notes regarding voice, timing and other comments

Symbols:

- H*, L* high/low tone on the stressed syllable
- H*+L high rising tone on the stressed syllable, followed by a steep fall
- H+L* falling tone which reaches its low target on the stressed syllable
- - ip-boundary without tonal specification
- H-, L- high/low final boundary tone of an ip
- L% low final boundary tone of an IP
- * stressed (prominent) syllable
- (*) destressed (non-prominent) syllable
- ¬ movement of prominent syllable (*stress shift*)

3.1. Neutral statements

The phrase *se sjədze mewəz* 'my tooth hurts' is a neutral statement in which no constituent is specially marked for focus or emphasis. The contour depicted in fig. 1 shows two H- at the end of both ω *se* 'my' and *sjədze* 'tooth', both lacking pitch accents. The only pitch accent in this IP is H+L* on the stressed syllable of the verb. Since the low target is reached late, H+L* (and not L*) was chosen as label. Note that in this example, the second H- is somewhat obfuscated by the following H+L* accent. It is safe to assume that the break and H- after *se* 'my' is due to elicitation as there is no obvious reason why the pronoun should be prosodically separated from its head and form a single ω and even a φ. Later on, it will be argued that NPs in Ulyap usually form a φ and that φs in non-prominent positions are marked with H-. The phrase-final L% may well be preceded by L-, but as of now no evidence for an additional L- can be furnished, which is why the annotation includes only one boundary tone.

3.2. wh-questions

The intonation pattern for open questions in Ulyap Kabardian is composed of one pitch accent and one boundary tone. As shown in figure 2, the wh-word *sjə* 'what' is accompanied by a high tone which is followed by a steep fall that continues to the left edge of the final verb. One could be led to consider a simple pitch accent H* sufficient to describe the pitch contour because of the obvious deaccentuation of the post-nuclear part of the utterance. However, in order to account for the steep fall that reaches its target well before the final L%, it appears to be more reasonable to assume a complex pitch accent H*+L. Note that the timing of the fall is late, reaching to the end of the second word *we* 'you'. The deaccentuated part is analysed as still belonging to the intonation phrase (but cf. e.g. [16]), therefore L% is placed at the right border of the phrase. Since F0 is stable and level during the whole final ω *q'wewəzər* 'hurts', again no ip-tone L- is set at the end of the phrase.

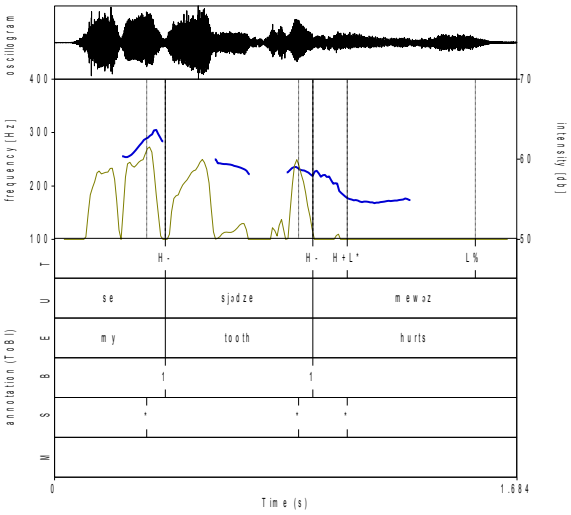

Figure 1: *Neutral statement intonation.*

3.3. Lists and incompleteness

It has been proposed that high F0 universally serves as a prosodic equivalent to incompleteness (e.g. [12], [7]). [1] choose H% to transcribe a final rise in non-final elements of lists in Turkish Kabardian. For Ulyap Kabardian, however, a different tonal analysis is needed, as the contour of the three-item list (fig. 3) suggests. First of all, the lack of resets suggests that the items do not constitute complete intonation phrases but intermediate phrases (the disjuncture between the ips discussed under 3.1 is weaker than here, but for the sake of simplicity, I shall restrict myself to only one phrase type below the IP). Second, the polysyllabic *q'amzjə̂xər* 'feathers' has a high tone in the stressed syllable, but not at the right boundary of their ip. It therefore appears appropriate to use H* followed by an unmarked ip-boundary to account for both the level contour on the monosyllabic *ŝhe* 'head' and the stepped contour on *q'amzjəxər*. A downstep can be observed for the second, but not for the third H*.

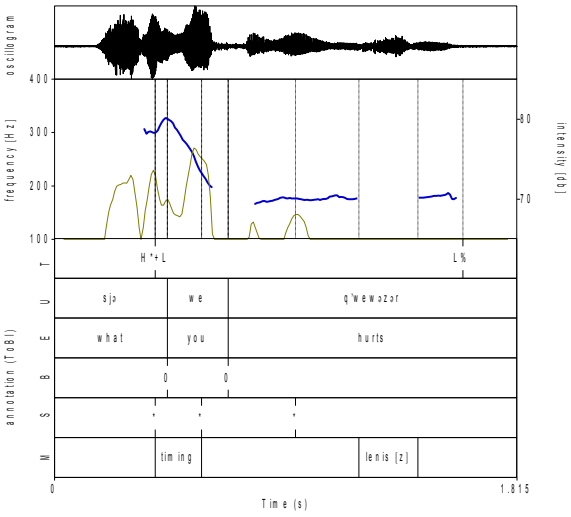

Figure 2: *Wh-question intonation.*

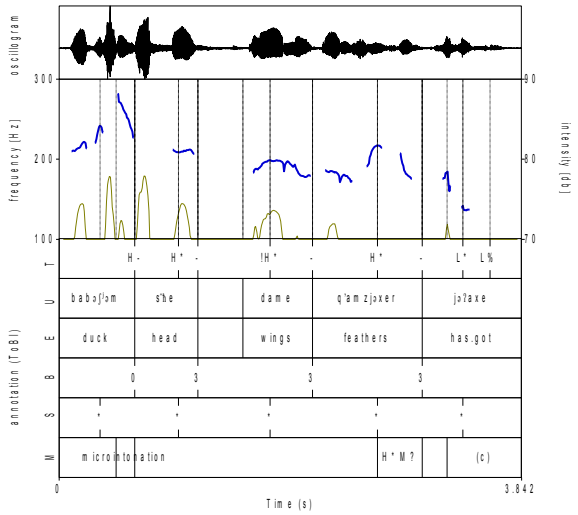

Figure 3: *List intonation.*

F0 on the first word *babə́ʃʲəm* 'duck' is rising steadily, which is best accounted for by a high ip-tone (although no real break can be perceived between the first two words). H- may have to be seen in the context of the topic-like function of *babə́ʃʲəm*, as H- is also used for background elements in questions with narrow focus (see next section). In order to determine the exact function of H- in Ulyap IS, however, further research is necessary.

The final low pitch accent L*, which has already reached its target on the stressed syllable, is followed by a creaky portion that ranges to the end of the phrase. The final *diminuendo* and the voice properties hint at a preceding long breath group, which supports the idea that the list elements constitute only ips, as one would usually expect at least one inhalation in a sequence with three IP-boundaries (H%).

3.4. Focus

In Ulyap Kabardian questions with contrastive focus, non-focussed elements form a φ and are marked with H-, as can be seen in fig. 4 and 5. The most striking feature of those questions is that the position of the most prominent syllable does not coincide with the normal position that word stress predicts. For instance, fig. 4 shows a phrase with focus on the first noun *fatjə́ma* 'Fatima' with obvious stress on the first syllable: not only is it perceptually highly prominent, but it also exceeds the remaining syllables in terms of intensity and spectral clearity. The relevant pitch movement – a high rise followed by a steep fall – should therefore not be ascribed to the left edge of the ip but to the neo-stressed syllable /fa/ (H*+L). Since the post-nuclear fall continues to the right edge of the first word, after which a clear break ensues, an additional low ip-tone L- was added in the annotation.

If one compares this IP to another IP in which a different word (*adəɣábze* 'Adyghe language') is focussed (fig. 5), it becomes evident that it is indeed the first syllable to which stress is (re-)assigned, regardless of its original position. In fig. 5, both intensity and pitch peak are located late on the first syllable, whereas the usually stressed third syllable is now less prominent (though it retains its normal length[2]). The same tonal analysis as in the first example can also be applied to this phrase. Irrespective of the (yet-to-be-defined) prosodic properties of feet in Ulyap Kabardian, the stress shift can be accounted for by the following rule.

(5) *focus stress shift*

$(\sigma_1 \dots \sigma_n)_\omega \rightarrow (\text{'}\sigma_1 \dots \sigma_n)_\omega$ / [__]$_{FOC}$

Similar stress shift rules on the word level have been reported for English in two contexts: focussing bound morphemes (as in *She was included, not éxcluded.*) [14] and when speakers want to avoid stress clash (as in *Japanése mágazines*) [6]. The shift discussed here does not fit either category: there are no bound morphemes in *fatjə́ma*, and the shift can even provoke a stress clash (fig. 5). Curiously, [16] report a similar phenomenon (though not an obligatory rule) for Turkish narrow focus in statements with H*+L, but unfortunately do not elaborate on the matter.

Measuring vowel length revealed that vowels in newly stressed syllables had an average 147.0% duration compared to their counterparts in non-focussed words. However, the deaccentuated vowels were longer (122.9%) as well. In fact, the only vowel that was found to be shorter in the focussed phrase than in unmarked contexts was the first /ə/ of *adəɣabze* 'Adyghe language'.

Intensity was a more reliable indicator for the acoustic measurement of stress. Table 1 and Figure 6 provide an overview of the intensity values of word-stressed vowels in non-focussed constituents (*fatjə́ma*), neo-stressed vowels in focussed constituents (*fátjəma*$_{FOC}$) and their respective counterparts (*fatjə́ma*, *fátjəma*$_{FOC}$). The highly significant differences indicate that the beginning peaks cannot be merely due to an initial rise but have to be the result of prosodic restructuring taking place before the post-lexical level.

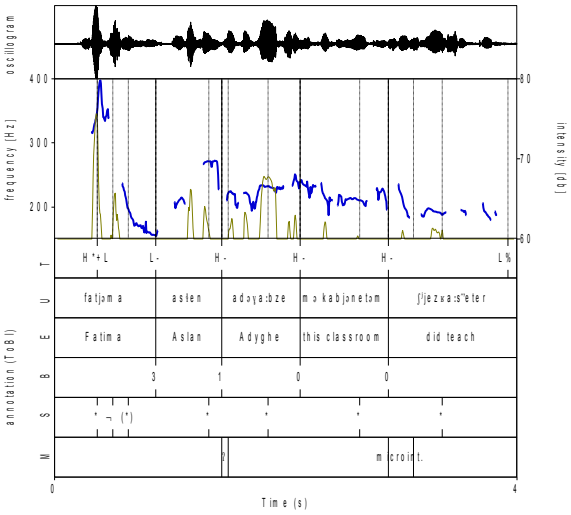

Figure 4: *Question intonation with contrastive focus on the first element.*

[2] The interaction of vowel quality and length in the Circassian dialects is quite complex and cannot be elaborated upon in this paper.

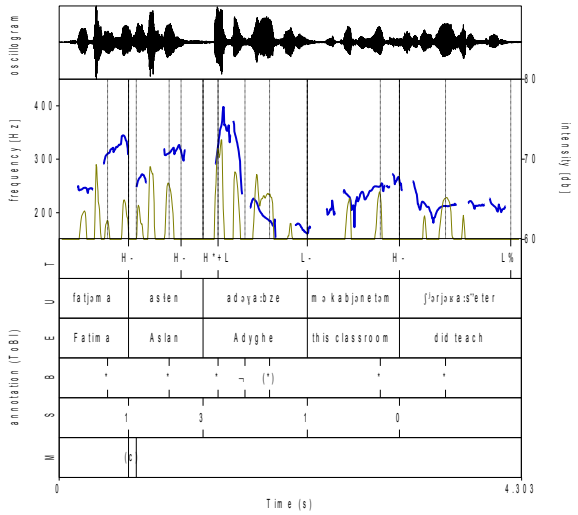

Figure 5: *Question intonation with narrow focus on the third element.*

		word-stress		neo-stress	
		-foc	+foc	-foc	+foc
word-stress	-foc	---	n.s.	*	**
	+foc		---	n.s.	*
neo-stress	-foc			---	***
	+foc				---

Table 1: *Significance levels of intensity values measured in various environments. Vowels in neo-stressed syllables were found to differ significantly (2-tailed t-test, 4 stimuli, 3 speakers) under focus from those in other contexts.*

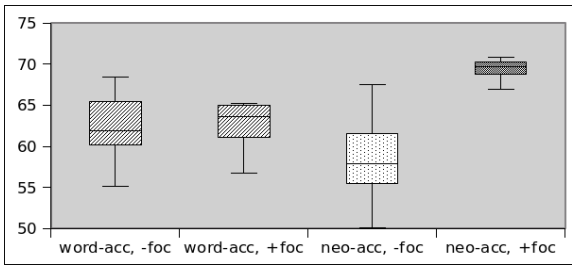

Figure 6: *Boxplot diagrams for intensity values (y-axis, mean energy [dB]) of vowels in different focus and stress environments (cf. Table 1).*

4. Discussion

4.1. Boundary tones

A common feature of all examples discussed so far is the absence of initial and the redundancy of final IP boundary tones. It would be premature to draw any conclusion about IP boundary tones in general at the current state of research. It has become clear, however, that at least for the contexts examined, IP boundary tones – in contrast to ip tones – do not appear to bear any functional weight at all.

4.2. Typological considerations

Table 2 offers a compact synopsis of typical tune patterns in Ulyap Kabardian, Turkish Kabardian [1], Russian [13] and Turkish [9], [16], [10]. The prosodic structure of Ulyap Kabardian shows some remarkable similarities to Turkish Kabardian, the main differences being the tonal interpretations and not the general tune trends. Fewer common features are shared with Russian, the major contact language of Ulyap Kabardian, whereas Turkish Kabardian exhibits remarkable parallels to Standard Turkish. *Stress shift* appears to be present in Turkish [16] but was not reported for Turkish Kabardian [1].

idiom → ↓ context	Ulyap Kabardian	Turkish Kabardian	Russian	Turkish
1 neutral statement	(H-)^{x} H+L* L%	%L H* L%	L* L%	(L H*)^{x} L%
2 wh-question	H*+L L%	%L H* L%	HL* L%	H* {L,H} %
3 list / incompl.	(H-) H*-^{x} L* L%	(H%)$_{x-1}$(H*)$_{x}$ L%	H*M %	?
4 focus question	H*+L L- L%	%L H*HL L%	H*L L%	?

Table 2: *Comparison of intonation patterns for two Kabardian variants and the respective contact languages.*

5. Summary

In this paper, a first model for Ulyap Kabardian intonation in the ToBI-framework was presented. Non-focussed non-verbal constituents in neutral statements are marked with H- only, whereas wh-words have H*+L and list elements have H* and an additional ip-tone. Focus constructions include H*+L and a prosodic rule that shifts word stress of focussed elements to the leftmost ω-position.

As the data analysed in this pilot study cover but a fragment of the Ulyap Kabardian dialect, further studies must take into account a broader data set. It is also beyond doubt that perceptive experiments are necessary to verify the tonal analyses proposed in this paper.

6. Acknowledgements

This research project was funded by the Faculty of Philology at the Ruhr-University Bochum, the Gesellschaft der Freunde der Ruhr-Universität e.V. and the Foundation for Fundamental Linguistic Research fund A-23 (2012). I want to thank G. Moroz for valuable comments during the field trip. Finally, I would like to express my gratitude to all informants for their willingness to contribute to gaining a better understanding of their dialect.

Abstract

State-of-the-art pronunciation tutoring (CAPT) systems are based on ASR technology. Consequently, they can provide a distinguished learning feedback which is focused on phonetic features and the positions of articulation errors. In contrast with the relative success with segmental errors, the acquisition and assessment of second language (L2) prosody is still a challenging problem. Although prosodic parameters like f_0 contour or duration measures are usually displayed, the consequential evaluation components are generally missing. Considering the strong variation in speech data, functional data analysis (FDA) is a useful concept which statistically analyses interrelations between principal components (e.g., given accentuation) and their contribution to superimposed forms (e.g., resulting f_0 contour). This article describes baseline processing and preliminary results of a pilot study on the intonation-based proficiency classification of German by using FDA methods. The experimental part contains the FDA-based classification results compared to a perceptual classification by German natives.

Index Terms: L2 prosody, proficiency, functional data analysis

1. Introduction

Computer-assisted language learning (CALL) and so-called intelligent language tutoring systems (ILTS) have been established components in second language education for more than a decade. Among the proposed methods and systems, automatic pronunciation tutoring (CAPT) plays an increasingly important role. Available CAPT systems offer a wide range of user feedback, such as recorded and reference waveforms, analyzed spectra and underlaying phoneme sequence or animated articulatory organs—often including the intonation contour of uttered phrases. Nevertheless, the pronunciation assessment including the marking of error positions is usually based on segmental (phonetic) features and relies on conventional automatic speech recognition (ASR) modules that rely on hidden Markov models (HMMs) and, for example, use Goodness of Pronunciation (GOP) score as confidence measure [1]. In the system development, elaborate speech databases (originally developed for ASR) can be reused. Although the importance of the prosody acquisition is widely agreed among linguists and teachers, research and development have limited focus on suprasegmental (prosodic) evaluation components. This lack of interest might be surprising, since prosodic core parameters like f_0 contour or rhythmic structures can be easily measured. During the development of the CAPT systems AzAR and Euronounce by TU Dresden and partners [2, 3], effort was invested in suprasegmental databases for the assessment of cross-lingual effects in the acquisition of second (L2) or third language (L3) prosody. The Euronounce database contains 130 speakers of German, Polish, Czech, Slovak and Russian (including 18 language students per L1/L2 pair) and about 200 hours of speech. In further projects the AzAR concept and databases were extended to Mandarin learners of German, to L2 learners of Basque [4, 5, 6], and a baseline method to evaluate intonation contours was suggested.

Considering the strong variation in speech, we found that the functional data analysis (FDA) introduced by Ramsay and Silverman [7, 8] can also provide a powerful approach in speech analysis by statistically exploring interrelations between principal components (e.g., accentuation) and their contribution to forms (e.g., f_0 contour). FDA-based methods in prosodic analysis and synthesis have been already suggested by Gubian et al. [9, 10]. In a recent study, Ward [11] applied principal components analysis (PCA) to several dozen contextual prosodic features in a large set of heterogeneous dialog data. The resulting prosodic components are interpretable as prosodic patterns, including some which involve behaviors of both interlocutors. We intend to apply FDA in different stages of the prosodic assessment—focused on CAPT. In the current article, we describe preliminary results of a pilot study on an automatic intonation-based proficiency classification for German language to test the potential of FDA methods in CAPT environment. In our case the proficiency classification by limited (i.e., only intonational) information is just a working assumption. A detailed prosodic analysis of single speaker utterances or a reliable "overall" proficiency level classification of a speaker is not intended within the scope of this paper. It is clear that the spoken language proficiency is characterized by complex feature sets such as active vocabulary, rules of grammar and phonology, phonetic correctness and so on. Section 2 introduces some previous work on L2 prosody assessment and provides links to proficiency classification. In section 3, we briefly explain the FDA concept. The pilot study on 16 speakers of German is described in section 4—including the L1/L2 database, the baseline processing and the experimental results. The results consist of two parts—addressing FDA-based classification results and a listening test with proficiency classification by native speakers of German.

2. Proficiency and prosody assessment in second language learning

2.1. Proficiency classification

Standardized tests of language proficiency such as the Test of English as a Foreign Language (TOEFL) [12] were already established in the 1960s focusing on reading, listening and writing rather than speaking abilities. In the TOEFL Internet-based Test (iBT) since 2005, the performance evaluation in reading and listening is based on questionnaires. The results of writing and speaking sections are evaluated by three to six human raters which is costly. Consequently, automatic classification methods

are mainly addressing the written proficiency of language learners using algorithms from machine translation [13, 14, 15]. The assessment of spoken language proficiency is focused on phonetic features using GOP or similar measures as already discussed in section 1. Features of non-native prosody, which limit the L2 proficiency, have been studied in different contexts—focused on L2 American or British English. Within the context of this article, some studies dealt with the non-native accent identification [16, 17, 18].

2.2. Prosodic assessment

Beyond the native versus non-natives classification problem, studies of Hönig, Batliner et al. [19, 20] tried to assess L2 productions with respect to intonation and rhythm on a continuous scale, and suggested a suitable set of prosodic features that approximated the decisions of human labelers. In [21], the surveyed feature spaces were extended by acoustic features known from speaker identification tasks (such as short-time spectral features) or general-purpose features from established paralinguistic analysis to indirectly capture complementary prosodic information. The studies consider the perceptual evaluation as a reference—as we do in our work—and describe promising classification strategies. Nevertheless, by fusing different prosodic or even complementary features, the impact of single components (e.g., specific word accentuation or phrase modus variation in the intonation contour) can not be adequately modeled, which results to a less specific user feedback. Our study is targeting on principal intonation components which contribute to the proficiency classification—as an indicator for the influence on L2 prosody—and not on the overall optimal feature representation and classification.

In a previous study [6], we identified Basque as an interesting object of L2 studies in prosody. Basque is an isolated language which does not belong to the Indo-European language group, as one would expect from its geographical location. It has two major neighboring languages, Spanish and French, and the influence of these languages on Basque is noticeable—especially for people studying L2 Basque. In this light it is not surprising that Euskaltzaindia, the Academy of the Basque language, has not yet made a decision about standard prosody due to the variety of accents and intonations across the dialects. L2 students of Basque do not have a clear reference of the preferable pitch pattern and often opt for that of their own L1. This indeterminacy effects the application of conventional quantitative intonation models. The proposition of the Basque study assumes the teacher voice including its intonation pattern as a reference. By providing same text example to the student (cf. "shadowing task"), the intonation quality is simply indicated by the root mean square error (RMSE) between realized f_0 contour of the student and the according reference utterance. For this purpose, f_0 contours need to be normalized on their mean value (gender normalization) and synchronized to the reference by dynamic time warping (DTW) as shown in figure 1.

3. Functional data analysis in prosody

In general, functional data analysis (FDA) names a branch of statistics that analyzes multivariate data which may be treated preferably as curves or surfaces varying over a continuum which is often time, but it can be, among others, spatial location or probability. The data may be subject to measurement errors or even have only an indirect relationship to the curve that they define. It is assumed that the curves are intrinsically smooth.

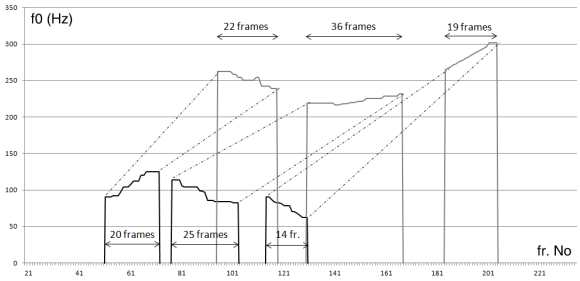

Figure 1: Exemplary f_0 contour mapping: Basque male (reference below) vs. Slovakian female uttering Basque word INDEPENDENTZIA from [6].

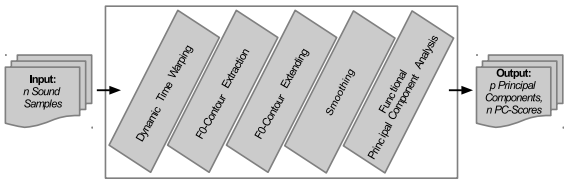

Figure 2: f_0 analysis steps in overview.

Ramsay, Silverman and others developed a set of descriptive and exploratory FDA techniques [7, 8]. Functional data analysis can also use information of slopes and curvatures—reflected in derivatives of the curves—which may reveal aspects of the data generation process. Functional data models and methods resemble those for conventional analyses of multivariate data, including smoothing techniques, regression models, splines and principal components analysis. Gubian et al. introduced the FDA to speech analysis [9] and, in particular, to the f_0 analysis (e.g., for discriminating questions and answers as in [10]). According to Gubian, FDA provides a qualitative/visual description of results and quantitative output in form of statistical values and can be, therefore, interpreted as an "interface between shapes and numbers". We follow this approach and use functional data analysis to abstract away from random f_0 variation in instances of the same utterance. Moreover, the FDA shall extract a maximum of relevant information from our dataset and supports a reliable estimation of the f_0 curves. The analysis process consists of five steps as shown in figure 2. In the first step, all utterances (waveforms) are aligned by dynamic time warping (DTW) to avoid timing mismatch. The subsequent f_0 curve extraction is based on Praat [22]. In the next steps, unvoiced parts are approximated with splines and the resulting contours are smoothed. The final part, the principal component analysis (PCA) for functional data, is the most important analysis step. The PCA reduces the number of functions in the dataset to a lower number of principal components (PCs). The PCs, based on eigenvalues and eigenfunctions by a complex reduction, represent a maximum of information of the whole dataset. For the PCA execution, we need the covariance functions of our data as described in [8],

$$v(s,t) = \frac{1}{n-1}\sum_{i=1}^{n}[x_i(s) - \overline{x}_i(s)] \cdot [x_i(t) - \overline{x}_i(t)] \quad (1)$$

and the definition of the extreme values for the eigenvalues

$$\mu = max_{\xi} \left\{ \sum_{i=1}^{n} [\int \xi(t) x_i(t)\, dt]^2 \right\}. \quad (2)$$

Henceforward one can formulate an eigenvalue problem:

$$\int v(s,t)\xi_j(t)\, dt = \mu_j \xi_j(s). \quad (3)$$

This problem is transformed into the form $\mathbf{V}\vec{\xi} = \mu$ and is solved in the numerical linear algebra by the aid of determinants and the unity matrix which results in PCs—built with their eigenfunctions and eigenvalues (cf. [10]),

$$PC_j(t) = \overline{x}(t) + \sqrt{\mu_j} \cdot \xi_j(t) \quad (4)$$

and principal component scores (PC scores) which are important for the subsequent classification (cf. [8]),

$$\mathbf{C}_{scr}(i,j) = \sum_{j=1}^{p} \sum_{i=1}^{n} \int \xi_j(t)[x_i(t) - \overline{x}(t)]\, dt. \quad (5)$$

By analyzing n utterances (in our case study 16 speaker samples), we calculate p principal components (in our case study 3 PCs) and obtain n (p-dimensional) principal component scores (16 PC scores).

4. Pilot study

4.1. Test design and speaker database

The simple test design aims at the question whether the extracted three principal f_0 components of a short test phrase contain relevant prosodic information to solve two practical targets—as intermediate step for the proficiency assessment:

- Speaker discrimination into native or non-native (L1 vs. L2 speaker of German),
- Proficiency classification on a six-point scale (in the style of the language levels A1, A2, B1, B2, C1 and C2 of the Common European Framework of Reference [23]).

The German test phrase NEIN, SIE KANN ES NICHT. ('No, she can not do it'.) was uttered by 16 speakers (one example per speaker). The test dataset includes eight native (L1 German) speakers and eight non-native speakers with mother tongue (L1) Russian. By disregarding further potential language interferences (e.g., L2/L3 English/German), we consider all non-natives as L2 German speakers. Table 1 summarizes the dataset. The reference classification of the speakers to the mentioned language levels is based on the decision of a language teacher. To simplify the task, we consider the highest L2 speaker level C2 equivalent to the mother tongue level of the L1 speakers (level 1 in the six-point scale).

Table 1: *Test database in overview*

Group	Speaker description	No. of speakers
1	L1 German, male ($L1m_x$)	4
2	L1 German, female ($L1f_x$)	4
3	L2 German, male ($L2m_x$)	4
4	L2 German, female ($L2f_x$)	4

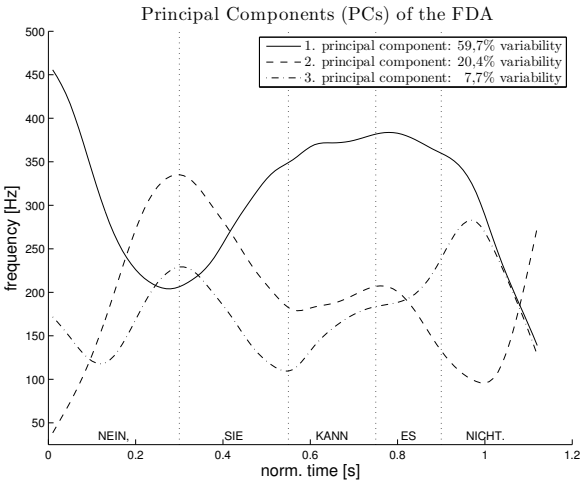

Figure 3: Analyzed principal components of the German phrase: NEIN, SIE KANN ES NICHT. ('No, she can not do it.')

4.2. FDA-based proficiency classification

The first three principal components (PCs) and 16 speaker-based PC scores are calculated as described in section 3. As a reference, the center of mass of each speaker group (L1m, L1f, L2m, L2f) in the PC scores is determined. The root mean square error (RMSE) of each group serves as distance measure. Each speaker distance to the center of mass is divided by the according group RMSE which results to a speaker-specific value of belonging to the certain group—enabling the discrimination into native and nonnatives. By using the PC scores, a geometric distance matrix for the reference speakers is generated (also weighting the PC score dimensions by their information content. The mean deviation of each speaker to its reference value in the matrix is divided by the mean sum of the reference matrix which generates a normalized value of belonging to a certain language level.

4.3. Experimental results

Figure 3 visualizes the first three PCs of the test phrase—representing an information content of 87.8% which we assume as a sufficient accuracy regarding the simple test design. Figure 4 displays all PC scores in two-dimensional PC spaces which leads to three PC combinations with $n = 16$ scores per diagram. The PC scores can be associated with the n f_0 contours. The L1m (male) and L1f (female) speakers create scatter plots which might be associated with feature clusters. Six of the eight L1 speakers can be visually classified. Nevertheless, the L2 speakers do not form visible clusters. Additionally, two L2 speakers seem to cluster with the L1 group.

4.4. Perceptual test

Besides the known proficiency classification provided by language teacher, we performed a perceptual test with 15 naive subjects—ten males and five females with a mean age of 26.3 years. The listeners evaluated 16 utterances (same phrase) in random order and had no prior knowledge about prosodic analysis or the surveyed interrelation to the proficiency assessment.

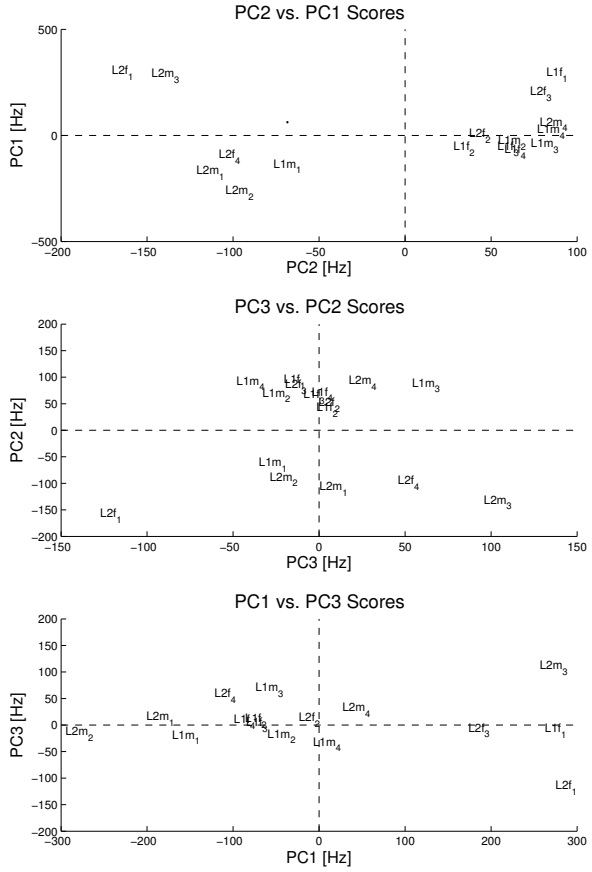

Figure 4: Speaker-specific visualization of the PC scores.

The questionnaire contained the following items:

- Speaker gender (m/f),
- Native speaker of German (y/n),
- Language level on a six-point scale ("1" best).

In L1/L2 classification, the mean decision has a deviation of 0.16 on the normalized scale ("0" L2 . . . "1" L1). In the language level classification, the decisions deviate by 0.98 on the normalized scale ("1" L1 speaker . . . "6" L2 beginner).

4.5. Comparison of FDA-based and perceptual results

By setting the decision threshold to 0.5, the resulting native/non-native classification is shown in figure 5. The "regular classification" is given by the teachers' reference. The listeners' classification ("subject group") is correct for all L1 speakers but includes two errors (speakers 5 and 8) and one border case (speaker 6) in the L2 speaker assessment. The FDA-based classification fails twice in both speaker groups (speakers 1, 5, 12 and 14). Figure 6 visualizes the language level classification of the speakers on the six-point scale. The teachers' classification is assumed as reference. Both, the mean subjective and the FDA-based decisions are correlated to the reference. For nine speakers, the subjective decision closer reflects the teachers' classification. In the remaining seven cases, the FDA-based classification is more accurate.

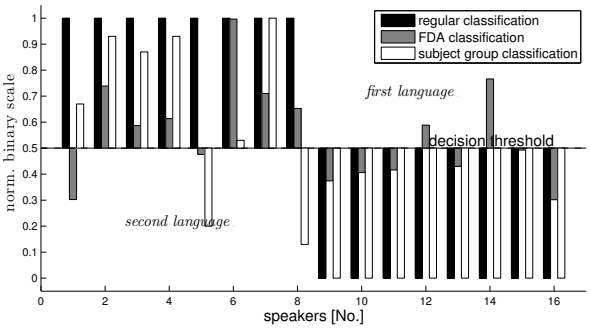

Figure 5: L1/L2 classification by teacher ("regular"), subjects and FDA

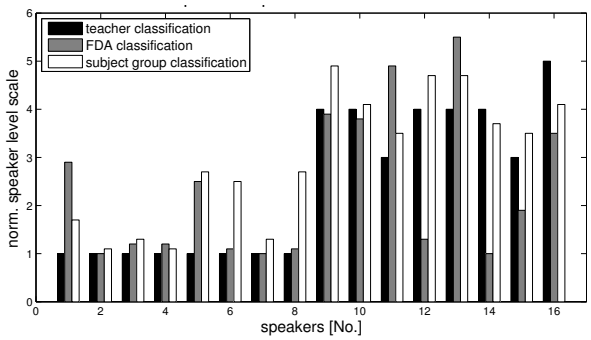

Figure 6: Language level classification by teacher, subjects and intonation-FDA-based ("1" L1 speaker . . . "6" L2 beginner).

5. Discussion

As we expect from our daily-life experience, naive listeners are able to identify non-native speakers and even classify their proficiency on a language level scale with a certain accuracy (widely reflecting the teachers' assessment). In the test design, listeners can use all noticeable problems in a single test phrase such as mispronounced phonemes, wrong segmental durations or accentuation. In contrast, the FDA-based classification is only leaned on the scoring of three principal components extracted from the f_0 contour. It is remarkable that the simple FDA-based classification, which is only using f_0 information and a highly reduced data description, leads to correct classification in the majority of the L1/l2 speaker decisions. The FDA-based language level classification achieves similar results as the perceptual testing, too.

6. Conclusion

The pilot study shows the potential of the functional data analysis in the proficiency assessment but the results are preliminary and need to be consolidated in further experiments with additional data (i.e., more speakers, phrases and variants, further prosodic parameters). In our study we focused on the question how the FDA concept can be utilized for prosodic analysis in the context of pronunciation training. As a preliminary study, two hypothetic classification tasks were carried out with a few simplifications, and only linear classifiers were used. Further extensions of this study will use trainable classifiers and investigate the viability of these methods in real-world assessments in pronunciation tutoring.

7. Acknowledgements

The L1/L2 test data are part of the Euronounce corpus and were recorded by Rainer Jäckel, TU Dresden. We would also like to thank Michael Graf and Ines Rennert, Leipzig University of Telecommunication (HfTL), for their valuable advice.

Tonal allophony in Vietnamese: Evidence from task-oriented dialogues

Kieu-Phuong Ha[1], *Martine Grice*[1], *Marc Brunelle*[2]

Abstract

In this paper we investigate the behaviour of the lexical rising tone (SAC) in disyllabic sequences in the Northern variety of Vietnamese. Results from task-oriented dialogues show that this rising tone (SAC), when occurring before the lexical high-level tone (NGANG), can be realised as low level or falling, resembling a different tone in the language (HUYEN). This is the case word-internally and within noun phrases. Two further observations give us an indication that a sandhi process could be developing: (a) this variation is not found in sequences across a larger juncture, and (b) the SAC tone does not undergo this change before other tones.

Index Terms: Northern Vietnamese, tone sandhi, neutralisation, disyllabic sequences, semi-spontaneous speech

1. Introduction

Tone sandhi is a well-known phenomenon in a number of East Asian tone languages such as Taiwanese, Cantonese, Mandarin and other Chinese dialects. It involves 'phonological changes that take place across word boundaries' or 'systematic tone changes, even when they take place word-internally across morpheme boundaries' [1:180]. Examples are *third tone sandhi* in Mandarin Chinese [2], *Min tonal circle* in Taiwanese [2], and *changed tone* in Cantonese [3]. This paper is concerned with the Northern variety of Vietnamese.

Northern Vietnamese has six lexical tones, two of which are level, high (NGANG) and low (or low-falling) (HUYEN), and four of which are contour tones, rising (SAC), falling-rising (HOI), rising-glottalised (NGA), and falling-glottalised (NANG). There is no established tone sandhi in this language, apart from tonal harmony processes in reduplication contexts [4], also referred to as tonal alternation [1]. Moreover, tonal coarticulation has been attested at a phonetic level [5]. However, although sandhi has not been found in controlled experiments, we have informally observed some allophonic variation in conversational speech in younger speakers, more specifically, in disyllabic words, in which the first syllable has a rising tone (SAC) and the second a high level tone (NGANG). In these words the first syllable appears to have a low level or falling pitch, akin to another tone in the language, HUYEN.

Such a change cannot be accounted for by coarticulation, there being no coarticulatory pressure to change a rise before a high-level tone into a fall. However, since this allophonic variation has been observed in spontaneous speech, this study is based on a task that ensures that speakers are formulating their utterances without an orthographic prompt, and that they are interacting with an interlocutor.

We focus in particular on disyllabic sequences within non-reduplicated words and noun phrases. Our specific research questions are whether in conversational speech in the laboratory we obtain 1) a low level or falling allophone of the rising tone (SAC) when produced before the high-level tone (NGANG) and, if this is the case, 2) whether the allophonic variant of SAC resembles the low-level/falling tone HUYEN.

Below we first present an overview of the methodologies used in the elicitation and analysis (section 2). Then we investigate the shape of tone SAC before tone NGANG in sequences with weak junctures against those with larger junctures (section 3.1). In section 3.2 SAC NGANG sequences with weak junctures will be compared with sequences where SAC precedes other tones with comparable junctures. Section 3.3 presents the shape of tone SAC in SAC NGANG sequences against the shape of tone HUYEN in HUYEN NGANG sequences. Conclusions and discussions are provided in section 4.

2. Methodology

2.1. Speech materials and participants

A map task dialogue was recorded using the methodology and design from the HCRC Map Task Corpus [6]. The reason for this choice is that map task dialogues provide real interaction between speakers and assure a certain degree of spontaneity of the data in which the sequences in question are produced.

Two participants have slightly different maps with 11 or 12 landmarks. Some of the landmarks are located differently. While only one map has a route from the start to the end, the other has only the start. The task is for one participant to instruct the other to reproduce the route on the second map without either seeing each other's map. This is done by discussing the route and landmarks. A small screen was placed between the two participants to prevent eye contact. The total duration of the dialogue is approximately 10 minutes. Speaker L is from Thanh Hóa (female, aged 26), speaker M is from Tuyên Quang (female, aged 28). Both provinces are in the Northern Vietnam. The speakers are colleagues and have been living in Hanoi for 4 and 10 years respectively.

2.2. Data transcription and categorisation

The dialogue was orthographically transcribed to enable the selection of the sequences in question. Our target sequences are SAC before NGANG. To investigate the first research question of whether there is an allophonic variant of SAC before NGANG, we first looked at sequences with different syntactic junctures. Then the SAC-NGANG sequences were compared with sequences from a control group, SAC before tones other than NGANG (control group 1). To address the question of whether we are dealing with a sandhi process of SAC-NGANG changed to HUYEN-NGANG (research question 2) we took into account a control group of HUYEN-NGANG sequences (control group 2). Sequences from both control groups had comparable juncture strength.

With respect to the target group, we found in total 75 SAC-NGANG sequences in the dialogue. These sequences were categorised according to their syntactic junctures. We found 4 groups of junctures: i) within disyllabic words, ii) across noun+modifier, classifier+noun, preposition+noun, and verb+object boundaries, iii) across subject+predicate boundaries, and iv) across a sentence boundary. In this paper we analysed only groups i), with the weakest juncture, and iv) with the strongest juncture, as they provide the most cases (in total **36 cases**). Table 1 provides an overview of these two groups of juncture, the frequency of the investigated cases and their syntactic junctures. Sequences that involved a self-repair, a hesitation, or a strong interaction with the intonation at the right edge of the utterances [7] were also excluded.

Table 1. *The frequency of occurrence and examples for each type of syntactic juncture for SAC NGANG sequences (word-for-word glosses in small capitals, corresponding translations in italics)*

Grp	Freq	Syntactic junctures and examples
1	19	disyllabic words
		phía trên SIDE TOP *above*, **phía ngang** SIDE CROSS *across*, **trái tim** *heart*, **ngón tay** *finger*
2	17	sentence+sentence (or fragment) or sentence+particle
		Không phải phía bên phải đâu **nhớ** NEG OUGHT SIDE SIDE RIGHT NEG PARTICLE *It is not on the right hand you know,* **bên** trái điểm-đến SIDE LEFT DESTINATION *on the left of the destination.* mình vẽ một nửa cái bán-cầu **đấy** WE DRAW ONE HALF CLF HEMISPHERE THAT **thôi** ONLY *We draw only half of that hemisphere.*
	∑=36	

Table 2 provides examples for the target group of SAC-NGANG sequences (TG) and two control groups (CG), and the frequency of these sequences; control group 1 (SAC before other tones: SAC-OTHER) and control group 2 (HUYEN-NGANG) had comparable juncture strength.

Table 2. *Examples and frequency of sequences in the target group SAC-NGANG disyllabic words (TG) and 2 control groups (CG1: SAC-OTHER, CG2: HUYEN-NGANG) (word-for-word glosses in small capitals, corresponding translations in italics)*

Grp	Freq	Examples
TG	19	**phía trên** SIDE TOP *above*, **phía ngang** SIDE CROSS *across*, **trái tim** *heart*, **ngón tay** *finger*

1	44	**uốn lượn** *to curve*, **cánh đồng** *field*, **nối thẳng** *link directly*
2	16	**đầu tiên** *firstly*, **vòng qua** *go round-to*, **rồi xong** *then*
	∑=79	

2.3. Acoustic analysis

To quantify the shape of the contour on SAC syllables, we first extracted the F0 values and calculated the distance between the F0 at the vowel onset and the value at the end of the syllable. The measurement at the vowel onset is chosen to mimimize effects of microprosody due to onset consonants on SAC syllables. If the values of this measure are positive, this indicates that SAC has a rising contour. If the values are negative or zero, it is an indication that SAC is falling or level. This step was conducted, not only for the target sequences SAC-NGANG, but also for the two control groups SAC-OTHER (control group 1) and HUYEN-NGANG (control group 2). All measurements were conducted using Praat.

3. Results

3.1. SAC-NGANG sequences across junctures

We examined whether the juncture strength between the two syllables in SAC-NGANG sequences affects the realisation of the SAC tone by comparing the interval in semitones between the beginning of the vowel and the end of the SAC syllable in the two different juncture conditions. Values for each of the juncture conditions are plotted individually for each speaker in Figure 1.

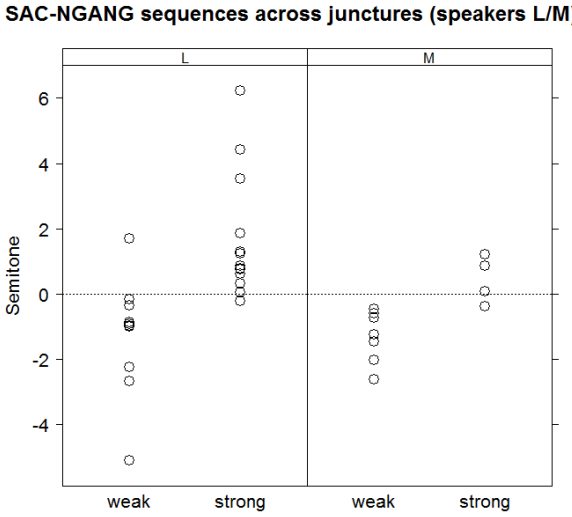

Figure 1: *Distribution of intervals in semitones between vowel onset and end of syllable for the initial syllable with rising tone (SAC) in SAC-NGANG sequences across two juncture strengths. Negative values=falling, positive values=rising; speaker L: weak juncture (N=12), strong juncture (N=13); speaker M: weak juncture (N=7), strong juncture (N=4).*

Here we can see that there is little overlap across the two juncture strengths in the realisation of SAC in SAC-NGANG. Specifically, we can observe a great number of low level or falling realisations (indicated by negative values or values around 0st) and very few rising realisations of the rising (SAC) tone (indicated by positive values) when the juncture is weak. Both speakers show the same tendency. Their roles in

the task (speaker L being instruction giver, speaker M being follower) resulted a greater number of utterances for L than M. The investigated sequences occur in both phrase-medial and phrase-final positions indicating that SAC is changed before NGANG regardless of the position of the sequences in phrases. When the juncture was strong, by contrast, there were predominantly rising realisations, i.e. the tone was realised in its canonical form as in citation contexts.

Figure 2 shows two examples of the contour on SAC in SAC-NGANG sequences produced by speaker L. The first sequence is the word "phía ngang" (Fig. 2a) *across* taken from the utterance:

Không đi lên đâu mà đi **phía ngang**.
NEG GO UP NEG BUT GO SIDE CROSS
Don't go up but go across.

The second sequence (Fig. 2b) has a strong juncture between the two syllables, namely between a sentence and a fragment:

xong vòng lên trên bênh-viện **nhớ,**
THEN CIRCLE UP ABOVE HOSPITAL IMP.PARTICLE
lên trên nóc bệnh-viện ý
UP ABOVE TOP HOSPITAL PARTICLE
Then go up to the hospital, up to the top of that hospital.

We see that in the first case, the contour on the SAC syllable is falling, whereas the contour in the second one has a rise similar to the lexical tone of the particle.

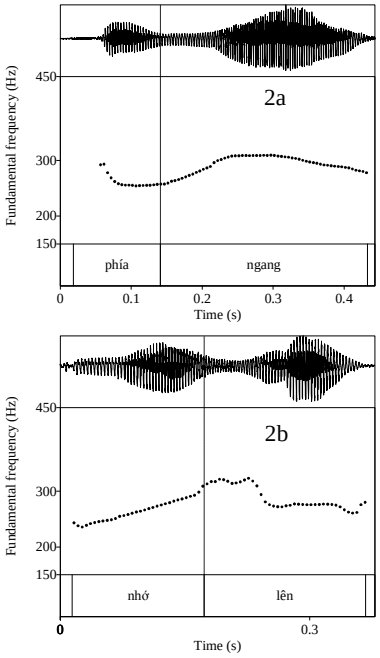

Figure 2: *Examples of the contour of SAC before NGANG in a compound (2a) and in a sequence with a strong juncture between the two syllables (2b). Dotted line shows the boundary between the two syllables.*

3.2. SAC NGANG vs. SAC OTHER sequences

The question that arises is whether, in cases of weak juncture, SAC tends to be produced as falling or level before only the tone NGANG or whether it also has this tendency before other tones. Figure 3 shows the interval in semitones between the vowel onset and end F0 in SAC syllables in SAC-NGANG sequences and SAC-OTHER sequences (all with weak junctures, see Table 2). Almost all values for SAC in SAC-NGANG are negative or at the 0 level, showing that the contours on SAC in these sequences are falling or level. By contrast, the values for SAC in SAC-OTHER sequences are almost all positive, showing that the contours on SAC syllables are rising. Again, both speakers show the same tendency. These results provide evidence of an allophonic variation of SAC when occurring before NGANG: in SAC-NGANG compounds or sequences with minimal junctures, SAC appears to have a falling or level contour, whereas in SAC-OTHER sequences with comparable junctures, tone SAC has a rising contour.

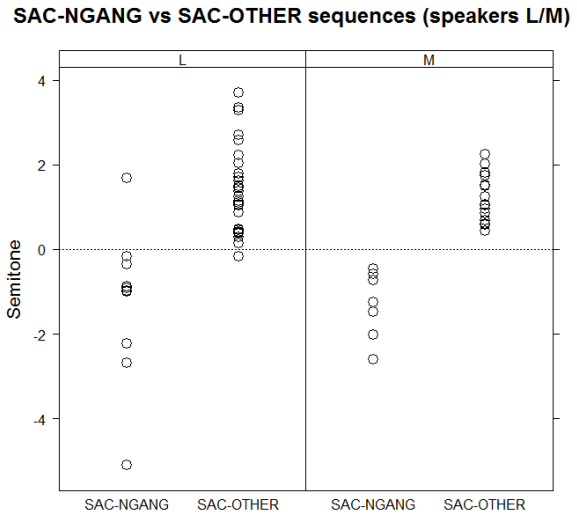

Figure 3: *Distribution of intervals in semitones between vowel onset and end of syllable for the initial syllable with rising (SAC) tone in SAC-NGANG sequences (speaker L, N=12; speaker M, N=7) and SAC-OTHER sequences (speaker L, N=28; speaker M, N=16).*

3.3. SAC NGANG vs. HUYEN NGANG sequences

So far, we have provided evidence of the tone SAC being produced as low level or falling before the tone NGANG. We compared this tone with the lexical low-level/falling tone HUYEN in the sequences HUYEN-NGANG. Figure 4 shows the intervals in semitones between the vowel onset and end F0 in SAC syllables in SAC-NGANG sequences and in HUYEN in HUYEN-NGANG sequences (again, all with weak junctures, see Table 2). Since speaker M only had one realisation of HUYEN-NGANG, we considered only the data of speaker L. The figure shows that a great deal of the intervals have negative values showing that the contours of both tones are falling or level. This indicates that tone SAC produced by speaker L resembles tone HUYEN when they precede tone NGANG.

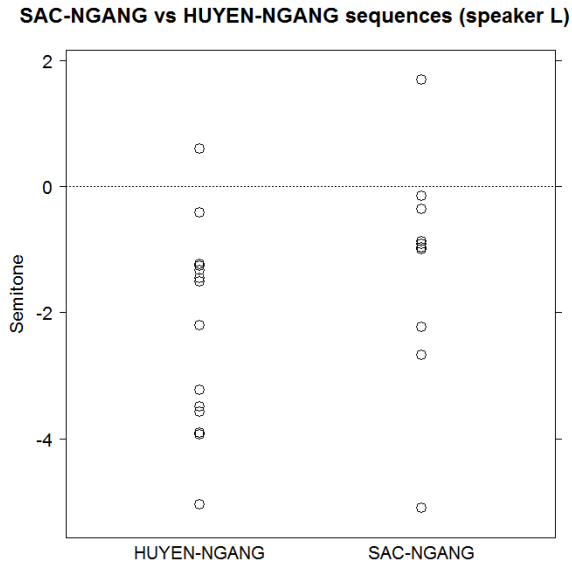

Figure 4: *Distribution of intervals in semitones between vowel onset and end of syllable for the initial syllable with rising (SAC) tone in SAC-NGANG sequences (N=12) and for the initial syllable with low-level/falling (HUYEN) tone in HUYEN-NGANG sequences (N=15).*

4. Discussion and Conclusion

In this study we found that in disyllabic words and within noun phrases the lexical rising tone (SAC) is realised as falling or level when occurring before the lexical high-level tone (NGANG). This tendency does not hold when there is a strong juncture between the two syllables, such as the juncture between two sentences or between phrases and particles. Furthermore, the rising tone (SAC) rarely changes before other tones, suggesting an allophonic variation of SAC before NGANG. The comparison of the rising tone (SAC) and the low-level/falling tone (HUYEN) before NGANG shows that these two tones resemble each other, confirming our informal observation that SAC might be neutralised to HUYEN when preceding NGANG in disyllabic words and within noun phrases. Here we only considered the first syllable in the sequences, but our results suggest that SAC may leave residual cues on NGANG for at least one speaker (L). A corpus controlled in terms of possible microprosodic effects is needed to investigate these possible residual cues. Nonetheless, the type of change on the first syllable of the sequence - from rising to falling before a high tone on the second - cannot be accounted for by coarticulation.

Historically, tone sandhi often originates from allophonic variants of tones [cf. 8]. Thus, there might be an emerging sandhi process of SAC changed to HUYEN when preceding NGANG in certain varieties of Northern Vietnamese. Although our speakers, L and M, come from provinces outside of Hanoi, they have been living in the capital for quite a long time (4 and 10 years respectively). It is so far unclear whether this variation of SAC before NGANG is restricted to Hanoi, and that our speakers have adapted this trend, or whether it is more geographically widespread.

Another issue that needs to be addressed is the question whether the neutralised SAC tone is comparable to the neutral tone in Mandarin Chinese [9]. Our data suggests that this is probably not the case, as we found the change of tone SAC not only in disyllabic sequences involving function words (e.g. classifiers) but also in disyllabic words. Tone SAC appears in these sequences to be comparable to tone HUYEN, rather than seemingly targetless or with a neutral mid target [9].

Further investigations will look at the second syllable (NGANG) and expand the corpus to include speakers of different ages and different speaking styles. Moreover, perception tests are necessary to ascertain whether listeners can actually distinguish between SAC and HUYEN before NGANG. These will help us understand the nature and extent of the allophonic variation and whether we are indeed dealing with an emerging sandhi process.

5. Acknowledgements

We would like to thank our two speakers for taking part in the recordings. Thanks are given to Vũ Kim Bảng and Đinh Hằng, Institute for Linguistics Hanoi, for their help with the recordings and discussions on the data. We thank Bastian Auris for his help with the data processing. This investigation is supported by the German Research Foundation on the project “Tone and Intonation in Vietnamese” at the University of Cologne and by the SSHRCC on the project “Prosodic Typology: Insights from Vietnamese and Eastern Cham” at the Universities of Ottawa and Cologne.

Laryngealization or Pitch Accent – the Case of Danish Stød

Nina Grønnum

Department of Scandinavian Studies and Linguistics, University of Copenhagen, Denmark

ninag@hum.ku.dk

Abstract

According to recent proposals Danish stød is the phonetic manifestation of a HL tonal pattern compressed within one syllable, making the stød/non-stød distinction a special case of the more general tonal word accent distinction in Swedish and Norwegian. This review of the relevant aspects of Danish stød and intonation demonstrates that (1) such a tonal representation of stød is contradicted by the phonetic reality. (2) Stød is distributed in words according to roughly the same principles across regional varieties of Danish, but tonal patterns are highly variable. (3) Word accents in Swedish and Norwegian are associated exclusively with stressed syllables, whereas stød occurs also in less than fully stressed syllables, devoid of autonomous pitch movements. (4) A word in Swedish and Norwegian can have one pitch accent only, but Danish words may have more than one stød.

Index Terms: stød, laryngealization, tone, Danish

1. Introduction

The acoustic, perceptual as well as formal properties of standard Danish stød and standard and regional Danish intonation are documented in [1-10]. There is a long tradition in Denmark to describe stød as a kind of creaky voice, explicitly independent of tone, from Høysgaard [11-13] through Martinet [14], Hjelmslev and Andersen [15-16], to Basbøll [17-18]. The phonology and morphology are extensively accounted for and formalized in Basbøll's *Non-Stød Model* [19-20]. Recent years, however, have seen proposals for a different analysis of Danish stød in [21-27], namely as the phonetic by-product of a H and L tone compressed within one syllable, inspired by Kiparsky's analysis of Livonian stød, [28], although Kiparsky himself confines the tonal analysis to Livonian and does not extend it to Danish. There could be several incentives for such a proposal. (1) It is entirely justifiable on physiological grounds, given what is known about the larynx and the vocal folds in F_0 lowering [29-31]. (2) In several South East Asian tone languages, low tone is often accompanied by laryngealization, as in Mandarin and Cantonese [32]. (3) There is an undisputed diachronic relation between the stød/non-stød distinction and the Accent I/Accent II distinction in Swedish and Norwegian, and the idea that stød arises from tonal contours is common in diachronic theories of *stødgenesis* [33-34]. (4) There is also a certain synchronic similarity in the distribution of Accent I/II and stød/non-stød. (5) Stød as pitch accent would unify Danish stød and the Scandinavian word accents in the current autosegmental-metrical framework as, e.g., in [35].

2. Laryngealization

Stød is prototypically a kind of creaky voice: non-modal voice with aperiodic vibrations and irregular amplitude, often but not invariably accompanied by a local fundamental frequency perturbation, an abrupt and brief F_0 dip, typically contained within the second half of long vowels or in the sonorant consonant after short vowels [1-2, 36], consonant with Basbøll's contention in [19] that stød is a property of the second mora of bimoraic syllables. A series of acoustic and perceptual investigations in the early 2000s, summarized in [3-4], showed, however, that the exact acoustic properties, the timing, and the segmental domain of stød are highly variable: vocal fold vibrations are more or less explicitly irregular; the irregularity may onset simultaneously with the stressed vowel or later in the syllable nucleus; it may be contained within the syllable rhyme or it may spill over into a succeeding post-tonic syllable. The considerable acoustic variability does not seem to affect perception: Stød is as clearly audible in the word in the middle as on the left in Figure 1 in spite of the rather stark contrast between the vibratory patterns in the two vowels. A further notable characteristic is its robustness: In fast or non-distinct speech styles, where segments and syllables are freely weakened or lost, stød is faithfully produced and perceived.

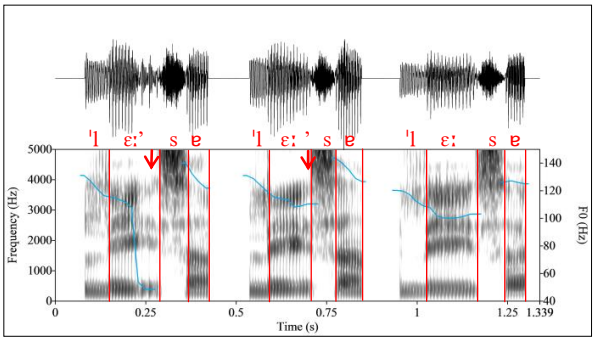
For a speculative account of the neuro-physiological mechanism behind this rather astounding acoustic variability in stød manifestation, see, e.g., [4]. – The variability in Danish stød is similar to what Blankenship reports in [37] about Mazatec and Mpi, and she finds *laryngealization*, i.e. stiffening of the vocal folds, which may or may not result in creaky voice, to be a better concept. So do Garellek and Keating in [38]. As in Danish stød, Gerfen and Baker find in [39] that laryngealization in Coatzospan Mixtec is highly variable within and across speakers and often realized with very subtle F_0 and amplitude cues.

3. Pitch

Figures 1-6 and 8 are Praat pictures ([40]), displaying spectrograms with superposed linearly scaled F_0 tracings. In figures 1 and 6 the microphone signal is included in order to elucidate the vibratory patterns underlying the F_0 perturbations. But otherwise the pertinent facts about stød as they are outlined in the text appear unambiguously from F_0 contour and spectrogram alone. Words depicted in apparent isolation in Figures 1, 4, 5, and 8 are spliced out from within longer utterance contexts. The utterances were scripted and read aloud, except in Figure 4 which presents non-scripted speech.

3.1 Standard Danish in Copenhagen is not HL

Figure 1 demonstrates that (1) the F_0 perturbation, the deep and steep fall, in the word on the left is contained within a very narrow time frame, not to be mistaken for a falling tone distributed over the whole syllable; and (2) there is an evident overall similarity, from lower stressed to higher unstressed syllable, in all three words – the two with stød left and mid and the one without on the right. This is the F_0 pattern associated with stressed and post-tonic syllables in Copenhagen Danish, cf. [8-10], apparent also in Figures 2 and 4-6. It would be characterized as L*H in current notational practice. A maximally developed F_0 pattern describes a very modest initial F_0 fall in the stressed vowel, succeeded by a steep and considerably larger rise, typically 3-4 semitones, to the first post-tonic syllable, and then a fall through succeeding post-tonics, if any. The shorter the stress group, the less extensive the F_0 pattern:



Figur 1: *Three words:* læser *'reads' with explicit stød (left), less explicit stød (mid), and* læser *'reader' without stød (right). Arrows point to the laryngealized part of the vowel. Male Copenhagen speaker.*

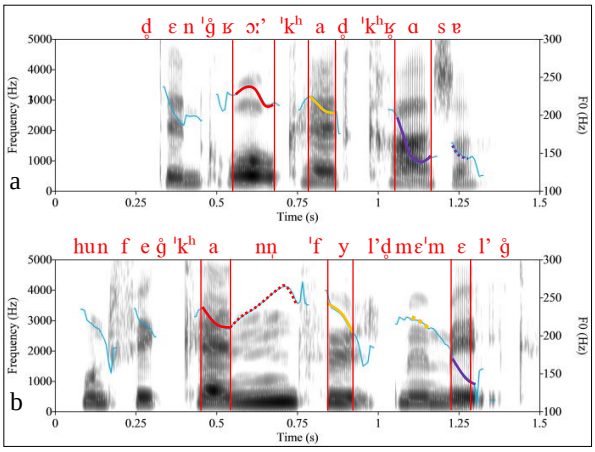


Figure 2: Den grå kat kradser *'The grey cat scratches' (a), and* Hun fik kanden fyldt med mælk *'She had the jug filled with milk' (b). Stressed vowels are touched up in full lines: red (first), yellow (second), and purple (third); unstressed vowels and the syllabic consonant in corrresponding dotted lines. Female Copenhagen speaker.*

compare *kanden* in Figure 2b with the two long words in Figure 4. In the absence of any post-tonic syllable, all that remains is the slight initial fall as in *grå* and *kat* in Figure 2a. Note specifically the pairwise similarity between the F_0 contours within the stressed vowels of (i) stødless *kan(den)* and *grå* with its nearly invisible stød (red lines); (ii) stødless *kat* and *fyldt* with stød and an explicit local F_0 drop in the [l] (yellow lines); (c) stødless *krad(ser)* and *mælk* with stød and a likewise explicit local F_0 drop in the [l] (purple lines). The red, yellow and purple stressed vowel lines are also situated, pairwise, at the same F_0 level in utterance a and b, respectively. In other words, the presence or absence of post-tonic syllables does not affect the scaling of the stressed syllables in the speaker's range. That precludes a suggestion in [35:224-5] that the pitch pattern in Danish is in fact HL, only the H is delayed (i.e.: to the post-tonic). But in the absence of any post-tonic syllable to carry the H tone, one would expect the stressed syllable to move upwards in the range and take up its rightful H position. That does not happen.

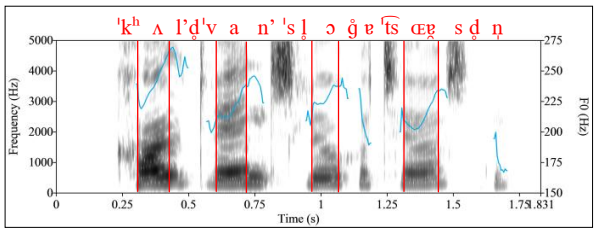

Figure 3: Koldt vand slukker tørsten *'Cold water slakes one's thirst.' Female Aalborg speaker.*

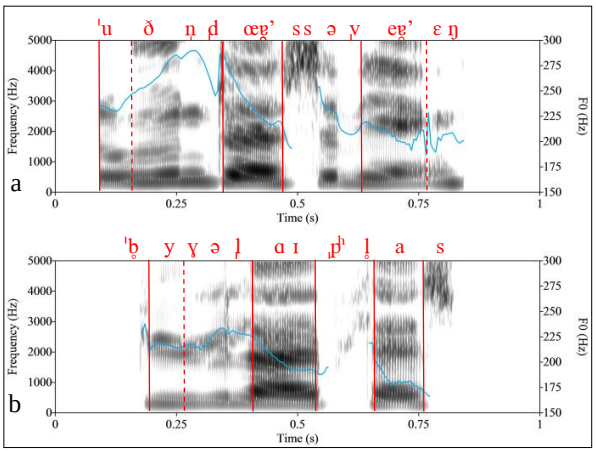

Figure 4*: Two compound words:* udendørsservering *'open air serving' with stød in the two syllables with secondary stress (a), and* byggelegeplads *'adventure playground' without stød (b). Female Copenhagen speaker.*

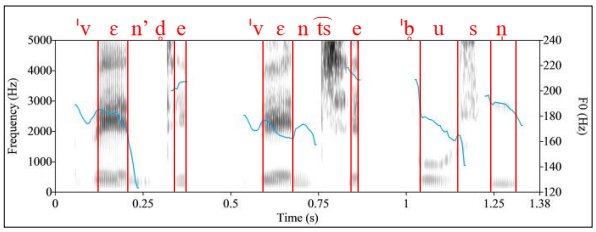

Figure 5: ... vend det ... *'turn it' (left),* ... ven til ... *'friend to' (mid), and* ... bussen ... *'the bus' (right). Same speaker as in Figure 2.*

Stød as a local F_0 perturbation, a brief and more or less explicit lowering of F_0, is independent of its location on the F_0 pattern. It may occur at the low turning point, prior to the rise to the post-tonic, as in *læser* in Figure 1 left, or *fyldt med* in Figure 2b. It may occur at the top of the F_0 pattern as in *koldt* and *vand* in Figure 3, and low on the falling flank in a long series of post-tonics as in *udendørsservering* in Figure 4a. There is nothing to distinguish stød in one position from stød in any other position. The fundamental F_0 similarity between stød and non-stød is also evident in the figures. Note particularly that there is nothing reminiscent of two HL pitch accents in the smoothly falling F_0 contour associated with the

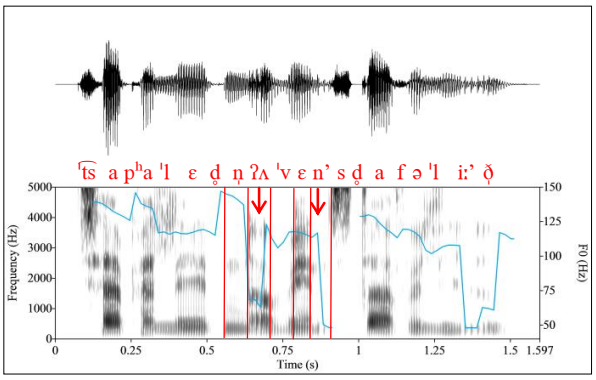

Figure 6: Tag paletten og vend staffeliet *‘Take the palette and turn the easel’. Same speaker as in Figure 1.*

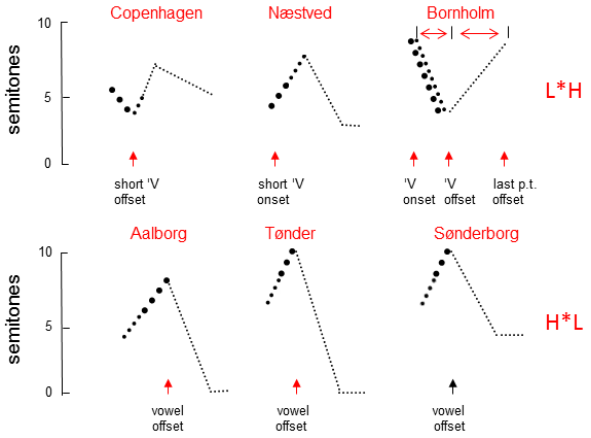

Figure 7: *Prosodic stress group patterns in six varieties of Standard Danish. Vertical arrows point to the segmental anchor point. See further the text.*

second and third parts of the compound *udendørsservering* in Figure 4a. In this respect it resembles the stødless word below in 4b, *byggelegeplads*, though the latter is produced within a narrower frequency range.

Figure 5 depicts two stressed monosyllables succeeded by an unstressed word, *vend det* with stød, *ven til* without stød, and a stødless disyllable *bussen*. Again, the overall F_0 patterns in the three disyllabic sequences are identical: a movement from lower stressed syllable to the higher post-tonic, three L*Hs.

Below the two arrows in Figure 6 are two very similar F_0 events: very steep and very local falls framing the sequence *og vend*. The first is associated with the glottal onset at the juncture before the vowel in *og*, the second accompanies the stød in *vend*. Presumably, no one would suggest that glottal attack at vowel onset be associated with a phonological pitch accent. Under a tonal analysis, then, the leftmost F_0 perturbation is the result of a glottal onset which is not quite a complete glottal closure here, but comes out as creaky voice, whereas the same F_0 perturbation on the right would be an autonomous tonal gesture with a laryngealized side effect.

Note also how microprosodic effects may induce extensive F_0 movements in a vowel. An uninitiated observer might ascribe a falling pitch accent to the first syllable of *bussen* in Figure 5: the extent of its F_0 fall is nearly as comprehensive as the fall in *vend*. But the first steep part of the fall in *bus-* is due to the transition from the unvoiced stop consonant to the vowel, the final steep movement is due to the transition from vowel to obstruent, and in fact the vowel is perceived as a non-dynamic level pitch. The pertinent, perceptible movement in the three disyllabic sequences – whether or not they contain a word boundary – is the movement from the lower stressed syllable to the higher post-tonic. None of these patterns contain a HL tonal sequence, they are all perceptually LH.

To sum up: The pitch pattern in Copenhagen Danish is essentially the same in words with and without stød, and it is LH, not HL. Furthermore, under temporal constraint the pattern is *truncated* rather than *compressed* into the stressed syllable. A representation in terms of a HL tone compressed into one syllable is as far removed from the phonetic reality as can be.

3.2 Regional varieties of Standard Danish

Figure 7 depicts, in six different locations in Denmark, stylized tracings of the F_0 patterns associated with the *prosodic stress group*: a stressed syllable plus all succeeding unstressed syllables, if any, irrespective of intervening word boundaries. They are not impressionistic drawings or educated guesses but based on acoustic data from a considerable number of recordings of four speakers from each region, recording the same scripted material under identical conditions, cf. [8]. Heavy dots depict the location of short stressed vowels on the F_0 pattern, medium dots depict the extension in long stressed vowels, and fine dots depict the course of unstressed syllables in the prosodic stress group. In Bornholm, the vertical strokes enclose movements which may be expanded or compressed in time, as suggested by the horizontal arrows, in concordance with the duration of the stressed vowel (long or short, the falling part), and the number of post-tonic syllables in the stress group (the rising part).

These F_0 patterns would adequately represent trisyllabic prosodic stress groups. This is of no particular concern for Næstved, Aalborg, Tønder and Sønderborg, because F_0 will generally reach its low minimum already in the second post-tonic and continue low and level. But in Copenhagen, where the fall from the high turning point in the first post-tonic is less steep, it would typically continue to fall further, beyond what is depicted in Figure 7, only to level out around a fourth or fifth post-tonic, as in *udendørsservering* in Figure 4a. In other words, there is no fixed pitch relation between a L* and the termination of a *preceding* stress group pattern: the L* will be approached from above after short stress groups, cf. *fyldt* in Figure 2b, and from below after long stress groups, cf. ... *med ru-* ... in Figure 8.

The variation in shape and range of F_0 patterns is considerable. Differences among them are easier to capture when the governing principle in their execution is made explicit: In all of them, except Bornholm, there is one point only in the melodic fragment which is constrained in terms of its alignment with a segment in the prosodic stress group, as indicated by the vertical arrows in the figure. This point is low relative to the first post-tonic in Copenhagen and Næstved and high in Aalborg, Tønder and Sønderborg. The former two may accordingly be characterized as L*H, the latter three as H*L.

The anchor is invariably associated with the stressed vowel, namely with its offset across the board in the H*L

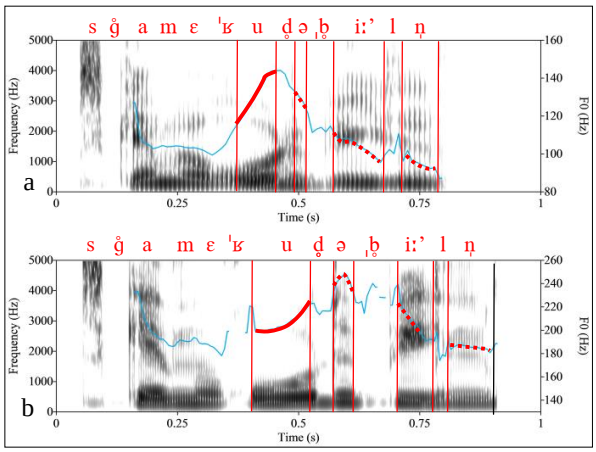

Figure 8: ...skal med rutebilen... *'are going by bus', male Aalborg speaker (a), female Næstved speaker (b).*

varieties, but with its onset in Næstved. In Copenhagen the low turning point coincides with the offset of the stressed vowel if that vowel is short, and occurs about halfway through a long stressed vowel. Leaving out Bornholm for the moment, *neither segments nor syllables in the prosodic stress group on either side of the anchor have separate tonal representations*. They are simply strung out on the melody like pearls of varying length on an undulating string. Voiceless segments interrupt the melody and may have very local microprosodic effects but do not otherwise interfere with the score. A complete pattern only materializes in so far as there are syllables to carry it, otherwise it is truncated from the end. Accordingly, monosyllabic stress groups with a short vowel surrounded by voiceless consonants exhibit only the part of the melody indicated by the heavy dotted line part in the five patterns in Figure 7.

Figure 8 shows two actual passages, ... *skal med rutebilen*... by a male speaker from Aalborg (a) and a female speaker from Næstved (b). The frequency scale spans exactly an octave in both cases, so the ranges covered by the two patterns are immediately comparable. The offset of the stressed vowel (full red line) coincides exactly with the peak of the F_0 pattern in Aalborg, as stipulated in the stylization in Figure 7, and the fall from the peak is rapid and extensive. Since the vowel is short, it does not make it to the peak of the pattern in Næstved, and the peak therefore coincides with the first post-tonic syllable, also as stipulated in the stylization in Figure 7. The fall is not as extensive as in Aalborg. The stød in the second part of the compound is acoustically rather weak in both instances, introducing a moderate perturbation only, although it is clearly audible in both cases.

Bornholm stands out from the other varieties by the very elastic relation between segments and F_0: the duration of the falling part of the tonal pattern varies – albeit slightly – with the duration of the stressed vowel so that that the low turning point coincides with the offset of the vowel, be it short or long. The duration of the rise varies with the duration of the unstressed part of the stress group so that the rise terminates on the last post-tonic syllable. This latter variation is considerable, between one and many post-tonics, and perceptually the rise is more conspicuous than the fall. In other words, the pattern has three targets, a high onset, a low turning point and a high offset. There is, however, a limit to how fast the fall-rise may be executed, a compressibility maximum, and when this limit is reached, as in a monosyllabic stress group with a short vowel surrounded by voiceless consonants, the fall disappears, and what remains is a steep rise from a low onset to a high offset. Given that the fall may be deleted and that otherwise the rise in the F_0 pattern is perceptually more salient than the fall, Bornholm may also be adequately represented as L*H.

Among the L*H varieties, two have stød, Copenhagen and Næstved, whereas Bornholm does not. Likewise, among the H*L varieties Aalborg has stød, but Tønder and Sønderborg do not. So much for an insoluble correlation between tonal movement and stød in Danish.

3.3 Stød under non-primary stress

Pitch accents in Swedish and Norwegian are associated with primary stressed syllables, and hence words – also compounds – can each have one pitch accent only, [41]. But we have stød in syllables with non-primary stress, cf. *udendørsservering* in Figure 4a and *rutebilen* in Figure 8. And, contrary to expectations in a tonal representation, these syllables are not associated with independent, autonomous F_0 movements. And of course, when syllables with secondary stress can have stød, words will have more than one when the stressed syllable also has stød as in, for example, [ˈˌgʌlˈfˌbʌlˈˌd] *golfbold* 'golf ball', [ˈlanˈsman'] *landsmand* 'fellow countryman'.

4. Discussion and conclusions

Despite all the pros listed in the introduction, stød as the manifestation of a compressed HL tone faces insurmountable empirical obstacles. There is nothing in the phonetic reality to support it. The overall F_0 pattern is similar in words with and without stød, and when stød is not accompanied by any F_0 perturbation at all, stød and non-stød F_0 patterns are identical. Likewise, the principles which govern the presence or absence of stød in words of different structure, are roughly the same across regional varieties of Danish, in so far as they have stød at all, but F_0 patterns are not. In other words, the laryngealization typically present in Danish stød is not a phonetic accompaniment to a compressed HL pitch accent. On the contrary: the F_0 perturbation is a by-product of the laryngealization and not invariably present. Laryngealization is the articulatory, acoustic, and perceptual constant in stød production, F_0 perturbation is not. Such a state of affairs is not exclusive to Danish either. Voice quality differences in some of the South East Asian languages are not merely the synchronic phonetic accompaniment to tonal differences. On the contrary, tones developed from phonation types, not the other way around [42-44]. Furthermore, in so-called *laryngeally complex* languages, like Mpi [45], Jalapa Mazatec [38], and Comaltepec Chinantec [46], tonal and phonatory contrasts coexist and cross-classify. Thus, laryngealization may accompany any tone, whether high or low.

Space does not permit a review of the similarly serious obstacles in the phonology and grammar of Danish stød, if represented as a H and L tone compressed in one syllable. The reader is referred to [6].

In conclusion: laryngealization as an autonomous syllable prosody, orthogonal to pitch and intonation, suffer none of the shortcomings attached to a tonal representation and is altogether more satisfactory than any representation of Danish stød as underlyingly tonal in nature.

Intonational Phonology of Cuban Spanish: A preliminary model

Ann Aly Bailey

Department of Linguistics, University of California, Los Angeles, United States

aabailey@ucla.edu

Abstract

The present study proposes a preliminary model of intonational phonology for Cuban Spanish in the framework of Autosegmental-Metrical phonology. Data from controlled and semi-spontaneous speech were used to establish the boundary tones and pitch accents which are contrastive in this variety of Spanish. It was found that Cuban Spanish shares various tonal categories with both the Pan Spanish ToBI (Tones and Break Indices) [1] and other Caribbean Island Spanish dialects (Puerto Rican [2] and Dominican [3]), but differ from these dialects in how those pitch accents and boundary tones are used to convey meaning. Cuban Spanish shares its primary prenuclear pitch accents and nuclear contours for imperative statement and narrow focus with the Pan Sp_ToBI, but shares the nuclear contours for broad focus, vocative, and wh-questions with Puerto Rican Spanish. Similar to the other Caribbean Island Spanish varieties, the Cuban Spanish boundary tone inventory consists of a subset of the attested boundary tones found in the Pan Sp_ToBI, and all three Caribbean varieties share low boundary tones in non-wh questions, a marker of Caribbean Spanish speech.

Index Terms: Intonation, Cuban-Spanish, Sp-ToBI

1. Introduction

This study study proposes a preliminary model of intonational phonology of Cuban Spanish within the framework of the Autosegmental-Metrical (AM) model, and the conventions of Cuban Spanish ToBI (Tones and Break Indices), adopting the labeling conventions of the current Pan Spanish Tones and Break Indices (Pan Sp-ToBI). The first description and proposal for Pan Sp_ToBI was developed in [4] and later revised and expanded in [1] to include additional phrase accents and boundary tones. Although the aforementioned studies have developed a transcription system that accounts for distinctive intonational features of the Spanish language in general, not all dialects and varieties of Spanish use these features in the same way. Therefore, more recently, descriptions of Spanish intonation and the transcription systems from ten different varieties have been developed (described in volumes such as [5]), including Puerto Rican and Dominican Spanish, two of the three Caribbean Island Spanish varieties. However, as established by [2] and [3], the intonation of the Caribbean dialects also differs in various ways, despite their geographic proximity. The investigation of the intonational phonology of Cuban Spanish, a Caribbean island dialect that is currently undocumented within the AM framework, will allow for additional comparisons amongst the Caribbean dialects and other varieties of Spanish in general.

2. Methodology

The strained political relations that Cuba has with other countries have made linguistic data on this dialect difficult to obtain. However, the large Cuban community in South Florida provides a unique linguistic context in which data collection is possible. This study presents both controlled speech from a reading task and semi-spontaneous speech from a Discourse Completion Task (DCT) modeled from [5] to allow for comparison. The speech of eight speakers (four Cuban-born, four Miami-born) was consulted for the present analysis. All consultants were either born in or currently live in South Florida and were a median age of 42.3 years old. The data were collected on an LS-11 portable recording device at a 16-bit rate at 44.1 kHz and analyzed in *Praat*, version 5.3.60 [6].

3. Intonational Phonology of Cuban Spanish

This section will present the prosodic structure of Cuban Spanish, defined by intonation (section 3.1), and the tonal inventory, with boundary tones and pitch accents in sections 3.2 and 3.3, respectively.

3.1 Prosodic Structure of Spanish

Like other varieties of Spanish, Cuban Spanish has a lexical stress system with stress usually occurring on the penultimate syllable of content words. Above the word level, there is evidence for Intermediate Phrases (ip) and Intonation Phrases (IP), although no evidence for tonal stacking at the end of an Intonation Phrases has been found [1]. An IP is defined by a boundary tone at its right edge, with lengthening of the IP-final syllable, and an optional pause after the IP. An ip is defined by a phrase accent at its right edge, with slight lengthening of the ip-final syllable, and a pitch reset starting on the word after the ip. An ip has at least one pitch accent which is realized on the stressed syllable of most content words. As in English, the last pitch accent in an ip is the most prominent, called a nuclear pitch accent.

3.2 Boundary tones

Similar to the boundary tone inventories established in the Pan Sp_ToBI, Cuban Spanish also contains both monotonal (H (High), M (Mid), L (Low) and bitonal (LH (rising), HL (falling)) boundary tones. Similar to the other Caribbean Island varieties [2, 3], Cuban Spanish contains only a subset of the monotonal and bitonal boundary tones established in the Pan Sp_ToBI and does not contain tritonal boundary tones.

3.2.1 Monotonal boundary tones

Three monotonal boundary tones were found to mark the right edge of both ip and IP: L, M and H. The low boundary tone marking the end of IP (L%) is found primarily in declarative statements, imperatives, exclamatives, wh-questions, and requests (for Cuban-born speakers only). The L% can be realized either as a falling or low plateau tone, depending on the nuclear pitch accent. A low boundary tone marking an ip (L-) is also used in this dialect, usually to connect sections of a longer utterance, such as a declarative with a tag phrase or utterances with relative clauses, suggesting a syntactic dependency that is sensitive to these phrase edges.

High boundary tones marking the end of an IP (H%) were used in various types of questions, such as yes-no questions, echo questions, requests, tag questions, and less frequently, for a subset of wh-questions. Similar to the L% boundary tone, H% can be realized either with a rising F0 (from the nuclear pitch accent) or as a high plateau continued from a high nuclear pitch accent. High ip boundary tones (H-) were used by speakers in listing contexts as well as to signal continuation in prolonged speech.

Mid boundary tones marking the end of IP (M%) were less frequent than L% or H%, and were seen in vocatives, polite questions, and more emphatic exclamative statements. M% boundary tones in this dialect are typically realized with a slightly falling F0 from a high nuclear pitch accent, or less commonly, a slightly rising F0 from a low nuclear pitch accent. Mid ip boundary tones (M-) were also used to signal continuation in prolonged speech, but was typically seen in faster, more disfluent speech as opposed to H-, which signaled continuation in more careful speech.

Figure 1 shows L%, M%, and H% boundary tones, respectively. The figures in this paper contain the following text grid tiers, from top to bottom: (1) orthography, (2) stressed syllable of content words, (3) tones, (4) breaks, and (5) English gloss.

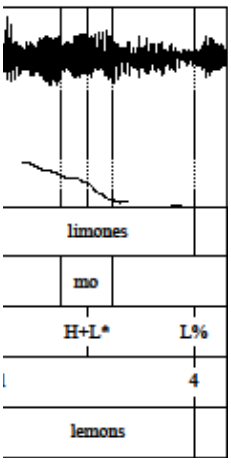

Figure 1a. L% boundary tone.

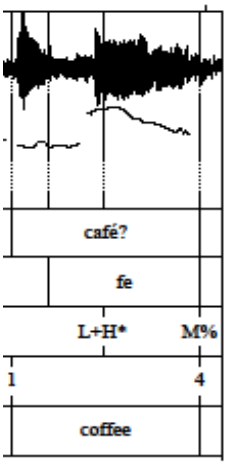

Figure 1b. M% boundary tone

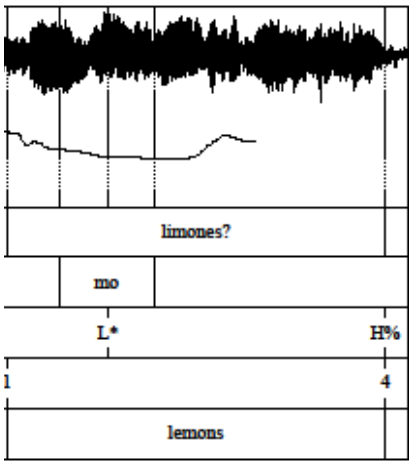

Figure 1c. H% boundary tone

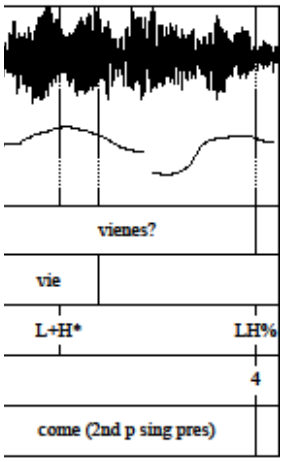
3.2.2 Bitonal boundary tones

Two bitonal boundary tones were found in this dialect, LH and HL. These occurred less frequently than their monotonal counterparts. LH% IP-boundary tones were found in disjunctive wh-questions, sarcastic/rhetorical contexts, and non-wh exclamative statements. LH is realized with a falling (or sustained) F0 after the nuclear pitch accent and followed with a rising F0 in the same syllable that may or may not be as high as a previous H tone in the same ip.

The falling bitonal boundary tone (HL) is seen at the end of an IP (HL%) in exhortative imperatives (both in statement and question form). This boundary tone is not seen at ip boundaries in the data collected. HL% is realized with a rising or sustained F0 after the nuclear pitch accent which falls within the same syllable. Figure 2 shows examples of both bitonal boundary tones at the end of IP, following L+H* nuclear pitch accents. Figure 2a shows a LH% boundary tone occurring on a word with penultimate stress and 2b shows a HL% realized on the only, thus stressed, syllable of the final word (*qué*). Here, in order to accommodate two H targets (H of L+H* pitch accent and H of HL% boundary tone), the syllable is substantially lengthened in Fig.2b.



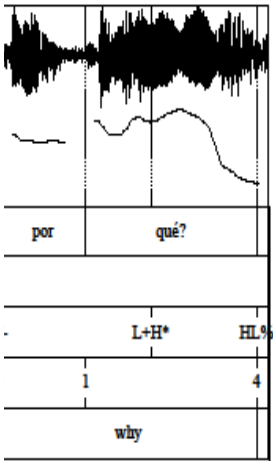


Figure 2. LH% boundary tone (2a, left) and HL% boundary tone (2b, right).

3.3 Pitch accents

This section will introduce the tonal inventory of pre-nuclear pitch accents (sec.3.3.1) and nuclear pitch accents (sec.3.3.2). Section 3.3.3 will discuss how narrow focus and stress clash affect the realization of pitch accents in Cuban Spanish.

3.3.1 Pre-nuclear pitch accents

As in Pan Spanish, three rising, bitonal nuclear pitch accents were seen in the data collected: one in which the stressed syllable is aligned with the pitch trough before rising (L*+H); one in which the stressed syllable is aligned with the peak of the pitch accent after a low F0 on the preceding syllable (L+H*); and lastly, a pitch accent in which rising to a delayed peak (realized on the next syllable) is seen in the stressed syllable (L+<H*) after a low F0 on the preceding syllable. The most frequent prenuclear pitch accent differed by task types, suggesting an effect for speech formality or style. In the

controlled task, L+<H* accounted for 53% of all pre-nuclear pitch accents and was the most common pitch accent before ip boundaries, occurring 78% of time. However, this pitch accent was found more often in semi-spontaneous speech: L*+H occurred in over 90% of the semi-spontaneous data but only 30% of the controlled data. L+<H* pre-nuclear pitch accents are mainly used in emphatic semi-spontaneous speech, further supporting the different styles associated with these pitch accents. The least common pre-nuclear pitch accent was L+H*, which only occurred in 17% of the data. Although uncommon, L+H* was the pitch accent used in over 90% of words with final stress in both tasks.

3.3.2 Nuclear configurations

Only two possible nuclear pitch accents were found in declaratives: H+L* and L+H*. H+L* was the most common nuclear pitch accent in declarative utterances, as L+H* was typically used only by Cuban-born speakers. An example is shown in Figure 3.

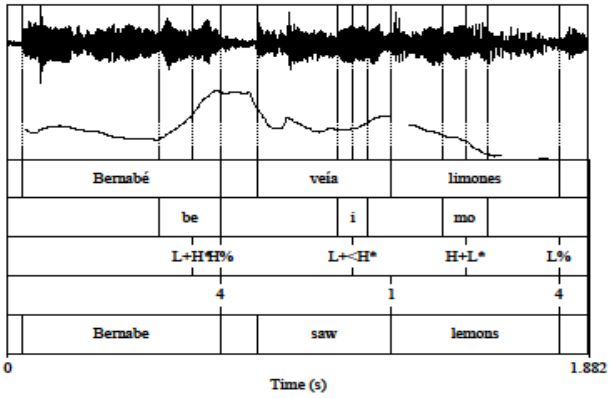

Figure 3. Declarative statement with H+L* L% nuclear configuration.

Unlike H+L*, which was the most common nuclear pitch accent only for declaratives (66% of analyzed cases) in Cuban Spanish, L+H* was the most common nuclear pitch accent and was used in various types of utterances. Besides a possible nuclear pitch accent for declaratives, L+H* was also used as the most common nuclear pitch accent for exclamatives (81%), imperatives, vocatives (79%), yes/no questions and requests (70%), and echo questions (76%). Although these discourse categories share the same nuclear pitch accent, they differ from each other by boundary tone or pitch scale. L+H* L% nuclear configurations are used for exclamatives (81%), commands (51%), and as an option for yes/no questions, mostly by Cuban-born speakers (45%)**;** L+H* H% is used in the tag phrase of tag questions and as the more common variant for yes/no questions, used by both speaker groups (55%), echo questions (62%), and a variant of wh-questions used more frequently by Cuban-American speakers (45%); finally, L+H* M% is the preferred nuclear configuration for vocatives (80%) and is used as an option for polite yes/no questions and requests, mostly by Cuban-born speakers (10%). Questions, especially polite questions, tend to involve upstepped high tones, creating a larger pitch range than a similar (L+)H* in non-questions. This is shown in Figure 4.

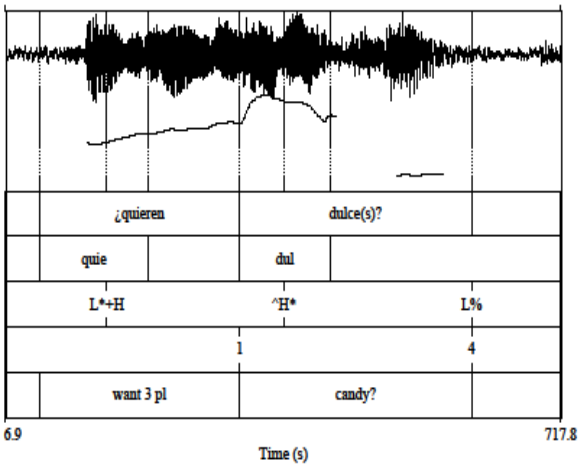

Figure 4: Yes/No Question with upstepped (^) (L+) H* L% nuclear contour

Monotonal nuclear pitch accents are less common in Cuban Spanish and are typically variants of rising pitch accents that are undershot due to stress location and position (e.g. L+H* H% may be realized as L* H% when stress is final). Figure 5 shows a tag question in which a monosyllabic tag phrase is realized as L* H% instead of L+H* H%.

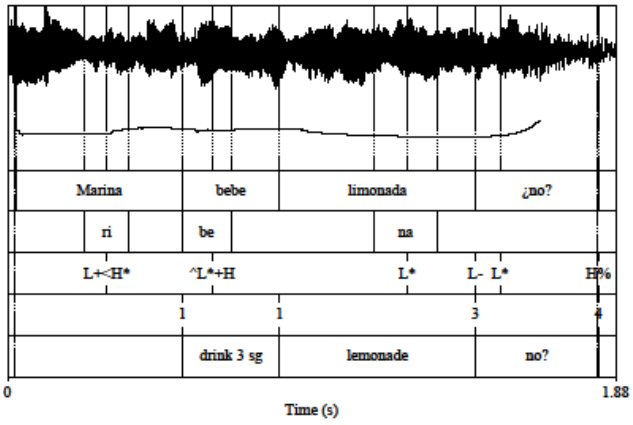

Figure 5.Tag question with L(+H*) L% tag phrase

3.3.3 Stress clash and focus

Data from both the controlled and semi-spontaneous tasks revealed that when two stressed syllables are adjacent and cause a stress clash, part of a pitch accent (in the case of a bitonal pitch accent) or an entire pitch accent may not be realized. In the case of adjacent rising prenuclear pitch accents, the most common stress clash is the result of a word with penultimate or final stress followed by a word whose first syllable is stressed. These clashes are resolved in one of two ways: either a phrase break is inserted between the two words and the pitch is reset on the second word (typical in slower, more formal speech) or, when the two are in the same ip, a portion of the second (bitonal) pitch accent is not realized (more common in faster, less formal speech). An example of this latter resolution is shown in Figure 5.

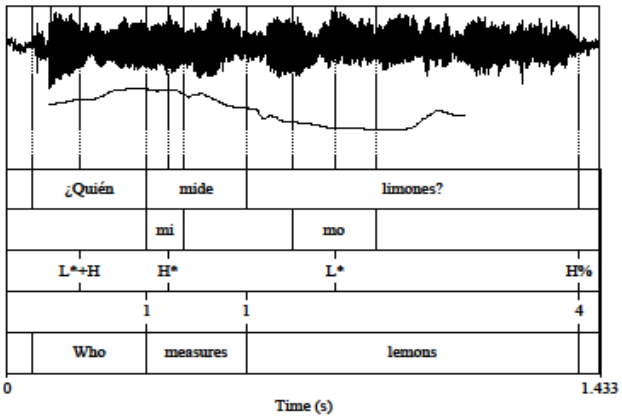

Figure 5. Stress clash between *quién* and *mid*e

When the L*+H nuclear pitch accent on a penultimate syllable is followed by a H% boundary tone, it was not clear whether the H part of the pitch accent is realized or not because both the H trailing tone and the H boundary tone occur on the IP-final syllable. In this case, only L* is labeled on the stressed syllable.

The basic tonal pattern of sentences found in the neutral focus context changed in several ways when speakers were asked to focus lexical items. The most typical focus realization included an overall expanded pitch range, an L+H* pitch accent on the focused item in nearly 100% of cases, and an IP boundary before or after the focused word (depending on the location of the focused items). When longer words with penultimate stress were focused, such as *limonada*, 'lemonade', two kinds of secondary stress effects were found: either primary stress was shifted to the first syllable instead of being realized on the penult, or both the initial and penultimate syllables were both realized with L+H* pitch accents. This latter pattern is shown in Figure 6.

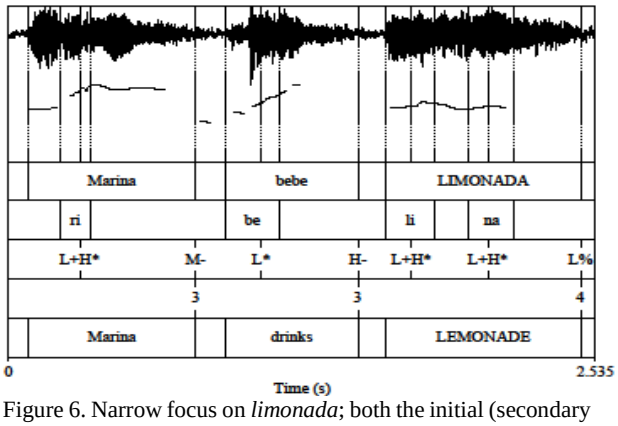

Figure 6. Narrow focus on *limonada*; both the initial (secondary stress) and penultimate syllable (primary stress) are prominent.

4. Discussion

The data analyzed revealed several within-dialect and cross-dialectal patterns with respect to intonation. Within the Cuban Spanish speakers, Cuban-born speakers produced more nuclear configurations per discourse category than Cuban-American speakers, whose realizations represented a subset of the Cuban-born speakers. These differences could have various sources; as the Cuban-American speakers are heritage speakers of Spanish who are also native speakers of American English, their contact with English could have an influence on their Spanish. Additionally, as South Florida has a diverse Hispanic community apart from the Cuban majority, dialect leveling (as seen with Puerto Rican Spanish in New York [7]) with other varieties of Spanish may have also influenced the non-Cuban-born Spanish speakers toward certain prosodic realizations. Data from other dialects of Spanish present in South Florida as well as English data from these participants is needed in order to investigate the source of this variation.

When the intonation data from the Cuban Spanish speakers is compared with that of the Pan Sp_ToBI and other Caribbean Spanish dialects, few similarities emerge. Cuban Spanish shares its prenuclear pitch accent and the tonal configurations for exclamatives and narrow focus with the Pan Sp_ToBI, but shares the tonal contours of categories such as broad focus, vocatives, and polite questions with Puerto Rican Spanish. The boundary tone inventory found in Cuban Spanish resembles the other Caribbean Island varieties more than the Pan Sp_ToBI; the Caribbean Island dialects (including Cuban) contain only a subset of the monotonal and bitonal boundary tones specified in the Pan Sp_ToBI and do not contain any tritonal boundary tones.

The use of L% in questions found in Cuban Spanish was not reported for Pan Spanish, but occurs in the other two Caribbean Island Spanish dialects [2, 3]. That is, all three Caribbean island varieties share L% boundary tones for non-wh questions, which is a marker of Caribbean Spanish dialects. Among the Caribbean dialects mentioned, however, Cuban Spanish was closer to Puerto Rican Spanish than to Dominican Spanish by employing M% boundary tones in vocatives, HL% for exhortative imperatives, and H% boundary tones in tag questions and some requests (mostly by Cuban-American speakers), but Cuban and Puerto Rican varieties still differ in the usage of their tonal inventory across discourse categories. As previously mentioned, the relative political isolation of Cuba as well as the dominance of the Cuban dialect in South Florida may be a source of this divergence with respect to the other dialects of geographical proximity.

5. Conclusion

The current study presents a preliminary model of intonational phonology of Cuban Spanish in the AM framework based on the intonation data from eight Cuban Spanish speakers living in South Florida. Using the conventions of the Pan Sp_ToBI, the tonal inventory of this dialect was proposed as well as the tonal contours that define various discourse categories and sentence types. The proposed tonal inventory was then compared with that of Pan Sp-ToBI and other varieties of Caribeean Spanish. Further analysis will consider additional discourse categories present in the semi-spontaneous data of the speakers as well as sources for within dialect variation.

6. Acknowledgments

I am thankful to the UCLA Graduate Summer Research Mentorship, which made data collection possible, and to my advisor, Sun-Ah Jun, for her help and support, my Research Assistant Ulysses Cázares for his invaluable help, and my colleague Mariska Bolyanatz for her help and input.

Modeling of a rise-fall intonation pattern in the language of young Paris speakers

Roberto Paternostro [1], *Jean-Philippe Goldman*[2]

[1] Université Paris Ouest – MoDyCo, France & Università di Brescia, Italy
[2] University of Geneva, Switzerland
paternostro.roberto@gmail.com Jean-Philippe.Goldman@unige.ch

Abstract

Intonation seems to be one of the major cues for identifying youth language in the Paris region. As part of a large-scale corpus-based analysis, this paper attempts to model a rise-fall final prosodic pattern, considered to be representative of a Paris working-class suburbs accent. Comparison with the emphatic rise-fall prosodic pattern, well-known in general French, will provide the opportunity for sociolinguistic insights. The ethnic hypothesis is dismissed in favor of a context-bound and interaction-sensitive interpretation.

Index Terms: socio-phonetics, prosodic patterns, linguistic variation and change, acoustic modeling.

1. Introduction

Among other linguistic elements, such as lexical items and segmental features[1], intonation is pointed out as one of the major cues for the identification of Paris youth language. Various studies suggest that the realization of a rise-fall final prosodic pattern, characterized by a strong pitch rise and a sharp fall in the fundamental frequency (henceforth F_0) that is particularly ample and with a possible lengthening of the penultimate syllable, is the main factor in the perception of a *banlieue*[2] accent [1]. Furthermore, such an accent is often associated with young speakers living in working-class areas of the city and coming from multicultural environments, especially of North or Sub-Saharan African origin [2], [20]. However, Paternostro [3] has shown that even though speakers in direct contact with multicultural environments seem to be the leaders of the spread of rise-fall final prosodic patterns and that their peers in indirect contact with multicultural environments seem rather to adopt and diffuse these phonetic variants, the two groups cannot be considered as two different populations. In fact they represent a methodological "artifact" which tends to separate into different populations speakers who are part of the same community of practice, sharing the same social experience and the same identity values. The ethnic hypothesis is thus dismissed and the dynamics of variation must be rather sought in a set of processes of adaptation to a feeling of communicational proximity [4]. Comparison with emphatic rise-fall prosodic patterns, well-known in general French, shows that *banlieue* intonation contours seem to convey emphasis[3] as well and are likely to express speakers' involvement in interaction. This paper reports on a large-scale study attempting to model the acoustic features of this intonation contour, on the basis of the 'Multicultural Paris French' (MPF) corpus currently being collected in the Paris region [5].

2. Background

Conein & Gadet [6] noticed the spread of a particular 'strong' prosodic pattern in the speech of young Paris speakers, characterized by a large melodic movement and a lengthening of the penultimate syllable. However, this pattern seems to be more hereditary than innovative, since its features overlap with those of 'popular' French. Fagyal [1] focused on the prosodic realizations of middle-school students living in the northern working-class suburbs of Paris. She noticed significant lengthening of the penultimate syllable, marked by a high tonal target. Lehka & Le Gac [7] observed similar intonation contours among adolescents in the working-class suburbs of Rouen, particularly characterized by a sharp fall on the last prosodic unit. However, no significant penultimate lengthening was observed. Le Gac *et al.* [8] compared Paris and Rouen realizations and found that Paris speakers tended to produce rise-fall patterns with a rather reduced pitch range whereas the informants from Rouen produced both reduced and expanded patterns.

Figure 1: *Implication contour by Delattre*

Rise-fall intonation contours, such as the implication[4] contour described by Delattre [9] or the emphatic contour described by Di Cristo [10], are well-known in general French[5]. Lehka-Lemarchand [11] already noticed similar features between *banlieue* and emphatic contours. Even though, her assumption is not backed up by acoustic and statistical analyses, she concludes that the difference between the two contours is greater than their similarity and prefers to consider *banlieue* contours as a specific phenomenon linked to non-standard language.

[1] We refer, for example, to back-slang words such as *meuf* (back-slang for *femme*, 'woman') or *keuf* (back-slang for *flic*, 'policeman'). Affrication of dental stops before high closed vowels /i/ and /y/ (such as in *voiture* [vwatʃyʁ], 'car' or *dire* [dʒiʁ], 'to say') and a strong unvoiced fricative /ʁ/ seem to be among the most important segmental cues [4].
[2] Working-class suburbs of Paris.
[3] By "emphasis" we mean "involvement" of speakers in interaction, according to Selting [14].
[4] The link between implication and emphasis (or involvement) is not fortuitous. Just as emphasis, implication presupposes implicitness and complicity between speakers.
[5] Stewart [18] compares *banlieue* intonation contours to Delattre's commandment and exclamation ones [9], which are clearly falling contours. However, Lekha & Le Gac [7] and Lekha-Lemarchand [11] argue that in the perception of *banlieue* contours the rise matters more than fall.

Banlieue contours	Emphatic contours
Ample movements of F_0	Ample movements of F_0
Steep slope and sharp fall of F_0	Normal rise, sharp fall of F_0
Shorter	Longer
Early alignment (penultimate)	Late alignment (last syllable)

Table 1: *Comparison between 'banlieue' and emphatic contours in the literature*

The link between emphatic contours and *banlieue* accent is not fortuitous. On the one hand, Stewart & Fagyal [12] suggest that *banlieue* intonation contours often convey aggressivity and are collectively perceived as quarrelsome, even when occurring in a neutral context. On the other hand, Paternostro [13] shows that the *banlieue* accent is highly related to the expression of communicational proximity and speakers' involvement in interaction and can be seen as the actualization of an emphatic speech style[1]. According to Selting [14], an emphatic speech style results from communication that is strongly marked by 'emotion' and displays a shared 'involvement' of the interactants. Prosodic cues seem to play a major role, since they are used as a "device to evoke context-sensitive interpretations of emphatic 'peaks of involvement'". Ample melodic movements of F_0, associated with increased duration and intensity, are the prosodic markers mainly used by an emphatic speech style in French [15].

3. Modeling *banlieue* contours

Our corpus consists of 593 occurrences of rise-fall intonation contours, taken from 3h05m of 6 teenagers' sample speech. The informants are 2 girls (Ana and Juline) and 4 boys (Koffi , Aziz, Hakim and Walid), living in the Paris *banlieue*. Interviews were carried out within the framework of the MPF project[2], with respect to the ecology of interactions. Informants were not selected according to a socio-demographic categorization, but rather according to an acquaintance network. Since investigators and informants were not strangers to one another, speech circulates freely, long stories emerge, and mutual speaker involvement takes place [16]. 391 contours were labeled "emphatic" and 202 "*banlieue*" by 72 Paris students, during a perception test, details of which are given below.

3.1 Perception test

The perception test consisted of two parts[3]. The first part aimed at determining whether rise-fall intonation contours are associated with the expression of emphasis. Our 72 judges were asked to listen to 50 filtered speech samples containing standard rise and/or fall contours (continuation and final intonation contours) or rise-fall contours considered to convey emphasis. Judges were asked to qualify each stimulus according to a grid of bipolar adjectives. They also had to evaluate the level of emphasis conveyed on a four-point scale (0, 1, 2, 3). Results show that standard continuation and/or final intonation contours were referred to as "neutral" and "calm" whereas rise-fall contours were referred to as "emphatic" and "angry". Rise-fall contours also conveyed more emphasis than standard ones: 1.40 (out of 3) vs. 0.84. Results are statistically significant[4].

The second part of the test aimed at determining whether judges[5] were able to distinguish between emphatic contours (henceforth *EM*) and *banlieue* contours (henceforth *BA*) and at evaluating the level of emphasis conveyed. It will also help us for corpus annotation and show whether *banlieue* contours convey emphasis or not. Judges listened to 100[6] short speech samples and ticked the answer in a reply form. The level of emphasis was evaluated on a four-point scale (0-3). Results show that judges were able to distinguish EM contours from BA contours in 59% of cases[7]. BA contours seem to convey more emphasis than EM: 1.67 vs. 1.48 (out of 3)[8]. These issues are discussed below.

3.2 Methods and materials

Rise-fall intonation contours were annotated manually under *Praat* according to 3 points: (1) beginning of the rise; (2) the top; (3) end of the fall (see: Fig. 2). Pitch values were verified and corrected manually, in order to avoid octave leaps and other detection errors.

Pitch values were extracted with their temporal position for each point. They were then converted to semi-tones (henceforth *st*), for the purpose of comparison between male and female voices. The last 3 syllables were also segmented to find out whether EM and BA contours align on the same syllable or not. The length for each syllable as well as for the complete contour (from point 1 to point 3, see: Fig. 2) was also calculated. Rise slope and fall slope were also estimated through the formula 'semi-tones per second' (henceforth st/s). Annotations and values were cross-checked several times, both manually and automatically.

[1] See also Fagyal & Stewart [19], as far as interactivity is concerned.

[2] MPF is the French part of the research project 'Multicultural London English – Multicultural Paris French' (www.mle-mpf.fr). It aims at investigating language variation and change occurring in Western European cities, in a situation of linguistic contact.

[3] Only details that are relevant for this paper will be discussed here.

[4] $F(1.46) = 10.04$ $p < 0.002$.

[5] The 72 judges were the same for both the first and the second part of the perception test.

[6] We were only able to test the judges' perception for 100 intonation contours, randomly selected out of 593. Testing the whole amount of data would have been impossible. The remaining intonation contours were labeled according to the annotator's perception.

[7] Results are statistically significant. Statistical significance was calculated using a chi-squared test for each stimulus. The limited space available here does not allow the results to be shown individually.

[8] Results are statistically significant: t 15.31 $p = 0.0001$ for EM, and t 15.54 $p = 0.0001$ for BA. Otherwise, interaction does not reach the significance level: $F(1.58) = 2.637$ $p < 0.10$.

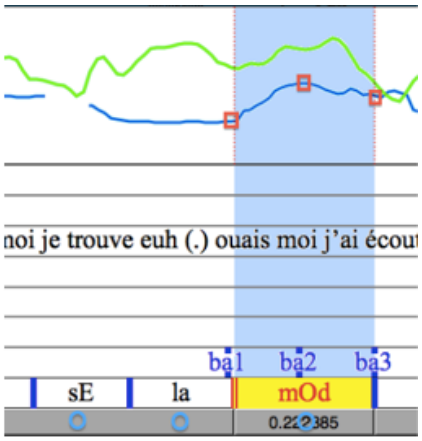

Figure 2: *Sample of 3-point annotation for a BA contour. Red squares, from left to right, correspond to the beginning of the rise (point 1 = ba1), the top (point 2 = ba2) and the end of the fall (point 3 = ba3). Blue circles, from right to left, correspond to the last syllable (syll 0, 'mOd'), the penultimate (syll 1, 'la') and the ante-penultimate (syll 2, 'sE').*

3.3 Analyses and results

3.3.1 Rise and fall

Results concerning rise and fall range show that BA contours rise and fall slightly more than EM contours (fig. 4). Results are statistically significant[1]. We will discuss below whether such a tonal difference is likely to be perceived or not.

Rise / Fall		S. dev.	Difference
EM rise	4.621	2.306	0.947
BA rise	5.568	2.592	
EM fall	-4.030	-1.955	-0.711
BA fall	-4.741	-2.420	

Table 2: *EM and BA contours' rise/fall range*

3.3.2 Duration and penultimate lengthening

As far as duration is concerned, there is no significant difference between the global duration of EM and BA contours (point 3 - point 1, on fig. 2)[2]. However, the fall of the EM contours is significantly longer (0.036 s) than that of BA.

Global duration		S. dev.	Difference
EM	0.240 s	0.075	0.002
BA	0.233 s	0.077	

Table 3: *EM and BA contours' global duration*

We also tried to determine whether the penultimate syllable is significantly lengthened compared to the last one. The French language usually has a fixed final stress on the last syllable of the prosodic group, which is mainly expressed by duration. Final stressed syllables are twice as long as unstressed syllables. Our results show that while the EM penultimate seems to be slightly shorter (-18%) than that of BA, there is no significant lengthening of the penultimate syllable.

3.3.3 Pitch alignment according to syllable

Results concerning intonation contour alignment show that 51% of EM contours align on the last syllable (syll 0) whereas 64% of BA contours align on the penultimate (syll 1). Only a small percentage of both contours align on the antepenultimate (syll 2), as can be seen below (fig. 3). Results are statistically significant ($p < 0.01$).

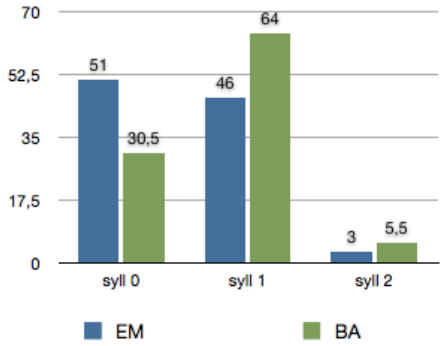

Figure 3: *EM and BA contour alignment according to syllables*

Nevertheless, interpretation of the results is not straightforward. BA contours show a general tendency to align earlier than EM ones. EM contours start to rise 18% later[3] than BA. EM contours also reach the high pitch target 5.8% later[4] and fall 3% later[5] than BA contours (see fig. 4 below). Results are statistically significant, $p < 0.01$.

Finally, we found that BA contours rise faster (10.5 st/s) and fall faster (12.7 st/s) than EM contours ($p < 0.001$).

3.3.4 Summary

To summarize, BA intonation contours seem to rise higher and fall lower than EM. BA contours are slightly shorter than EM, especially as far as final syllables are concerned. BA penultimate syllables are actually a bit longer than EM. However, BA and EM penultimate syllables are never significantly longer than final ones. BA contours align earlier and rise faster than EM.

These results may indicate that there is a difference between BA and EM intonation contours. The question now is whether this difference is marked enough to be perceived.

4. Discussion

Our results concerning the BA contours' rise and fall range show lower values than those found by Lehka-Lemarchand [11] in Rouen suburbs (9.6 st for rise and -8.6 st for fall). No quantitative values can be found in the literature for Paris, apart from the study comparing Paris and Rouen [8]. Paris

[1] EM vs. BA rise: $F(1.592) = 22.21$ $p < 0.0001$. EM vs. BA fall: $F(1.592) = 15.71$ $p < 0.0001$.
[2] Given the large amount of data, values have not been normalized.
[3] Point 1, on fig. 2.
[4] Point 2, on fig. 2.
[5] Point 3, on fig. 2.

speakers do not seem to realize very strong BA contours, compared to the rise-fall configurations found in Rouen.
As far as alignment is concerned, the beginning of the rising slope always aligns on the last syllable for BA contours in the Rouen corpus, while Fagyal [1] found that they always align on the penultimate in Paris. Our study showed that BA mainly aligns on the penultimate whereas EM mainly aligns on the last syllable. However, the percentage difference is not that high and does not reach the significance threshold. BA and EM do not differ much as far as alignment is concerned: 46% of EM contours actually align on the penultimate syllable, as do BA contours. In fact, further analyses have shown that globally both BA and EM intonation contours mainly align before the beginning of the last syllable (see fig. 7 below)
With regard to rise and fall speed, not only do BA rise higher and fall lower than EM, they also rise and fall faster. This probably induces the perception of stronger intonation contours, which is also strengthened by early alignment on the penultimate. Intensity has not been measured, but we hypothesize that it can play a significant role in intensifying the perception of 'stronger' high-low prosodic patterns.

In order to answer our question as to whether the acoustic difference between BA and EM contours can be perceived or not, the *glissando* threshold put forward by t'Hart *et al.* [17] can be taken into account. *Glissando* threshold refers to the variation of F_0 and defines when this range is perceived as a rise and/or fall tone. It is usually expressed in semi-tones per second and indicates the speed needed for the rise-fall pattern to be perceived. The authors indicate that it should be equal to or greater than 0.16 st/t^2. Our results show that the *glissando* threshold of rising BA contours is 0.83 st/t^2, which is 0.16 higher than the *glissando* threshold of rising EM ones (0.67 st/t^2). This result is significant enough for the BA contour rise to be perceived as different from the EM one ($p < 0.05$). On the contrary, the results are not significant as far as falling BA and EM contours are concerned.

Finally, amongst our numerous results, early alignment and the *glissando* threshold of BA intonation contours seem to be the two key elements leading to the perception of 'stronger' BA intonation contours.

5. Conclusions

Acoustic analysis has shown that there is a slight difference between *banlieue* and emphatic contours. BA intonation contours start to rise earlier, rise higher, faster, and fall lower than EM intonation contours. Nevertheless, their similarities seems to be greater than their differences, since the features of BA contours are defined in comparative terms.

Closer analyses of judges' perception showed that the stimuli evaluated at a 100% rate of agreement were all BA contours whereas stimuli evaluated at a < 30% rate of agreement were EM contours. The higher the rate of agreement, the 'stronger' the contour. The lower the rate of agreement, the 'weaker' the contour.

As can be seen below (fig. 4), the modeling of BA and EM does not in fact show two different kinds of rise-fall intonation contours. This suggests that BA contours are similar to EM but 'stronger'. Comparison with a control group of 119 standard continuation contours (CONT), annotated in the same corpus (fig. 4), reinforces this assumption in that BA and EM intonation contours are quite different from other contours in general French, but they are not substantially different from each other.

Acoustic differences alone are not sufficient in themselves to assert the existence of two different high-low prosodic patterns. Extra phonetic, linguistic and semiotic details are required for a *banlieue* accent to be perceived.

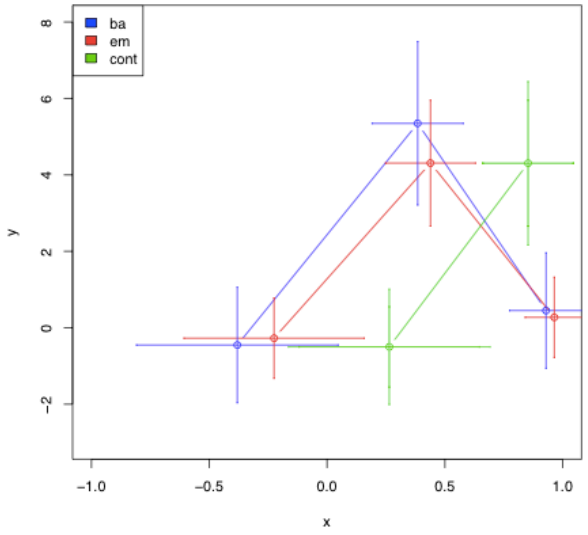

Figure 4: *Comparison between EM (red), BA (blue) and CONT (green) alignment with regard to final syllable (normalized between 0 to 1 on x-axis) and penultimate syllables (prior to 0.0 on x-axis). The y-axis represents the tonal difference (in semi-tones). The reference point of the pitch is set on the beginning of the rise. Crosses represent mean and standard deviation in temporal (x-axis) and tonal (y-axis) dimensions.*

The acoustic data seem then to match sociolinguistic insights: the high-low prosodic pattern cannot be considered a new phenomenon and is far from being specific to young people coming from working-class suburbs and/or from immigration. The novelty resides in the fact that EM/BA contours are likely to be used in context for pragmatic purposes, according to speakers' mutual involvement in interaction and communicational proximity. "*La vie dans la cite, c'est chaleureux*"[1], said one of our informants. That is why we suggest that the two kinds of intonation contours, emphatic and *banlieue*, can be considered as a single phenomenon, situated on a continuum, and that they are context-bound and interaction-sensitive. Thus, the realization of such a prosodic pattern ranges from one extreme to the other, depending on the speakers' shared understanding of the communicative situation and the speakers' level of interactivity.

Topic and Focus Intonation in Argentinean *Porteño*

David Le Gac[1]

Abstract

This paper investigates the intonation of topics and focus in Argentinean *Porteño*. We have found that whereas tonal alignment is phonetically conditioned, pitch height and duration constitute the main cues to express various types of focus in declarative and interrogative sentences; at least four intonational categories seem to be used by our speakers and the relevance of a register feature is discussed. As for topics, they are marked by special tunes that depend on the type of sentence; in particular, the topic tune in questions is the opposite of those found in declaratives.

Index Terms: *Porteño* Spanish, focus, topic, question, tonal alignment, pitch height, register feature, duration

1. Introduction

It is now well established that, in many languages, intonation plays a major role in the expression of the two main components of the information structure: topic and focus ([1], [2]). In English ([3]), French ([4]–[8]), Modern Greek ([8], [9]) and Spanish ([10]–[13]), among other languages, focus affects the intonation of the whole sentence: it assigns the nuclear pitch accent to the focus word and all the post-focal words are de-accented. Previous studies have also shown that 'informative' focus and contrastive focus are given different prominence ([1], [5], [14]). Furthermore, focusing has been found to lengthen the duration of the focus word and to shorten pre- and post-focal parts ([5], [9]). As for topics, they generally appear at the beginning of a sentence and express the 'aboutness' of a sentence, that is, "what is being talked about", and serve as the "the point of departure of the message" (see [15]). They are often described as implying a continuation rise at the end of the topicalized phrase in declarative sentences as in French ([4], [7], [6], [8]) and Modern Greek ([8], [9], [16]); in Spanish, [12] proposed that a phrasal H- indicates the end of the constituent conveying old information. In Greek, though, topics in questions have an inverted intonation pattern compared to that of the topics in declaratives: they display a L* instead of the H* and are right bounded by a low tone ([8], [9], [16]). This tonal inversion may also be produced in French ([4], [6], [8]), and has not yet been adequately explained.

Turning to the Argentinian Spanish, the intonation of the variety spoken in Buenos Aires, called *Porteño*, notably diverges from the Castilian and Latin American standards of Spanish. Pitch peak in pre-nuclear accents is described as being regularly located within the stressed syllable ([11], [17]–[19]) instead of being aligned with the post-tonic syllable as in the other varieties of Spanish. Broad focus declaratives differ from narrow focus ones in the alignment and height of the non-final pitch peaks ([19]–[21]), which happens earlier for the latter. However, in a pilot study investigating the perception of narrow focus in *Porteño*, [22] found that pitch alignment patterns cannot account for the distinction of narrow from broad focus in this dialect. Increasing pitch values and/or vowel duration, as well as de-accenting of material after a word in narrow focus, as opposed to the pitch accents present in broad focus contribute to a narrow focus perception. Focus thus deserves further study in order to determine its intonational properties in *Porteño*. As for topics, to the best of our knowledge, no study has yet explored their prosodic expression in this variety of Spanish.

This paper investigates the prosodic cues of topic and focus in both declarative and interrogative sentences, adopting the autosegmental-metrical theory of intonation ([23]). Regarding focus, we examine the melodic pattern and the duration of three types of narrow focused words: i) *'informative'* focused word (henceforth "IFoc") – i.e. the answering part of a WH-word; ii) *contrastive* focused word ("CFoc"); and iii) a focused word in a *yes-no question* ("QFoc"). These focused words are all located after the topics, in the middle of the sentence, and are compared to a pre-nuclear ("PNucl") non-focused word in the same position. We aim at determining which pitch accents and edge tones these words are associated with and to what extent tonal alignment, pitch height and duration contribute to distinguish them. Concerning topics, we will examine what type of pitch accent and what type of boundary tone they are associated with; in particular, we will determine whether their tonal pattern varies according to the type of sentence (declarative *vs*. question).

2. Methodology

In order to trigger the various kinds of focus, we used a question-response paradigm with a general lead-in context about two friends talking about a party. (1) and (2) below are two examples of these dialogues. Topics began the sentences and consisted of either one NP (a head noun and an adjective; cf. (2)) or two XPs (cf. (1)). The different focus words ("Q/C/IFoc" words) were proper nouns (*Penélope*, *Verónica*) in subject position followed by a verb (*hablaba*) and its complements. Except for the verb and the functional words, all words were stressed on the antepenultimate syllable. We obtained eight dialogues. We also used a broad focus sentence with the same structure as the other ones to study the prosody of PNucl word. These dialogues were written on cards and randomized with other sentences designed for other experiments. Each sentence was repeated four times by two female speakers of *Porteño* (one in her fifties, speaker PH, the other one in her thirties, speaker LD). The recordings took place in quiet rooms, and were done using the computer's sound card (44kHz 16bits) directly.

(1) Qu.: *¿*[*El miércoles*]$_{\text{TOP}}$ [*en Córdoba*]$_{\text{TOP}}$ [*quién*]$_{\text{WH-wd}}$ *hablaba con Nélida de mecánica?*
'Wednesday, in C., who was talking with N. about mecánica?'

Ans.: [*El miércoles*]$_{\text{TOP}}$ [*en Córdoba*]$_{\text{TOP}}$ [*Penélope*]$_{\text{IFoc}}$ *hablaba con Nélida de mecánica.*

(2) Q: ¿[*El miércoles último*]$_{\text{TOP}}$ [*Verónica*]$_{\text{QFoc}}$ *hablaba…* ?
'last Wednesday was Verónica talking…'

A: *No,* [*El miércoles último*]$_{\text{TOP}}$ [*Penélope*]$_{\text{CFoc}}$ *hablaba…*

The acoustic analysis of duration and fundamental frequency (F_0) were done using the Praat software package [24]. To compare the melodic realizations of the speakers and the various types of focus and topics, we converted the

original F_0 values in Hertz into semi-tones ("ST") by taking the frequency minimum of the utterances as the reference value. Moreover, in the vein of [25] and [26], we also generated time-normalized contours using the syllable as the domain of normalization and a 10-point time resolution per syllable.

3. Results and discussion: focus

Figure 1 below shows the time-normalized F_0 curves in ST of the PNucl and focus words in the different types of sentences (questions and declaratives) averaged across repetitions of the same type of focus.

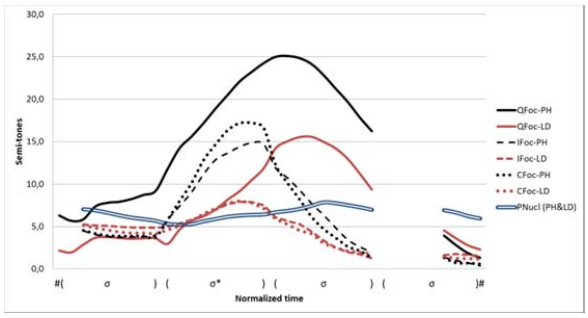

Figure 1: *time-normalized curves in semi-tones of PNucl- C/I/QFoc words for speakers PH and LD*

3.1. Pre-nuclear noun in broad focus sentences

Figure 1 shows a somewhat unexpected result concerning the pitch accent of the PNucl noun. As seen in the introduction, *Porteño* is said to differ from the other varieties of Spanish by realizing pre-nuclear accents as H* tones located *within* the stressed syllable. As can be seen in Figure 1, however, the accentual peak appears in the center of the post-tonic syllable, preceded by a low tone aligned with the beginning of the stressed syllable. This accentual 'late' rise is actually similar to the one found in the other varieties of Spanish (see [12]).

This accentual peak displacement is likely to be related to the proparoxytonic nature of the PNucl noun *Penélope*. Indeed, the other pre-nuclear proparoxytonic nouns in our corpus (*Verónica, Nélida, mecánica*) display the same tonal alignment; on the other hand, the paroxytonic verb *hablaba* occurs with the expected H* within the stressed syllable. A closer look at the literature about the prosody of *Porteño* reveals that most words taken into account in the previous studies are paroxytonic (or oxytonic); when proparoxytones are under investigation as in [27]'s study, these nouns undergo the same tonal alignment of H* as the one found in our recordings (see [27]'s figures).

3.2. Narrow focused nouns

As shown in Figure 1, all speakers realize a clear melodic contrast between the PNucl noun and the narrow focused words in terms of pitch height and tonal alignment. In declarative sentences, C/IFoc words are marked by a F_0 peak located *within* the stressed syllable, generally in the middle of the stressed vowel; we didn't find any evidence in our data for an early peak marking narrow focalization as reported by [19] and [21]. The peaks of C/IFoc words are preceded by a low tone located in the pre-tonic vowel. Figure 1 also shows that C/IFoc words are right bounded by another low tone, which reaches the low level of the speaker's range. Moreover, like in other languages and varieties of Spanish, all words after the focused element in declaratives are realized as a low plateau up to the end of the sentence or, at least, with very reduced pitch accents.

As can be seen in Figure 1, Sp.PH further distinguishes the C/IFoc words from the PNucl word by strongly increasing the height of the focal peaks in comparison with that of the PNucl word (+7.9 ST). Consequently, the words in focus are usually pronounced higher than the other pitch maxima in the sentence (those of the topics; see section 4.), whereas the PNucl high tone appears as downstepped compared to the preceding pitch accents ([11]–[13], [20], [21]). The melodic configurations of Sp.PH are thus along the lines of [19], [20]'s observations that focal peaks in *Porteño* are substantially higher than the non-focal ones. Notice though that Sp.LD does not focus words in this way; PNucl noun and I/CFoc words culminate at the same height.

As for questions, the stressed syllable of the QFoc word is realized by both speakers with a large rising contour (12/15 ST of range). This rise differs from those of the C/IFoc words in the alignment of the pitch peak: starting from the pre-tonic syllable, it ends with a peak anchored to the onset consonant of the post-stressed syllable, and not to the center of the stressed vowel as observed in C/IFoc words. In addition, for both speakers, the tonal peak of the QFoc words reaches a much higher F_0 value than that of the peaks of C/IFoc words; the difference is about 9 ST.

Nevertheless, Figure 1 reveals differences between the speakers as far as the tonal height is concerned. Sp.PH presents the highest F_0 values for the QFoc (25.1 ST), which reaches the top values of her pitch range (*falsetto* voice); she also realizes a pitch height contrast between the IFoc (14.7 ST) and CFoc (17.5 ST) words. On the other hand, although Sp.LD distinguishes between a QFoc word and C/IFoc words, she realizes the QFoc peak at a similar height to that of Sp.PH's C/IFoc words in declarative sentences.

As far as the tonal pattern of WH-word *quién* is concerned, it seems, *mutatis mutandis*, to be similar to that of the QFoc word. They are both characterized by a rise culminating at the same height. Their peak is aligned with the consonant immediately to the right and is followed by a steep fall. But the intonation of the rest of the sentence differs according to the type of word. In WH questions, all pitch accents rightward from the WH-word are de-accented; there is sometimes an optional final rise such as the one described by [11], [21] and [28]. In QFoc sentences, on the other hand, both speakers systematically produce a rising-falling contour at the end of the sentence; this contour is a kind of copy of the QFoc tone pattern and may be downstepped or not.

3.3. Duration of PNucl and focused words

The duration of the PNucl and focused words is given in Figure 2 below. As in other languages, there is an effect of focus on word duration: PNucl word is shorter than the focused words for both speakers. However, there are notable differences between the speakers. While Sp.PH exhibits a similar duration for all types of focus words, Sp.LD produces the CFoc noun with a much longer duration than the IFoc one; in addition, she greatly increases the length of the QFoc word as well. In fact, she is likely to lengthen the QFoc and CFoc words in order to compensate her lower F_0 values compared to

those of Sp.PH. Rising pitch or increasing duration thus seems to be two complementary strategies used by *Porteño* speakers to signal question and focus.

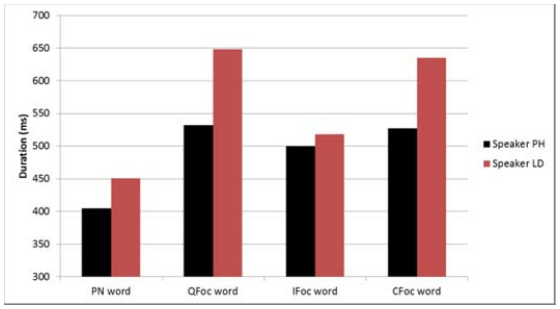

Figure 2: *duration of PNucl word and focus words*

3.4. Phonological representation

Let us first consider the tonal alignment of the various pitch peaks we have observed so far. It appears that the alignment of these peaks is actually *predictable* from the phonetic context. As seen above, the words in focus ends with a very low tone. Following [12], [29] and [20], we will interpret this tone as a phrasal tone L- and assume that it triggers the displacement of the peak toward the center of the stressed vowel in C/IFoc words. As for the delayed peak on QFoc and WH-words, it may be viewed as the result from an additional effect of the extra-high target to be reached. When there is no phrasal tone, as in PNucl words, the peak surfaces on the post-tonic syllable.

In the spirit of [12] and [20], we will therefore assume a unique underlying /(L+H)*/ pitch accent. The L tone accounts for the low valley that begins the PNucl and focus words and which contrasts with the high onset found at the beginning of the topics in questions (see section 4). The L tone is linked to the onset of the stressed syllable, and the H tone is more loosely associated. Like in standard Spanish, we will suppose that the post-tonic syllable is the default surface location of the H tone if there is 'enough room' ([12]) within the word, specifically, within proparoxytones in the case of *Porteño*. However, a gradual phenomenon conditioned by such factors as the proximity of other tones and word boundary moves the peak toward the left. Our proposal is, moreover, consistent with the results of [22] suggesting that, in this dialect, the perception of narrow focus is not achieved by tonal alignment but rather by duration and pitch height. Nevertheless, it remains to clarify whether the early peak in *Porteño*, reported by previous authors, is due to the (par)oxytonic nature of words.

The second issue we need to address is about the representation of the *tonal height* of the proposed pitch accent (L+H)*. Previous authors argued for a binary choice between two categories of high tones contrasting in pitch height: [11] claims a H+H* pitch accent to account for the pitch range increasing found in questions; [19]–[21] use an upstepped high tone they note "^H" or "¡H" for capturing the contrast between "neutral" high tones "H" and those marking questions or emphasis. These two categories of high tones allow us to adequately describe the melodic patterns of Sp.LD, using the label /(L+H)*/ for the PNucl and C/IFoc words and /(L+^H)*/ pitch accent for the QFoc and WH-words.

However, the tonal patterns produced by Sp.PH suggest a phonological contrast between three heights for the pitch peaks: indeed, the difference in pitch height between the PNucl noun, the C/IFoc words and the QFoc/WH-words varies in the same proportion (8 to 10 ST); and remember that for Sp.PH, pitch height is the only feature that distinguishes the C/IFoc words from QFoc and WH-words. Moreover, Sp.LD dramatically increases duration to distinguish between these different types of words. In other words, we think that there actually is a three-way categorical intonational contrast between the PNucl word, the focused words in declarative sentences and those in questions. But, the speakers adopt a different strategy to achieve this contrast: Sp.LD increases both pitch height and duration whereas for Sp.PH, contrasting pitch height appears to be the main distinctive feature. We will therefore hypothesize the following three pitch accents for Sp.PH: /(L+H^1)*/ *vs.* /(L+H^2)*/ *vs.* /(L+H^3)*/, H^3 indicating the top levels of the pitch range. Further investigations have to be carried out to answer whether Sp.LD has the H^3 tone in her intonational system; this tone might signal questions with surprise or incredulity for instance ([28]).

4. Topics

Let us begin with topicalization in the declarative sentences. In sentences with two topics (Figure 3 top), the speakers employ the (L+H)* pitch accent on each topic. The accentual H tone undergoes the gradual moving toward the left we've seen on the focus, that is, when the post-tonic syllable bears a low target, the H tone aligns with the middle of the stressed syllable (see F_0 track "D-2TOP-1"); if there is no subsequent low tone ("D-2TOP-2/3"), then the H tone appears on the post-tonic syllable. Both topics may end with a high tone that we analyze as a phrasal H-; this H- either surfaces as a rising contour LH- ("D-2TOP-1") or as a level high tone from the accentual H ("D-2TOP-2"). This is along the lines of [12] who proposed a phrasal H- signaling old information. In some recordings (cf. "D-2TOP-3"), however, there is a gradual fall from the accentual H up to the following accentual L belonging to the subsequent topic or focus; in other words, topics may end with no tonal target. Finally, note that there is no evidence for downstepped or upstepped topics.

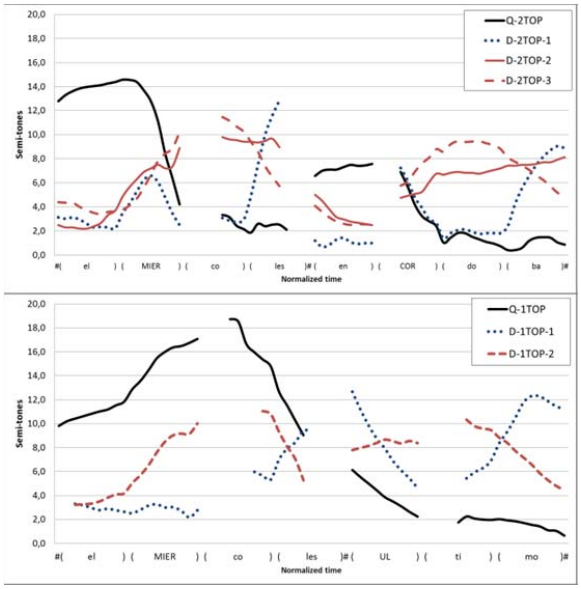

Figure 3: *time-normalized F_0 tracks in ST for the topics in questions ("Q-") and in declaratives ("D-"). Top: two topics (2TOP); bottom: one topic (1TOP).*

As for the topics comprising a single NP (Figure 3 bottom), two strategies are employed by the speakers. Sp.LD generally uses sequences of two [(L+H)*Ø] tunes associated with each lexical word (cf. "D-1TOP-2") and where the high peak is delayed because of the lack of phrasal tone. Sp.PH (cf. "D-1TOP-1") usually realizes the stressed syllable of the head noun *miércoles* with an L* tone, which is followed by a gradual rise to the beginning of the accented syllable of the adjective *último*. The adjective bears a single H* tone, which appears early within the stressed syllable because of the rising contour LH- ending the topic and the absence of an accentual leading L; we will label this topic tune as [L*..H* LH-].

Turning to questions, the tonal patterns of the topics are remarkably stable across both speakers; Figure 3 thus displays a unique averaged F_0 curve for each type of topic. In sentences with two topics, the tonal pattern of each topic is characterized by a steep fall on each stressed syllable, whose onset is associated with the peak and the end with the low target. We will represent this pitch accent as (H*L*), with two starred tones to indicate that they both associate within the stressed syllable. As can be seen in Figure 3, there is no evidence for a low tone before the H*: the melodic onset of the topics is almost at the same height as that of the H* and this clearly contrasts with the low onset at the beginning of the topics in declaratives or of the PNucl / focus words. The presence of an L* within the stressed syllable is further demonstrated by the very early alignment of the H* in comparison with those we have seen so far. Each topic ends with a low tone pronounced in the lowest part of the speakers' pitch range like the one right bounding the focus; we will therefore analyze this low tone as a phrasal L-.

As Figure 3 shows, the H* tone of the second topic is a lot lower than the first topic H* tone (about 7 ST) and accordingly seems to have been downstepped by the preceding H*L*. However, the H* tone of the second topic reaches similar values (around 7 ST) as those of the peaks found on the second topic in declarative sentences. Moreover, an intermediate phrase boundary (L/H-) arguably blocks any downstepping rule. On the other hand, there is a markedly increase in pitch height of the first topic H* tone in questions compared to the height of those found in declaratives (around 7/8 ST). In fact, the height in ST of the first topic H* tone corresponds to that of the focus in declarative sentences pronounced by Sp.PH or that of the QFoc uttered by Sp.LD (14-17 ST); we will thus claim that this H* tone belongs to the same tone category as the focus one, namely the H^2 category.

As regards the questions with a single topic, we also observed a unique tune for both speakers, we will represent as follows: [H^2*..L* L-]. This tune is characterized by an H^2* tone occurring at the end of the first stressed syllable. Again, this H^2* tone distinguishes itself from those occurring in declarative sentences in terms of pitch height (17 ST *vs*. 9 ST/ 3 ST respectively). It is connected to an L* tone appearing on the stressed syllable of the subsequent adjective by a gradual fall; the L* tone is then followed by a phrasal L-. Like two-topic sentences, no phonological tonal target is inserted at the onset of this tune because melodic curve confirms that the F_0 values at the beginning of the topics depend on the vicinity of the H^2* tone: the closer to the beginning the latter is, the higher the F_0 is produced.

The similarity between the tunes of both types of topicalization leads us to propose a more general template that we will note [(H^2*..L*) L-]. (H^2*..L*) refers to a 'splitting' pitch accent where both starred tones *must* be realized *within* a stressed syllable: inside a topic phrase, either they associate to separate stressed syllables as in the case of the single topic or, if there is only one stressed syllable, they both associate to the latter as we saw it in sentences with two topics.

We will conclude this paper with two final considerations. First, like in Modern Greek and French (cf. [7]–[9], [16]), it appears that, in *Porteño*, topic phrases in declaratives and questions exhibit opposite tonal patterns: in questions, topics have a (H^2*..L*) pitch accent followed by a L-, whereas, in declaratives, they have a (L+H)* or a L*..H* pitch accent followed by a H-. This type of inversion is thus likely to be a common intonational phenomenon that would deserve to be investigated and understood in more depth. In particular, one may wonder whether it is due to some phonological rule of tone inversion ([8]) or to a perception-oriented process that would help the listener determine whether the utterance she is processing is a declarative or a question. The tone inversion could also be induced by a difference in the activation state of the discourse referents in the sense of [15] (see also [16], [30], [31]): in our corpora, the topics of the questions are actually *inactive* ('new') whereas those of the declarative are *active* ('given').

The final point we wish to address is about the phonological structure of pitch height in *Porteño*. We saw that one can distinguish three (Sp.LD) or four (Sp.PH) pitch levels, which were given scalar values (L, H^1, H^2 and H^3). Like in tonal languages ([32]–[34]), however, it may be more accurate to use binary features such as the [±Upper] – a 'register' feature – and [±high] of [33] to account for the various pitch levels of *Porteño*. Within this system, we obtain the following equivalences: H^3=[+U,+h], H^2=[+U,-h], H^1=[-U,+h] and L=[-U,-h].

The main advantage of using these features is that it allows making generalizations across the speakers and the tonal patterns of the sentences. Thus, instead of merely seeing that Sp.LD uses a H^2 to signal questions and Sp.PH a H^3, it may now be stated that all speakers mark questions with the [+U] feature. Furthermore, being an autosegment, this feature may associate with other [high] features within the sentence. This would account for the increased pitch appearing both at the beginning and the end of questions. Let's say that *all* accentual tones in questions, except the one linked to the QFoc and WH-words ([+U,±h]) are actually underlying *low* tones, i.e. [-U,-h]. One may now propose that questions are further marked by the association of the [+U] borne by QFoc and WH-words with the *first* pitch accent of the sentence, generating a [+U,-h]* tone (i.e. H^2*), and, optionally, to the *final* sentence accent or boundary tone, giving the final rising or falling contours. Using a unique feature [+U] allows to generalize [11]'s proposal of a sentence initial H% and a H+H* pitch accent that express questions in Spanish: [11]'s H% and a H+H* are two distinct objects but they both have the same effect of upstepping pitch; on the other hand, a single [+U] feature provides a unified explanation to the increased pitch characterizing questions in Spanish.

liangzhang1025@gmail.com, summeryuan_2003@126.com, liaj@cass.org.cn

Abstract

This paper investigates factors that influence pause duration in Chinese reading texts through examining the stress degree in pre-pausal and post-pausal positions and the rhetorical structure in discourse as a whole. The RSTTool is used in diagramming the rhetorical structures of the texts. The recordings, extracted from the ASCCD corpus, are further analyzed acoustically and statistically by applying Praat and R. The statistical analysis results show that the stress degree in both pre- and post-pausal positions has a significant impact on pause duration. Moreover, the nuclearity in both positions have also been shown to have a remarkable influence. Specifically, the nucleus in pre-pausal and satellite in post-pausal positions can significantly lengthen the pause duration.

1. Introduction

The Rhetorical Structure Theory (RST) (Mann & Thompson, 1988) is a theory of text organization that has led to areas of application beyond discourse analysis and text generation. It has been applied to several linguistic areas, i.e. theoretical linguistics, psycholinguistics, and computational linguistics. RST defines a set of relations to identify the specific relationship that holds between two Elementary Discourse Units (EDUs) of a text. These relations are categorized into two types: mononuclear and multinuclear relations. After the elaborate description and categorization on the relations in large amount of real discourse spans, 30 rhetorical relations were studied in Mann (2005). A novel feature of RST is the concept of nuclearity. As well as presenting the relationship between two text spans, rhetorical relations also convey the information about which span is more central to the writer's purposes. Relations such as background and circumstance are of nucleus-satellite in that the EDUs linked by these relations are distinguished by their centrality: one is called the nucleus (N) and the other is called the satellite (S), with satellite subordinate to the nucleus.

Among various discourse structure theories, RST has been used widely in recent years to diagram the rhetorical hierarchy annotation. The popularity of RST has led to the development of an RST Treebank of manually annotated English texts, which is available for training and testing purposes (Carlson et al. 2003). It consists of 385 Wall Street Journal articles from the Penn Treebank (Marcus et al. 1993) with a total of 176,383 words. Another well-annotated RST corpus is Potsdam Commentary Corpus (PCC), which consists of 172 commentaries from Mearkische Allgemeine Zeitung, a German regional daily (Stede, 2004). Some other researchers (Stent, 2000; Taboada, 2004) also tried to apply RST to annotate spoken dialogues in Task dimension.

The development of RST in analyzing Chinese discourse was mainly in the areas of syntactic analysis (Chen, 2008), prosodic analysis (Tseng, 2006), Systemic Functional Grammar (SFG) (Wang & Dong, 1995), and Second Language Acquisition (SLA) (Wang and Xia, 2005). The other application field has been Computer Sciences and Language Processing, aiming principally at auto-annotation of rhetorical structures by training the model with hundreds of essays or news articles (T'sou et al., 1992; T'sou et al., 1996; Skoufaki, 2009).

Yue (2006) enriched Chinese language resources through building up a Chinese news commentary Treebank, using the RST as the theoretical framework. The corpus, consisting of 400 news texts of about 780,000 characters, has been applied to computation of a priori scores, needed in Chinese summarizers and be used as a platform for training and testing statistics-based discourse parsers. Their annotation efforts have proved, on a fairly large scale, the cross-language transferability of RST and its formalization.

The research on interfacing RST and prosody has attracted much attention. However, little work has been done in Mandarin Chinese discourse. Yang and Yang (2012) examined how rhetorical structures were reflected by boundary prosodic parameters in Mandarin Chinese discourses, through investigating recordings of ten paragraphs of news commentaries, with the prosodic parameters (pause duration, pitch reset, and final lengthening). The results were in line with previous studies (Noordman et al., 1999; Ouden et al., 2009). Nonetheless, no further detailed analysis has been done on stress degree, nuclearity and any other possible influential factors.

The above overview of previous studies shows that RST, which has been adopted in interdisciplinary research, were mainly restricted in the discourse dimension. The empirical study on the interface of prosody and RST, from the perspective of stress degree and nuclearity, is of fundamental importance but is largely under-explored. The work reported in this paper aims to fill this gap. Particularly, this paper is concerned with the duration of rhetorical pause in reading speech of Mandarin. We investigate the effect of the stress degree and nuclearity of preceding and upcoming EDUs, and its rhetorical structure on pause duration at different hierarchy within a RST diagram of the text.

2. Data

The materials selected in this current study are three reading texts chosen from the Annotated Speech Corpus of Chinese Discourse (ASCCD), which was built by the Phonetic Lab, Institute of Linguistics, Chinese Academy of Social Sciences (CASS). The data were collected from ten Mandarin speakers (5 males and 5 females) in Beijing. The C-ToBI system was used for annotation and four tiers were labeled. In this research, the stress tier (ST) is used, in which each prosodic unit were annotated with one of the four degrees (0: weak; 1: normal; 2: secondary stress; 3: primary stress). The stress degrees of preceding and succeeding rhetorical pauses are extracted for further analysis.

The RSTTool provided by O' Donell (1997) was used in this study to create the RST diagram. One disadvantage of RST, as mentioned in previous study, is the comparative subjectivity in labeling relations. The diagrams used in this study were double-checked by another researcher in the same field, in order to avoid inaccuracy as much as possible. The resultant RST diagram is showed in Figure 1.

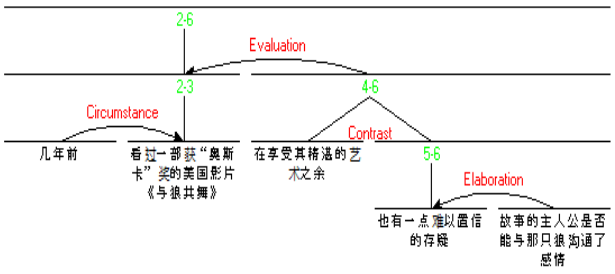

Figure 1. *An example of RST diagram*

(A few years ago/ I watched an Oscar-winning film: Dances with Wolves/ besides the enjoyment of exquisite art/ I found one point incredible/ whether the hero of the story really communicated with the wolf.)

In all multi-span diagrams, each rhetorical pause is marked with the sum of spans of adjacent EDUs. For instance, “Circumstance” in Figure 1 would be labeled as 4 (2+2, sum of first and second EDU span, with the highest span excluded). Similarly, we get 6 for “Contrast” and 6 for “Elaboration”. For three texts in total, the spans are ranked from 3 to 14. To facilitate statistical analysis, the spans are re-categorized into four hierarchies with 3 consecutive spans in each category.

Pause duration is defined as the silence interval between the ending of one segment and the beginning of the next segment. Based on the rhetorical structures of each discourse, the durations of rhetorical pauses are further annotated and extracted from the corpus.

In the three texts, 156 rhetorical relations are diagramed, and accordingly 1560 pause durations are extracted.

3. Methodology, Results and Analysis

In this section, the study systematically examines three factors that could influence the pause duration: rhetorical hierarchy, stress degree and nuclearity in the preceding and succeeding pause positions. These three factors fall into two categories: prosody and rhetorical structure. Through R for statistical computing, t-test and ANOVA analysis are adopted to investigate the inner-relations and correlations of these variables.

3.1. Rhetorical Relations and Hierarchy

To study the effect of hierarchical position with four levels on pause duration, an ANOVA analysis is conducted. The results show that the depth of the hierarchies significantly affects the duration of the pauses ($p<0.001$), indicating that pause duration gets longer when the depth of hierarchies increases. This is consistent with the findings from previous studies on Chinese and other languages such as Spanish, English.

The result shows that the schema *Title* takes the longest pause in all, which reflects the widest semantic distance between adjacent segments, while *Summary* takes the second longest. No significant difference is found ($p=0.166$) between causal and non-causal relationships.

Despite the accordance with the previous results in Yang and Yang (2012), this paper, by involving stress degree and nuclearity, further analyzed their effects on pause duration, and their inner relationship with rhetorical hierarchy.

3.2. Stress Degree

For the stress degree in the pre-pausal position, statistical analysis result (Figure 2) shows a significant difference ($p<0.001$) between ST1 and ST3. As the stress degree goes higher (from 1 to 3), the pause duration decreases.

The same significant difference is observed in the post-pausal position between ST1 and ST2 ($p<0.05$) and between ST1 and ST3 ($p<0.001$). However, with stress degree goes higher, the pause duration increases.

Based on the above results, it is clear that the stress degrees at both preceding and succeeding pause EDUs have a significant influence on pause duration, while the stress degree in the post-pausal position shows a higher influence on each stress degree, as demonstrated in Figure 2. The X-axis is the stress degree in previous EDU, while the boxplot is colored according to stress degree in post-EDU. The post-pausal stress degree, from red to blue, shows an increasing trend without the restriction of stress degree in pre-pausal position. While for pause duration in preceding pause position, there is no visually obvious decrease from normal to primary stress.

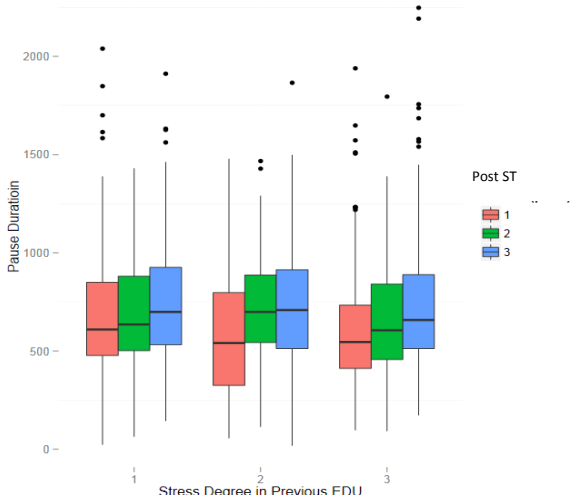

Figure 2. *The significant influence of upcoming stress degree on pause duration*

In the next step, we examine the distribution of duration in combined stress type in four hierarchies. With reference to the results above, as showed in Figure 3, comparatively speaking, the ST combination “3-1” (up right square) and “1-3” (down left square) generates the shortest and longest duration respectively.

Another noticeable point is that the pause duration and rhetorical hierarchy theory generally but does not necessarily apply to every subordinate category (see circles in Figure 3). This inspires us to make a novel assumption: there is a ranking of the influential factors of pause duration, which leads to the question: what is the ranking of the factors, such as hierarchy,

stress degree, nuclearity, sentence complexity that influence pause duration in reading texts? Further attention should be paid to this interesting point and more experiments need to be done. It is however currently beyond the scope of this paper.

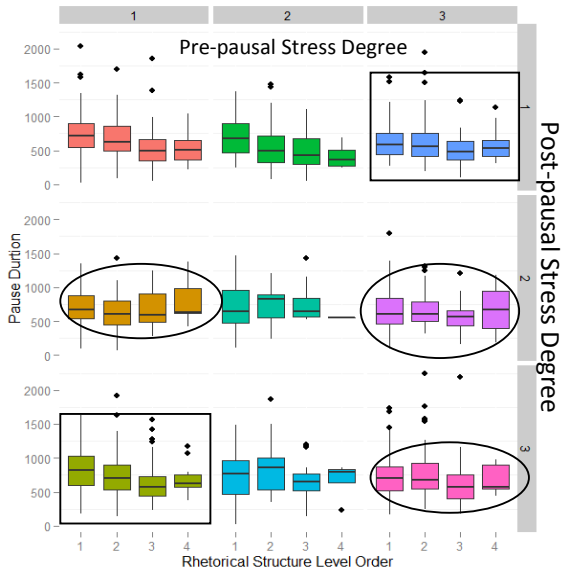

Figure 3. *Pause duration in different stress degree combinations in four rhetorical hierarchies*

3.3. Nuclearity

This part examines the nuclearity of EDUs in proceeding and succeeding rhetorical pause position, aiming at investigating possible influence of nuclearity on pause duration.

3.3.1. Nucleus and Satellite EDU

In the nuclearity of the pre-pausal EDU, statistic result shows a significant difference ($p<0.001$) between N and S. The result indicates that if the EDU is a nucleus in the rhetorical relation, the duration of its succeeding pause would be significantly longer than that after a satellite EDU.

The same significant difference is found in the post-pausal EDU between N and S ($p<0.001$). However, the result is opposite to the previous one: if the EDU is a nucleus one in the rhetorical relation, the duration of its preceding pause would be significantly shorter than that before a satellite EDU.

Therefore, when the test came to pause duration in mononuclear relations as a whole, we assume and has confirmed that the influence of nuclearity on duration is neutralized with no significant difference appears in t.test between N-S and S-N combination, even though practically the N-S combination produces slightly longer pause duration than that in the S-N combination.

3.3.2. Nuclearity and Rhetorical Relations

A closer examination is performed on the components of rhetorical relations in both combinations. Among the 345 tokens of N-S relations, nearly one third are *Evaluation* relations, which, unlike other relations, carry particular emotions (Hou, 2012). Moreover, from the discourse analysis point of view, *Evaluation* indicates the change of footing registration of the writer, with the purpose of jumping out of the narration and gaining interaction and solidarity with readers. The change in registration were clearly obtained by the reader, and thus in the recordings, they may produce a longer pause to indicate the register change.

With the purpose of further analysis of the distribution of mononuclear relation in four hierarchies, Figure 4 is plotted out with the nuclearity combination and pause duration.

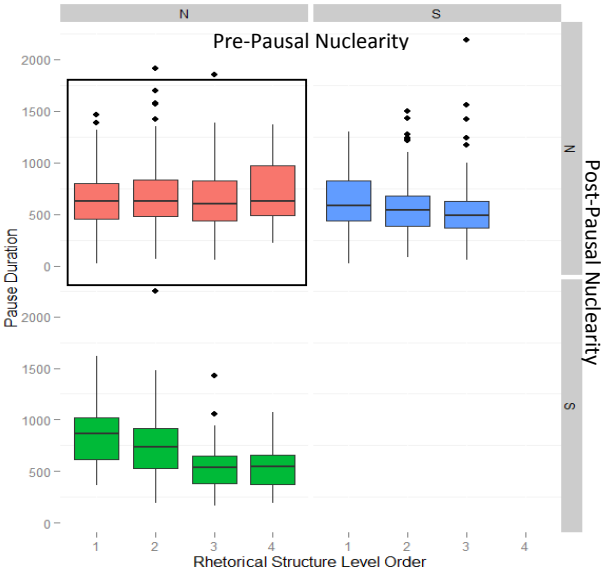

Figure 4. *Pause duration in different nuclearity combinations in four rhetorical hierarchies*

Two points are notable in the boxplot above.

1. The neutralization of pre-and post-pausal nuclearity influence could be resulted in by the uneven distribution of S-N combination in four levels.

2. The pause duration in multinuclear relations (in the square) does not follow the hierarchy pattern show a decrease with the increase of hierarchy. There was no significant difference at all between each rhetorical hierarchy. This leads back to the assumption that mentioned in the stress degree section. Is the duration of multinuclear relations not restricted by the hierarchy theory? Could nuclearity rank first in the restraints? These questions definitely require more attentions and further detailed experiments.

4. Discussion

The study, with the adoption of RST and stress degree on three reading texts may suffer from several biases in the following aspects. First, it is a comparatively small corpus, which may result in skewness of the data. To be specific, there is no S-N combination in forth rhetorical hierarchy. Secondly, though double-check was applied during the process of labeling rhetorical relations, there could still be few mistakes since the

inevitability of subjectivity. Third, the accuracy and consistency of stress degree annotation, which was done based on pure perception of experienced linguistics.

The results also show a gendered variability, in which the male speakers tend to have longer pause duration than the female speakers in every dimension.

5. Conclusion

Through RST labeling on Chinese reading texts and statistical analysis on stress degree and nuclearity in pre- and post-pausal position, the present study explores the influential factors of pause duration. The following observations can be inferred based on the results: stress degree in both pre- and post-pausal positions has significant influence on pause duration, in which "1-3" indicates longest duration while "3-1" the shortest. Nuclearity in both positions separately showed remarkable effect on pause duration: nucleus in pre-pausal and satellite in post-pausal position significantly lengthened pause duration.

This is a pioneer research between RST and prosody with the parameter hierarchy, stress degree combination and nuclearity, which not only jumped out of the hierarchy restriction, but also casts new light on the interface research.

Further experiments are worth investigation given the assumed sequence of influential factors of pause duration, such as stress degree combination, multinuclear relation, and rhetorical hierarchy. Larger corpus is needed for a more thorough research. It may also involve logical speech discourses, such as presentations or story-telling, which are more complicated in topics and less structured in construction.

Statistical and temporal properties of prosodic units in French conversational speech

Irina Nesterenko

INALCO, France

irina.nesterenko@inalco.fr

Abstract

Our study investigates statistical and temporal properties of prosodic units, which were previously identified within laboratory phonology paradigm, in a corpus of French conversational speech. Prosodic annotation of our corpus implements two-level hierarchical model distinguishing major prosodic units (Intonational Phrases, *IPs*) and minor prosodic units (Accentual Phrases, *AP*). Both temporal data and distribution of the number of APs in an IP evidence the global tendency to produce shorter units in conversation. Moreover, Intonational phrases containing no more than two Accentual phrases cover 80% of the data. We discuss the implication of these results for both phonological studies on the constraints on prosodic phrasing and oral document tagging.

Index Terms: French, prosodic phrasing, conversational speech, temporal organization

1. Introduction

Our study focuses on the issue of prosodic phrasing in conversational speech. Prosodic phrasing refers to the structuring of speech material in terms of boundaries and groupings. These boundaries vary as to their relative strength thus defining a number of levels in prosodic constituency. Recently, prosodic phrasing has been the subject of advanced formal modeling within the framework of prosodic phonology [1-2] though the extensive phonetic and phonological studies dealt with laboratory speech.

In the models of prosodic phrasing proposed for French it is common to distinguish two levels of phrasing above the word (cf. [3]): Intonational phrases (IP) and Accentual phrases (AP, though the label can differ between the authors, cf. rhythmic units of [4], prosodic words of [5] and phonological phrases of [6]). Both units receive in speech a specific phonetic marking. Thus, there is an obligatory F0 rise on the last syllable of the accentual phrase (labeled LH* in autosegmental-metrical model of Jun & Fougeron) accompanied by pre-boundary lengthening [7] and, optionally, by an initial rise (Hi) on the first syllable. On the other hand, the intonational phrase is the domain of a major intonation contour and is characterized by greater degree of pre-boundary lengthening [3, 8]. There is as well semantic-pragmatic and syntactic constraints on Intonational phrase boundaries distributions: for example, several syntactic constructions, such as root clauses, vocatives and parenthetical expressions, form *IPs* of their own; cf. as well Sense unit constraint as defined in [9] and tested in [10] .

In our study we rely on the axiom that prosodic units previously identified within laboratory phonology paradigm could be identified in conversational speech [11]. We consider that such corpus studies are about how the language is spoken and how available prosodic means are exploited by the speakers, prosodic units in conversation being endowed with organizing function. We addressed the issue of interaction between two levels of prosodic hierarchy in conversational speech and we focused on temporal properties of prosodic constituents.

2. Corpus and methodology

Our study is based on an excerpt from the *Corpus of Interactional Data* [12] (http://crdo.up.univaix.fr/corpus.php?langue=fr). We focused on one dialogue between two familiar female speakers who conversed on humorous situations in which they may have found themselves involved. From the interactional point of view, the corpus is not homogenous, combining negotiation sequences, question-answer exchanges and substantial monologues. The total size of the corpus was 12681 words.

The corpus was manually transcribed using an enriched orthography: in order to facilitate further processing of the corpus, our transcription conventions include special notations to signal a number of reduction phenomena (i.e. elisions, word truncations). Next, this transcription was automatically converted to a phonemic transcription of speech material and then automatically aligned to the speech signal. Subsequently, the corpus was enriched with various linguistic annotations (manual or (semi-)automatic) as a means to study interfaces between phonetics, phonology, prosody, morphology, syntax, pragmatics, discourse and gesture as they operate in conversational speech. In the following paragraphs we detail the syntactic and prosodic annotation underlying our study.

2.1. Prosodic annotation

The general prosodic annotation scheme for the corpus includes

- metrical structure in terms of perceived prominences;
- tonal structure: we distinguish the level of underlying tones and the level of surface tones (INTSINT);
- prosodic constituency.

The corpus was manually annotated in terms of IP and AP boundaries. This annotation was guided by perception, based on a distinction between strong and weak prosodic breaks. Acoustic cues to prosodic phrasing, salient in perception, were also taken into account. Thus acoustic and perceptual cues to an IP boundary are: i) an intonation unit is associated with a specific melodic contour; ii) there is a high (H) or a low (L) boundary; iii) there is *pitch reset*; and iv) there is pre-boundary lengthening. Acoustic and perceptual cues to an AP boundary are: i) specific pitch movement (final rise); ii) relative scaling of adjacent APs; iii) slight degree of preboundary lengthening.

Before proceeding with the phonetic and statistical analyses, we ascertained that our annotations were sufficiently reliable (cf. [13, 14] attesting mean kappa Cohen values of 0.79).

3. Results

3.1. Two levels of hierarchy

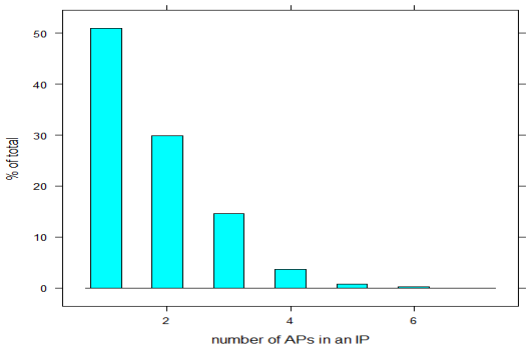

Figure 1: Distribution of the number of Accentual Phrases per Intonational Phrase

First, we looked at the distribution of number of APs in an IP (Fig.1). On average, an IP groups together 1,74 APs. Note that almost half of the identified IP units contain only one AP. In [15] studying radio speech in English, the author communicates that the IPs with no more than two accents cover 80% of the corpus, though almost equal proportions of IPs with one (39%) and two (41%) prosodic prominences was observed in this study. In our data, IPs containing only one AP, i.e. with only one intonational prominence, dominate. We consider such a distribution as quite typical for conversational data: in fact, conversation abounds in short replies and interaction words, speakers need to provide context settings for their interlocutors; as a consequence, quite often, but not always, such units tend to form a prosodic unit on their own and are quite often cumulated at the beginning of a phrase (cf. Fig 2 which illustrate the waveform, the F0 contour and phrasing annotation of the utterance $[(Demain)_{AP}]_{IP}[(c'est)_{AP}(le\ repas)_{AP}(de\ Noël)_{AP}]_{IP}$, 'Tomorrow, there is a Christmas meal': time setting adverbe *demain* 'tomorrow' being set apart in a separate IP (of 0.517s); *we should specify that there is no error in Praat's pitch detection at the end of first IP, the gap being induced by creaky voice*).

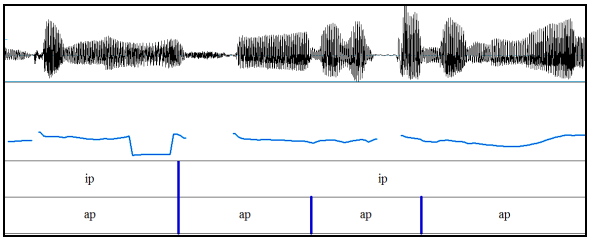

Figure 2: Waveform, F0 contour and phrasing annotation of the utterance $[(Demain)_{AP}]_{IP}[(c'est)_{AP}(le\ repas)_{AP}(de\ Noël)_{AP}]_{IP}$, 'Tomorrow, there is a Christmas meal'

Our data attest that there is a relatively small number of units with more than 3 APs: such a finding has its implications for studies of prosody-syntaxe mapping and theoretical issue of prosodic levels in French. In fact, laboratory studies showed that IPs with more than three APs tend to be restructured and such a restructuring is accompanied by the emergence of an additional level of phrasing, that of Intermediate Phrases (*ips*) (such restructuring applies to specially identified syntactic structures [17,18],; cf. as well the constraint on prosodic phrasing authorising only 2 prosodic prominences per unit). Our data indicate that such a restructuring is probable in only 20% of units, all the syntactic structures put together. We suggest that Intermediate phrase level in French should not be described not within Strict Layer Hypothesis on prosodic phrasing [9], but within a probabilistic framework for which corpus studies are an important source of data: the level of Intermediate Phrases emerges whenever the required conditions are met, as to the distribution of prosodic prominences, focusing and speech rate.

3.2. Temporal organisation of perceived units

Next we looked at temporal organisation of prosodic units in spontaneous speech and analysed the distributions of durations.

3.2.1. Intonational phrases

Mean duration of IPs in our data is of 0.841s. (75% of units are shorter than 1.14s., though they exhibit a rather important variation, coefficient of variation C_v = 0.589). In our previous study based on Russian spontaneous speech [16] we obtain similar results for major prosodic units (mean duration of 0.86s.). Both contrast with the data on reading in which the authors communicate the mean durations of prosodic units as of 1.2-1.6 s. Consequently, mean IP duration seems to be a property, which allows distinguishing conversation and reading and consequently, tagging oral documents from these two styles.

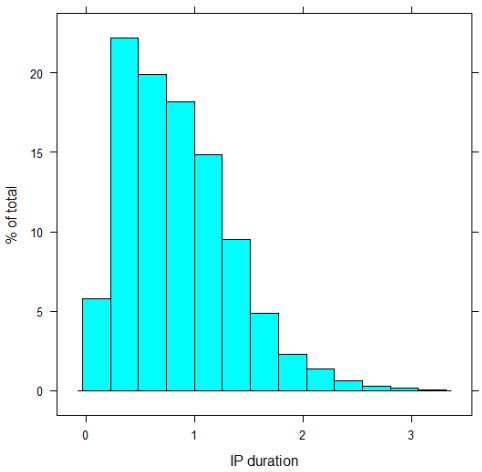

Figure 3: Distribution of Intonational Phrase durations

On the next step, we compared IP length distributions for two speakers separately (Table 1). In our study, one of the speakers tends to produce shorter units than the other, but the mean values are still under the level observed in earlier studies of reading. The differences between the speakers could be related both to speech rate differences (cf. [17] on longer units in fast speech) and to different strategies for prosodic structuring of speech (this hypothesis could be tested by comparing unit lengths in number of syllables).

Table 1. *Description of IP durations distributions for two speakers*

Speaker	AB	CM
Min	0.08	0.084
1st quartile	0.528	0.358
Median	0.845	0.625
Mean	0.905	0.709
3rd quartile	1.208	0.96
Max	3.194	2.844

3.2.2. *AP durations*

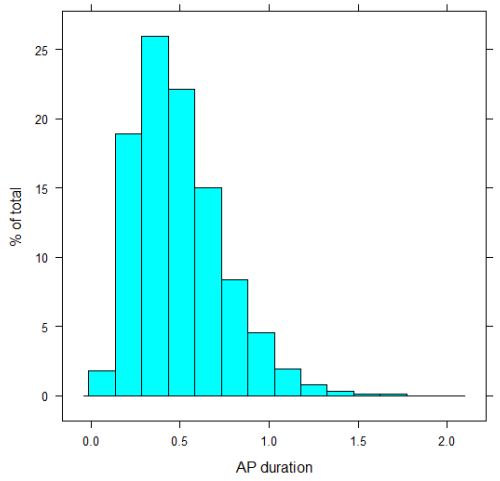

Figure 4: Distribution of Accentual Phrase durations.

The AP lengths in our corpus present the similar distribution as IP lengths with mean AP duration being of 0.496s. (75% of units being shorter than 0.636s. with substantial internal variation, C_v = 0.501).

3.2.3. *Speech-in-interaction effect*

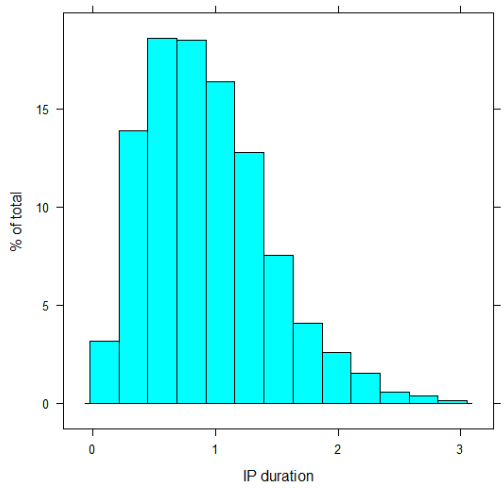

Figure 5: Distribution of Intonational Phrase durations in spontaneous monologues

As described earlier, our corpus contains both task- and strategy negotiation sequences and monologues from one and the other speakers. During these monologues, the participation of the second interlocutor is limited to backchannels and some rare questions and reactions. Thus, to sort out speech-in-interaction effect we limited ourselves to monologue sequences only and looked for IP duration distributions in this sub-corpus. IP number was thus limited by 30%. The mean IP duration for sub-corpus is slightly higher than for the totality of data: mean IP duration is of 0.937 and 75% of IPs are shorter than 1.234s, variation coefficient value (C_v=0.541) indicating great dispersion of values around the mean. This finding goes in the sense of our hypothesis

4. Discussion and Conclusions

Based on a large corpus, our study is about prosody production. Starting with the idea that prosodic constituents previously identified in laboratory speech are relevant for the analysis of conversational prosody, we investigated hierarchical relation between major (Intonational phrases) and minor (Accentual phrases) prosodic units in French. In the analysis of the results we took into account both phonological constraints on prosodic phrasing and details of phonetic (temporal) organisation of these units.

We found that Intonational phrases containing only one Accentual Phrase are dominating in our corpus, quite in agreement with its style. In this aspect, our corpus contrasts with the read speech and news broadcasts [15], though we do not possess directly comparable data in French. Moreover, Intonational units containing no more than two Accentual Units cover 80% of the data. This finding has its implications for the issue of number of levels in prosodic structuring in French: in fact, it means that there are the appropriate conditions for the emergence of an intermediate level of phrasing in only 20% of contexts. We need to further test the hypothesis if there really are any phonetic indices (greater pre-boundary lengthening and/or tonal cues) indicating the presence of an intermediate phrase boundary in these potential locations. We propose that further modeling of prosodic phrasing in spontaneous speech integrates this probabilistic data of the number of phrasing levels.

As to the temporal dimension of prosodic units, we obtained that spontaneous speech is structured in shorter units than read speech (mean IP duration of 0.841s in our study and that of 1.2 -1.6 s. communicated in reading). For the restricted corpus of monologue sequences, mean IP length slightly augments up to 0.937s. Restricted corpus contained less short units which function as backchannels, though there is still a number of context setting phrases promulgated to the level of IPs in conversation. Both the data on IP duration and that on AP duration exhibit a great dispersion around the mean value. At the same time, our data on conversational speech show that mean IP duration could potentially be one of the parameters allowing for tagging apart conversations from other oral documents.

We observed as well speaker's effect on phrase duration, our data attesting the tendency of one of the speaker to produce shorter units than the other. This difference could be imputed to speech rate differences and subsequent tendency to produce larger units (cf. [17] uncovering at least two mechanisms available to the speaker in fast speech rate which have an impact on the number and the strength of prosodic boundaries) or individual strategies in speech structuring. Both hypotheses need further investigation.

Intonational Patterns of Telephone Numbers in Brazilian Portuguese

Oyedeji Musiliyu [1], *Miguel Oliveira Jr.* [2]

[1, 2] Universidade Federal de Alagoas, Alagoas, Brasil

bodeses@yahoo.fr, miguel@fale.ufal.br

Abstract

The main purpose of this paper was to identify intonational patterns of a quite common type of numeric grouping in Brazilian Portuguese: the one associated with telephone numbers. To this aim, 30 samples of spoken telephone numbers, read aloud by 85 native speakers of Brazilian Portuguese were analysed. The description of the intonation contours was observed by using *Momel/Intsint* [1] and *ProsodyPro* [2] scripts for *Praat* (version 5.3.53) [3], through a semi-automatic analysis of pitch variations in numeric groupings that form the telephone numbers. The results show a pattern of intonation and numeric grouping strategy that are sufficient enough to characterize prosodically different types of spoken telephone numbers in Brazilian Portuguese.

Keywords: telephone numbers, intonation, Brazilian Portuguese.

1. Introduction

In the past few years, speech technology advancements have made frequent the use of automatic speech recognition and synthesis systems in multiple applications. Some services based on these automated systems make use of concatenated numeric digits for various purposes, such as: activation of credit cards, banking information, telephone directories, booking inquiries and assistance services for blind and visually impaired individuals, for example.

Services that make use of numerical groupings as input or output data depend on a good voice or textual data processing system of alphanumeric digits information. An efficient system will recognize adequately spontaneous speech and produce a voice or textual output corresponding to adequate enunciation of a given numeric grouping.

In many cases, however, the performance of these systems are considered deficient, either for not processing adequately natural speech (in the case of speech recognition systems), or for not presenting in its production the expected characteristics of naturally produced speech (in the case of speech synthesis systems). This is due in part to the fact that such systems are mostly based on outdated, non-spontaneous speech data.

Progress has been achieved in that respect as a result of the description of enunciation of natural numbers in various languages, such as German [4], Japanese [5] and French ([6] and [7]). To this date, however, no study has yet described, in a systematic and comprehensive manner, the various acoustic features of the organization of natural numbers in predetermined structures in Brazilian Portuguese.

1.1. Aims of the study

The aim of this study is two-fold: firstly, to segment the number sequence into prosodic sub-groupings in order to investigate the grouping and wording strategy applied to telephone numbers of different length in Brazilian Portuguese. Secondly, to conduct a prosodic analysis in order to determine the typical intonation contours of telephone numbers as spoken by native speakers. The results of such study may serve as valuable information in improving automatic speech recognition and synthesis systems in application connected to telephone numbers in Brazilian Portuguese.

2. Experiment

2.1. Speech materials

The corpus of the present study consists of read-aloud samples of a total of 30 telephone numbers, listed in Table 1. The numbers were all selected from a local telephone book. The numbers were chosen randomly to cover (a) the landline and mobile telephone numbers with eight digits, (b) the special service numbers with three digits and (c) the toll free number with eleven digits.

In order to test a possible relationship between the graphic displays of numbers and the spoken strategy applied in their utterance, the landline numbers were presented in three different types of graphic displays: (i) into two groups of four digits (NNNN-NNNN), (ii) into a group of three digits followed by two groups of two digits each (NNN-NN-NN) and (iii) a group of eight digits (NNNNNNNN). Telephone books contain numbers with these three types of grouping, although the type (i) is the most common.

The 30 telephone numbers were presented in a slideshow at regular interval of seven seconds. The numbers were recorded from 85 adult, native speakers of Brazilian Portuguese (48 women and 37 men). Speech materials were recorded using a minidisc (Sony, MZ-R700) through a digital microphone (Sony, ECM-MS907) placed at 15 centimetres of participants' mouth. Before the recording, the participants did a quick rehearsal with six numbers. They were instructed to utter spontaneously the numbers that were displayed in a computer screen, and were informed that there is no correct way of speaking telephone numbers and that they were not being evaluated in that task.

Table 1: *List of telephone numbers use in the analyses of this study.*

Telephone numbers			
3 digits	8 digits		11 digits
120	32224034	2226 31 96	08002812112
104	32514251	3221 47 54	08007010114
147	33274686	3271 00 84	08007011566
190	34238577	3428 09 24	08007070044
193	34412276	3465 30 46	08007704418
	3228 6924	8803 91 48	
	3251 7343	9605 36 81	
	3424 2767	9619 94 53	
	3452 1425	9909 62 94	
	3465 2746	9948 09 93	

2.2. Segmental analysis

The spoken telephone numbers were extracted from the recordings and archived in *.wav* format using *Praat* as

previously shown [3]. Each spoken telephone number was segmented into intonation units and transcribed orthographically into grouping represented by the digit 1 (unary), 2 (binary), 3 (ternary), or 4 (quaternary), and into wording represented by the letter U (units), D (tens), C (hundreds) or M (thousands) as exemplified in Figure 1.

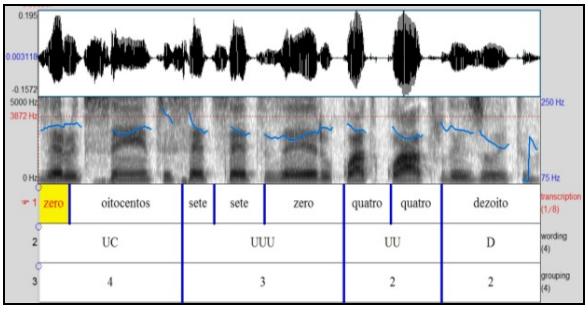

Figure 1: *Praat's textGrid showing the waveform, spectrogram, pitch contour, segmentation and transcription of 08007704418 as spoken by participant woman_2.*

2.3. Intonation contours analysis

Intonation contours of the spoken telephone numbers were extracted through the following method: Firstly, melodic variations of each spoken telephone number were analysed in a semi automatic way with the *Momel/Intsint* script as previously shown [1] in *Praat* (version 5.3.53), using the script' default values (This plugin allows a *Praat* user to convert the pitch contour into a stylized curve, which can be afterwards modified manually according to an auditive evaluation, and finally annotated following the *INTSINT* notation. *INTSINT* is "a transcription system by means of which pitch patterns can be coded using a limited set of abstract tonal symbols, {T,M,B,H,S,L,U,D} (standing for: Top, Mid; Bottom, Higher, Same, Lower, Upstepped, Downstepped respectively)" [8]). Figure 2 shows an example of a telephone number prosodically annotated with the *Momel/Intsint* script.

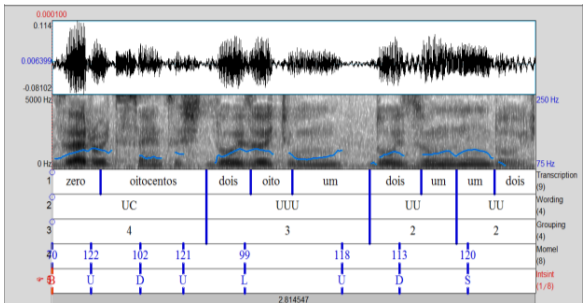

Figure 2: *Praat's textGrid merged showing the waveform, spectrogram, pitch contour, fundamental frequency values, contour variations' coding, transcription and segmentation of 08007704418 as spoken by participant man_69.*

After that, each wording corresponding to a grouping in the spoken telephone numbers was extracted and analyzed with the *Prosodypro* script for *Praat*. In equidistant time intervals, the script was set up to select ten values of fundamental frequency (F0) in the wordings, thereby making it possible to observe adequately intonation contours of wordings of different length through graphic representations. An example is shown in Figure 3.

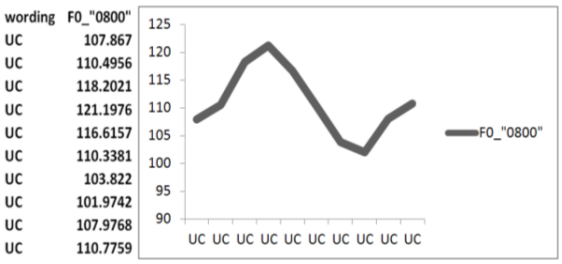

Figure 3: *Graphic representation of intonation contour of "0800" in "08002812112" as spoken by participant man_69.*

3. Results

3.1. Grouping strategy

For eight-digit telephone numbers, the most common grouping strategy is of type "2-2-2-2" in 85% of all cases, which is, four binary groupings.

The grouping strategy with three-digit telephone numbers, in its totality, is of type "3" in 100% of all cases, which is, a ternary grouping.

And with eleven-digit telephone numbers, the grouping strategy is mostly of type "4-3-2-2" in 98% of all cases, which is, a quaternary grouping followed by a ternary and two binary groupings.

The predetermined grouping of the telephone numbers did not seem to influence the grouping strategy adopted by the participants. The grouping strategy of type "2-2-2-2" was preferred in 85% of predetermined grouping of type "NNNN-NNNN", in 80% of predetermined grouping of type "NNNNNNNN" and in 81% of predetermined grouping of type "NNNN-NN-NN".

3.2. Wording strategy

Grouping strategy of type "2-2-2-2" with eight-digit telephone numbers, mostly presented wording of type "$UU_{(1)}$-$UU_{(2)}$-$UU_{(3)}$-$UU_{(4)}$" in 48% of all cases, which is, four binary groupings rendered as units. Other relatively significant wording types are "UU-UU-D-D" in 9%, "D-D-D-D" in 9% and "UU-UU-D-UU" in 9% of all cases.

Grouping strategy of type "4-3-2-2" with eleven-digit numbers, preferentially presented wording of type "UC-UUU-$UU_{(5)}$-$UU_{(6)}$" in 19% of all cases, that is, a quaternary grouping rendered as units and hundreds, followed by a ternary and two binary groupings rendered as units. Other relatively significant wording types are "UC-C-D-D" in 17%, "UC-UUU-D-D" in 16% and "UC-C-D-UU" in 13% of all cases.

Grouping strategy of type "3" with three-digit numbers, mostly presented wording type "C" in 66% of all cases, that is, a ternary grouping rendered as hundreds. Other relatively significant wording type is "UUU" in 34% of all cases.

3.3. Coding of intonation

In spoken telephone numbers with three digits of wording type "C", the most recurrent intonation coding generated by *Intsint/Momel* script in *Praat* is of type "MUD", that is: a Mid

tone, followed by an Upstepped tone and ending with a Downstepped tone.

In telephone numbers with eight digits of wording type "$UU_{(1)}$-$UU_{(2)}$-$UU_{(3)}$-$UU_{(4)}$", the most recurrent intonation coding generated in the first grouping "$UU_{(1)}$" is of type "MUD", that is: a Mid tone, followed by an Upstepped tone and ending with a Downstepped tone. In the second grouping "$UU_{(2)}$", the most generated intonation coding is of type "DU", that is: a Downstepped tone ending with an Upstepped tone. The third grouping "$UU_{(3)}$", mostly, presented the intonation coding of type "UD", that is: an Upstepped tone ending with a Downstepped tone. In the last grouping "$UU_{(4)}$", the most generated intonation coding is of type "UB", that is: an Upstepped tone ending with a Bottom tone..

Lastly, in telephone numbers with eleven digits of wording type "UC-UUU-$UU_{(5)}$-$UU_{(6)}$", the most generated intonation coding in the first grouping "UC" is of type "MUDU", that is: a Mid tone, followed by an Upstepped tone, a Downstepped tone and ending with an Upstepped tone. In the second grouping "UUU" the most generated coding is of type "MD", that is: a Mid tone ending with a Downstepped tone. In the third grouping "$UU_{(5)}$" the most generated coding is of type "UD", that is: an Upstepped tone ending with an Upstepped tone. And in the last grouping "$UU_{(6)}$", the most generated intonation coding is of type "UB", that is: an Upstepped tone ending with a Bottom tone.

3.4. F0 contour

We analyzed variation of the ten selected F0 values at equidistant time intervals in each grouping of spoken telephone number. F0 contours and their patterns were represented.

With eight-digit telephone numbers, Figure 4, 5, 6 e 7 show, respectively, intonation contours of exemplified groupings of type $UU_{(1)}$, $UU_{(2)}$, $UU_{(3)}$ and type $UU_{(4)}$ and their global patterns as spoken by participants.

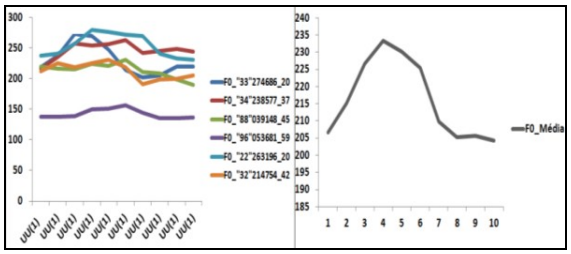

Figure 4: *Intonation contours of exemplified groupings of type $UU_{(1)}$ and their global patterns.*

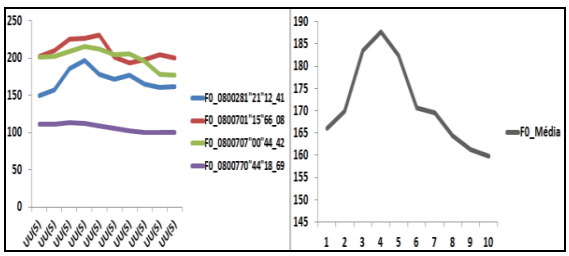

Figure 10: *Intonation contours of exemplified groupings of type $UU_{(5)}$ and their global patterns.*

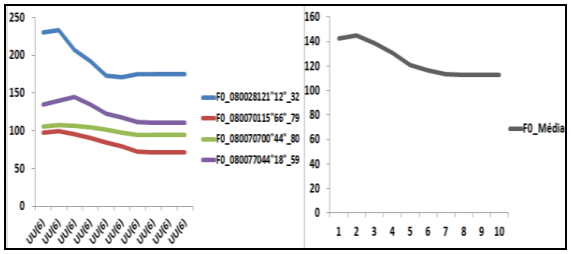

Figure 11: *Intonation contours of exemplified groupings of type $UU_{(6)}$ and their global patterns.*

Figure 12 shows intonation contours of exemplified groupings of type "C" and their global pattern with three-digit telephone numbers as spoken by the participants.

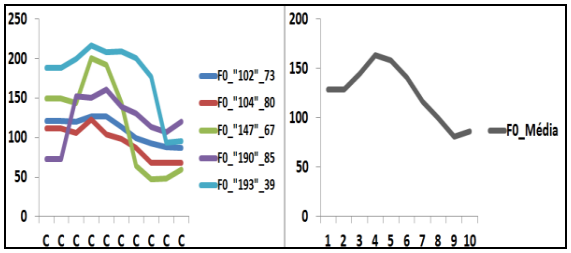

Figure 12: *Intonation contours of exemplified groupings of type "C" and their global pattern.*

3.5. Intonation contour

Results of analyses have shown grouping, wording strategies and intonation contour patterns in spoken telephone numbers in Brazilian Portuguese.

In three-digit telephone numbers, a ternary grouping rendered as hundreds is preferred. As example, the telephone number "190" is spoken as "*cento e noventa*" with the intonation contour shown in Figure 13.

Figure 13: *Intonation contour and corresponding intonation coding of three-digit telephone numbers as spoken by native speakers of Brazilian Portuguese.*

In eight-digit telephone numbers, a four binary groupings strategy rendered as units is preferred. As example, the telephone number "3445 2348" is spoken as "*três quatro*"-"*quatro cinco*"-"*dois três*"-"*quatro oito*" with the intonation contour shown in Figure 14.

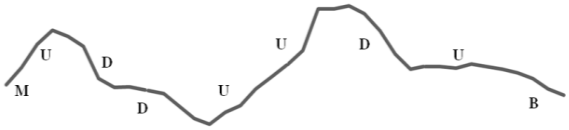

Figure 14: *Intonation contour and corresponding intonation coding of eight-digit telephone numbers as spoken by native speakers of Brazilian Portuguese.*

In eleven-digit telephone numbers, the preferred strategy is a quaternary grouping rendered as units and hundreds, followed by a ternary and two binary groupings rendered as units. As example, the telephone number "08002812112" is spoken as "*zero oitocentos*"- "*dois oito um*"- "*dois um*"- "*um dois*" with the intonation contour shown in Figure 15.

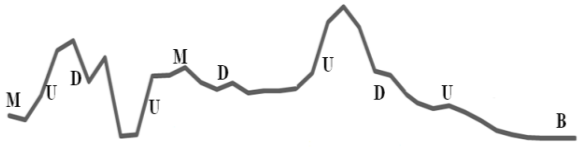

Figure 15: *Intonation contour and corresponding intonation coding of eleven-digit telephone numbers as spoken by native speakers of Brazilian Portuguese.*

4. Conclusion

The main purpose of the present study was to identify intonational patterns of spoken telephone numbers in Brazilian Portuguese. It was demonstrated that intonation alone is enough to characterize prosodically three different types of telephone numbers in Brazilian Portuguese.

A comparison of this study's results with those of [9] shows that the final fall trend reproduce by *Intsint* in Brazilian declarative sentences is also evident in telephone numbers and transcribed by *Intsint*, in this study, with the symbols D (Downstepped tone) and B (Bottom tone) as presented in Figure 13, 14 and 15 respectively. We assume that the intonational patterns of Brazilian Portuguese sentences are used to express the telephone numbers, but the phrasing is adjusted to deliver the sense of grouping.

Other finding of this study is that a similarity in melodic variation exists between telephone numbers in Brazilian Portuguese and those of other languages. The final fall tone of telephone numbers in Brazilian Portuguese is also observed in studies realized on telephone numbers in German [4], Japanese [5] and French [7].

It would of course be interesting to investigate other prosodic features in the characterization of telephone numbers in Brazilian Portuguese, such as intensity and duration. A future investigation involving these features is planned for future analyses. It is also planned to run perceptual tests, based on the intonational patterns identified here in order to find out whether the patterns, applied to synthetic speech, are considered acceptable by Brazilian Portuguese speakers. This research may be regarded as a contribution to the study of spoken numbers in general and to the improvement of automated dialogue systems connected to numbers in particular.

5. Acknowledgements

The completion of this study was made possible with the assistance of *FonUFAL* (Fonetics and Fonology study group of the *Universidade Federal de Alagoas, Brasil*) and the financial support of *CNPq* (*Conselho Nacional de Desenvolvimento Científico e Tecnológico*).

Abstract

Since a long time, it is known that singing helps persons who stutter to produce their utterances more fluently. The prosodic characteristics of spoken and sung utterances differ considerably in their rhythmic and tonal structure. Therefore, it has been proposed that song prosody helps stutterers to improve their rhythmic planning of verbal material [1]. In order to investigate this idea, we examined temporal aspects, namely Voice Onset Time (henceforth, VOT) of voiceless plosives, in sung and spoken utterances of young German stutterers and non-stuttering controls. VOT tends to be reduced in song compared to speech. We expected a more important reduction in the stuttering group as voice onset timing should be facilitated in song compared to speech. Eight stuttering adolescents and eight normal fluent peers read and sang an altered version of "Happy Birthday" with test words containing the three voiceless stops /p/, /t/, /k/. Results showed that stuttering as well as non-stuttering adolescents reduced VOT during singing compared to speech. In contrast, only adolescents who stutter were less variable in their VOT production in song compared to speech. Additional analyses indicated further group differences in vowel duration following the stop consonant. These findings suggest that young stutterers benefit from sung prosody in their timing abilities.

Index Terms: Stuttering, Song and Speech Prosody, Voice Onset Time

1. Introduction

When stutterers sing, their disfluencies can reduce in a substantial way [2, 3, 4]. The reasons for this intriguing phenomenon are still unclear. In the 70ies, Wingate (1969) proposed that stuttering occurs in part because of a rhythmic deficit that can be attenuated by altering prosodic variables of the vocalization [1]. Both parts of this idea, the rhythmic deficit hypothesis [5] and the altered vocalization hypothesis [6] have been pursued in subsequent research. With respect to altered vocalization, it has been found that prolonged phases of phonation are good predictors of fluency in stutterers [7, 8]. In singing, phonation is fostered by prolongation of vocalic and sonorant portions of the speech signal [9]. However, recent research suggests that increased phonation time is not sufficient to explain all fluency-evoking conditions (e.g., paced speech [10]). This raises the question if rhythmic processes could play a more important role. In song, temporal intervals between syllables become more regular and hence, more predictable due to musical beat structure [11]. This could help stutterers by timing segmental material at the right moment during their production [12] and thereby enhance their fluency [1].

In this study, we aim to investigate temporal processes during singing in stuttering children and adolescents. Voice Onset Time is an indicator of fine-grained motor and timing control of laryngeal processes [13]. Stuttering (young) adults tend to show longer and more variable VOTs than non-stuttering adults, even in fluent speech [14, 15]. For children, the situation is less clear. In children of 4 and 9 years on average, no significant differences in VOT were found compared to age-matched peers, but their productions were overall more variable [16, 17].

In this paper, we examine how VOT of voiceless plosives changes in stuttering adolescents during singing compared to speaking, a question that was not addressed so far. An age-group was chosen that was intermediate between the groups tested in previous research (young stuttering children, adults). In general, VOTs are compressed in singing compared to spoken speech [18]. If singing enhances temporal planning and control, stuttering adolescents should benefit from this in their VOT productions. VOTs in spoken speech should be longer and more variable than in age-matched controls. On the other hand, VOTs in singing shouldn't differ from controls as far as timing processes are facilitated by song. Therefore, we hypothesize that VOTs will reduce more in the stuttering group than in controls when comparing spoken vs. sung productions. In addition, several other acoustic parameters such as stop closure, vowel duration and pitch were examined in order to better understand the influence of prosodic differences between sung and spoken utterances in both groups.

2. Method

2.1. Participants

Eight stuttering children aged from 11 to 15 years (M = 12.4, SD = 1.9, 6 males) participated in the study. Their stuttering symptoms ranged from mild to severe on the SSI-3 scale [19]. The participants were tested while attending the therapy course "SAS - Stärker als Stottern" in Starnberg near Munich. The control group consisted of 8 age-matched children (M = 13.0, SD = 2.3, 6 males). The control group was recorded at home or at the Institute of Phonetics and Speech processing, LMU Munich. All participants were native speakers of German and were untrained singers (no choral activity, no singing lessons).

2.2. Procedure

The experiment had two parts. First, participants were asked to read repeatedly a simple text consisting of three sentences which was based on the lyrics of the song "Happy Birthday". Participants were instructed to read the sentences at a

comfortable moderate reading pace. At this time, the participants did not know that the lyrics were derived from the "Happy Birthday" song. In the second part of the experiment, participants sang the text to the melody of "Happy Birthday". Again, they were asked to sing at a moderate tempo that was comfortable to them. The material was presented on handouts and participants had the opportunity to practice their reading and singing with one repetition or stanza before recording. All participants declared to be familiar with the song.

Each participant was recorded separately in a quiet room with the experimenter present who controlled the recording. The participant was seated at a table and had the visual handouts before him / her on the desk. The sung and spoken texts were repeated nine times with different test words per repetition (see Material). Data collection was done with a Beyerdynamic headset (TG H54c) and a H-4N Zoom recorder. The data was recorded at 44100Hz/24bit.

2.3. Material

The three German voiceless stops /p, t, k/ were inserted in bisyllabic nonsense words. Each test word had a trochaic strong-weak accent pattern. The critical stop was in the onset of the first, stressed syllable followed by a long vowel. The test words were /'pi:ta/, /'pa:ta/, /'pu:ta/, /'ti:ta/, /'ta:ta/, /'tu:ta/, /'ki:ta/, /'ka:ta/, /'ku:ta/. These words were inserted in the German version of "Happy Birthday". In the German version, the name of the birthday child is used in every sentence ("Dear X, all the best to you"). The test words were inserted five times in each repetition at the place where the name occurs as demonstrated for /'ki:ta/ in (1).

(1) *Liebe* /'ki:ta/, *viel Glück, liebe* /'ki:ta/, *viel Glück, liebe* /'ki:ta/, *liebe* /'ki:ta/, *liebe* /'ki:ta/, *viel Glück*.

"Dear /'ki:ta/, all the best to you, etc..."

Overall, 15 read / spoken samples were collected for each stop per participant. This resulted in overall 45 × 2 items per participant for analysis.

2.4. Analyses

VOT was measured manually for each plosive by inspecting the oscillogram and spectrogram of the audio signal in Praat [20]. VOT was annotated for each plosive [13]. The time interval was marked between the onset of the stop release and the beginning of vocal fold vibration of the following vowel onset. The second zero crossing of the glottal pulse was consistently used to mark the beginning of voicing. Furthermore, standard deviations of VOT were calculated for each participant in order to assess variability in sung and spoken VOT productions. Some additional measures were taken. First, closure duration was measured from the point where vocal fold vibration of the preceding Schwa-vowel stopped until the onset of the stop release. Second, vowel duration following the stops was extracted from the recordings. The left vowel boundary was determined by marking the beginning of periodic glottal pulses in the oscillogram (second zero crossing). The right boundary was assessed by inspecting the formant patterns and the subsequent spectrum of the consonantal context. Pitch targets were used for the evaluation of vocalic pitch. Maximum pitch per vowel was analyzed using the pitch analysis algorithm in Praat (range: 75-600 Hz) [20]. Furthermore, overall pitch characteristics (median pitch and range) as well as the total duration of each utterance (i.e., one stanza or repetition of the text / song) were assessed. Pauses (e.g., respirations, hesitations, stuttering) were subtracted from the total utterance duration.

3. Results

Test words containing disfluencies or errors of any kind (such as misreading, stuttering) were discarded from analysis. Overall, stuttering symptoms were not very frequent in the test group, and occurred equally often in speech and song (i.e., in 1.6 % of all words in the material). Mean duration and variability for VOT values per stop consonant as well as closure and vowel duration (all vowels confounded) were calculated. Before averaging, outliers were excluded (20 values of closure duration in both groups). These values as well as overall duration and pitch of the utterance and vocalic pitch are displayed for for both groups in Table 1 and Fig. 1.

	Adolescents who stutter		Control group	
Measures	Reading	Singing	Reading	Singing
Utterance				
Mean overall duration (s)	8.25 (1.56)	8.88 (1.63)	7.05 (0.88)	8.94 (0.88)
Median pitch (Hz)	198 (51)	213 (48)	200 (49)	232 (61)
Mean pitch range (st)	11.2 (2.8)	12.2 (3.4)	12.6 (5.9)	13.0 (2.9)
Stop and subsequent vowel				
Mean closure duration (s)	0.093 (0.016)	0.076 (0.011)	0.080 (0.013)	0.067 (0.013)
Mean vowel duration (s)	0.099 (0.033)	0.174 (0.042)	0.115 (0.022)	0.224 (0.039)
Maximum vocalic pitch (Hz)	222 (55)	241 (61)	216 (52)	255 (85)

Table 1. *Overall mean values of prosodic utterance, stop and vowel measures (in seconds (s), Hertz (Hz) and semitones (st)) of the sung and read performance in both groups of participants. Standard deviations are displayed in brackets.*

As can be seen in Fig. 1, sung stops displayed smaller VOT values than read stops in both groups. The VOT data were entered in a three-way mixed-design Analysis of Variance (ANOVA) with the within-subject factors Stop (/p/, /t/, /k/) and Vocalization (reading vs. singing) and the between-subject factor Group (test vs. control). Results showed main effects for Vocalization (F (1, 14) = 62.13, $p < .001$) and Stop ($F(2, 28) = 34.55$, $p < .001$). No interactions or group differences were found. Additional pairwise comparisons confirmed that VOT differed significantly in all three stop classes (with /k/ > /t/ > /p/). This is in line with previous research reporting differences between stop categories [13].

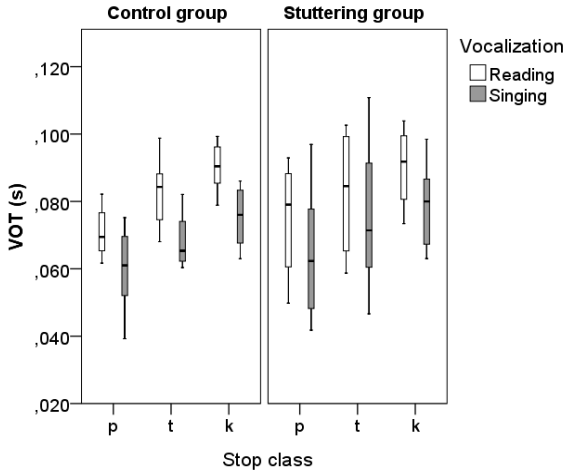

Figure 1. *Boxplots of VOT values of three German voiceless stops in sung and read speech displayed for adolescents who stutter and for the control group.*

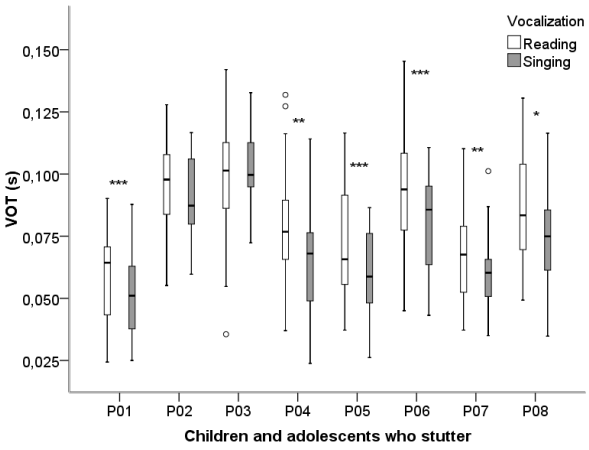

Figure 3. *Individual VOT reduction patterns in read and sung speech in participants who stutter. Stars indicate significance levels (*** $p < .001$, ** $p < .01$, * $p < .05$).*

Another ANOVA with the same factors reported above was performed for VOT variability (the standard deviation of the mean per participant, see 2.4). Main effects were found for Vocalization (F (1, 14) = 19.46, $p < .005$) and Group (F (1, 14) = 6.68, $p < .05$) as well as a significant interaction between both factors (F (1, 14) = 10.77, $p < .01$). The interaction is displayed in Fig. 2. Two-sided t-tests (Bonferroni-corrected) confirmed that adolescents who stutter significantly reduced VOT variability from speech to song (t (7) = 6.12, $p < .001$). This was not the case for the control group.

In order to examine individual VOT patterns, especially in the test group (see Fig. 3), statistical analyses were performed on VOTs for each participant separately (two-sided paired-samples t-tests on VOTs in sung vs. read speech averaged over all three stop classes).

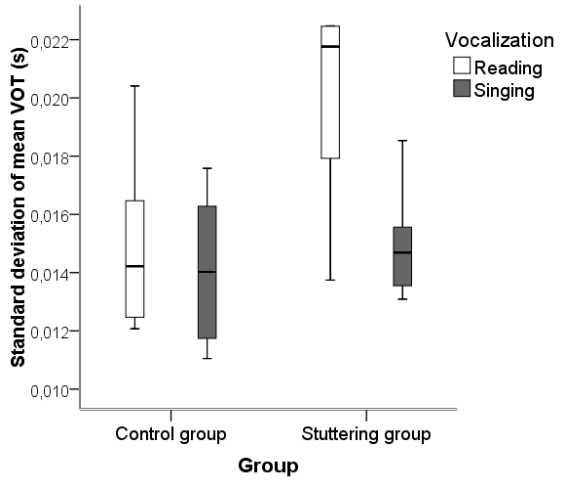

Figure 2. *Variability of VOT in sung and read speech displayed for adolescents who stutter and for the control group.*

Results revealed that VOT reduction was significant only in six out of eight stuttering children. In the control group, all children showed a significant reduction of VOT from speech to song (with at least $p < .01$). In order to examine further temporal differences between speech and song and their realizations by the test and control group, additional statistical analyses were performed on stop closure, vowel and utterance duration and their variability (see Table 1). The same ANOVA design as for the VOT analyses was used except that for vowel and utterance duration, no third factor (Stop) was needed.

For closure duration, a similar reduction pattern from speech to song was found as for VOT (F (1, 14) = 32.58, $p < .001$). A main effect was also found for Stop class (F (2, 28) = 47.72, $p < .001$). Groups did not differ, there was only a marginal trend for the test group showing longer closure than the control group ($p = .098$). Closure variability was also reduced from speech to song (F (1, 14) = 7.63, $p < .05$) with again a marginal trend for the test group to be more variable than controls ($p = .088$). In contrast to VOT and closure duration, vowels were lengthened in song vs. speech (F (1, 14) = 87.15, $p < .001$). Adolescents who stutter displayed overall shorter vowel duration than the control group (F (1, 14) = 4.89, $p < .05$). Moreover, vowel variability was greater in song than in speech in both groups (F (1, 14) = 6.31, $p < .05$). Finally, total utterance duration was longer in song than in speech (F (1, 14) = 14.86, $p < .005$) and less variable in song than in speech (F (1, 14) = 7.66, $p < .05$). Adolescents who stutter merely showed a trend to have longer ($p = .075$) and more variable utterance duration ($p = .063$).

As we did not control for tempo during the recordings between speech and song, we evaluated to what extent VOT or closure duration and reduction and vowel duration and lengthening was related to utterance duration differences. First, we correlated utterance duration with mean VOT and closure duration as well as mean vowel duration per utterance for sung and spoken speech separately. VOT as well as vowel duration, but not closure duration, were positively correlated with utterance duration in both speech (VOT: r (142) = 0.23, $p < .01$; vowel: r (142) = 0.29, $p < .001$) and song (VOT: r (142) = 0.25, $p < .01$; vowel: r (142) = 0.38, $p <$

.001). In other words, longer utterance duration was related to longer VOT and longer vowel duration in both reading and singing.

Second, we assessed if differences in utterance duration were likely to influence VOT reduction. As children and adolescents who stutter tended to show longer utterance duration, but still similar VOT values as the control group, it might be the case that we underestimated group differences without a temporal normalization. In order to answer this question, we calculated difference scores between speech and song by subtracting utterance duration in speech from utterance duration in song for each trial. The same calculation was performed for VOT reduction which was estimated by subtracting sung mean VOTs per trial from read VOTs. A linear regression with the predictor variable utterance difference and the dependent variable VOT reduction was performed. No significant relation was found between utterance duration differences and VOT reduction. Hence, we conclude that the results from the VOT reduction data are independent of utterance duration differences.

4. Discussion

In the present study, we investigated the impact of sung prosody on temporal aspects of young stutterers' verbal productions. In a control group, the VOT of voiceless German plosives was found to reduce significantly in sung speech compared to read speech. This result extends prior research as we show the same result for children and adolescents as done for adult populations [18]. VOT reduction was also found in a group of eight stuttering children and adolescents. Importantly, VOT variability (defined as the standard deviation of the mean) was a good indicator of group differences. VOT variability was significantly reduced during singing compared to reading in adolescents who stutter whereas the control group did not show differences in both tasks.

These findings suggest that singing influenced timing aspects in the present group of young stutterers. First, we demonstrated that VOT reduction occurs as well in stuttering adolescents as in age-matched peers, but against our initial hypothesis, this reduction was not more important in the test group. VOT values were comparable to age-matched peers in sung and, in particular, in spoken productions. This is in line with previous research on VOT in the speech of stuttering children (mean age < 10) [16, 17], but differs from results on adults that showed longer VOT in spoken speech [14, 15]. It is likely that VOT differences only arise consistently at an adult age. Children and adolescents follow individual patterns of development and are in general more variable in their timing capacities [21]. For instance, individual differences were found in our group of adolescents who stutter. Two participants did not show a VOT reduction. Future studies should investigate if the degree of VOT reduction is a predictor of other variables as for example stuttering severity or the efficiency of altered vocalization in reducing disfluencies.

Although VOT duration per se did not allow to distinguish between test group and controls, VOT variability did. Adolescents who stutter were significantly less variable in their VOTs during singing than during reading. It has been shown in previous studies [16], that persons who stutter have more variable VOT in speech production compared to controls. Similar results have been found for perception as well [22]. Our finding shows for the first time that singing has the potential to reduce VOT variability in the productions of adolescents who stutter. This lends support to the hypothesis that singing helps stutterers to improve their timing abilities. Consequently, as suggested by Wingate [1], disfluencies would reduce because rhythmical planning is facilitated. In our sample, disfluencies were rarely occurring in either spoken or sung speech, probably due to the simple and repetitive nature of the German text of "Happy Birthday". A more difficult text/song could be used in future studies in order to observe fluency enhancement during singing in relation to VOT variability reduction.

Further variables were examined in order to better understand the temporal differences between speech and song in our participants. It is well-known that vowel lengthening is very prominent in singing [9] and this tendency was also confirmed by our data. In contrast, previous research on VOT [18] suggests that consonantal parts of the segmental stream undergo a durational compression in song unless consonantal lengthening is part of the phonological system of a language [23]. Our data confirmed compression for plosives by showing the same temporal reduction of closure duration in song vs. speech as found in VOT. While no group differences appeared for closure duration, vowel duration was shorter in participants who stutter. This was unexpected as stutterers tended to show longer utterances which should have led to longer vowel duration. Previous studies have found shorter vowel duration in stutterers' speech [24]. The shorter vowels in our spoken and sung material are probably reflections of this segmental characteristic of stuttering.

In sum, our findings show that singing positively impacts on timing abilities in adolescents who stutter. Future research should address the question to what extent rhythmic characteristics interact with tonal aspects in singing to reduce disfluencies. In a previous study, Glover et al. (1996) discussed the possibility that fluency-enhancement in singing could also arise due to a better representation of global melodic structures, normally not present in speech [6]. For instance, in the domain of neurological rehabilitation, Melodic Intonation Therapy [25] combines both melodic and rhythmic alterations of verbal productions in order to enhance fluency in aphasic patients. In fact, both, rhythm and melody have been shown to impact on production in this task [26, 27]. Future research using neuro-imaging and electrophysiological methods could further unravel the role of melody and rhythm for fluent sung and spoken productions in persons who stutter [e.g., 10, 28].

5. Acknowledgements

The research leading to these results has received funding from a SSHRC-MCRI AIRS (www.airsplace.ca) research grant as well as from the European Union Seventh Framework Program [FP7/2007-2013; FP7-PEOPLE-2012-IEF] under grant agreement n° 327586 to Simone Falk. We thank Thilo Müller and the team of the SAS course for their help with recording the stuttering participants as well as Jonathan Harrington, Phil Hoole, Ulrich Reubold and Florian Schiel of the IPS Munich, Simone Dalla Bella, Euromov, Montpellier, and two anonymous reviewers for their advice and helpful comments.

Some aspects on individual speaking style features in Hood German

Stefanie Jannedy [1], *Melanie Weirich*[2]

Abstract

Multiethnic urban German (Hood German) as spoken by adolescents in Berlin differs in several significant ways from more standard varieties of Berlin German. It is characterized by a variety of morpho-syntactic alternations and phonetic variants uncommon to the regional standard spoken in Berlin. Previous quantitative corpus analyses have shown that overall speakers of the multiethnic youth style German have a strong tendency to centralize /ɔɪ/ compared to speakers rendering the local regional standard.

This paper now summarizes this centralization tendency and investigates auditory salient realizations of variation by individuals which show tendencies towards a hiatus in the diphthong /ɔɪ/, breaking the nucleus and the off glide. Moreover, there are other prosodic and segmental co-occurring features in the speech of some adolescents which are displayed since it is suspected that some of these may be(come) markers of Hood German.

Index Terms: speaker specificity, diphthong, Hood German

1. Introduction

Hood German [1], a youth style multiethnolect as spoken in larger urban areas of Germany is characterized by several morpho-syntactic alternations such as the 'overuse' of the discourse particle *so* 'like' marking unspecificity ([2]), the use of bare NPs (Hast Du problem? 'Do you have (a) problem?'), lack of prepositions (*Ich gehe Schule*. 'I go (to) school'), the lack of copula verbs (*München weit weg*. 'Munich (is) far away') or the lack of congruency (*mein Schwester hat …* 'my-NOM sister has…') ([3]). There are several qualitative accounts of such alternations from a range of different places in Germany, such as Berlin ([4], [5]; [6]; [7]), Böblingen, Munich, Nürnberg, and Urbach near Stuttgart, ([8], cited in [3]), Frankfurt ([9]), Hamburg ([3]; [10]); and Mannheim ([11]).

Just recently, we have conducted quantitative corpus studies on this youth variety. Data was collected through interviews with adolescents from the Berlin districts Wedding, Kreuzberg and Neukölln. All interviews were orthographically transcribed and then added to the ZAS spontaneous speech corpus on Hood German which is based on the Labb-CAT system [12] . Moreover, data was also collected from Berliners speaking the local standard variety of Berlin German. With the help of this corpus the phonetic realization of /ç/ as [ʃ] or [ɕ] was documented to be a feature of the youth style multiethnic urban variety spoken in Berlin, i.e. Hood German ([13]). This feature was also found to be a stigmatized and highly salient marker of *Hood German* for monoethnic Berliners ([1]). In our perception study ([1]) listeners were asked to categorize identical stimuli (comprising resynthesized fricatives ranging from more /ç/-like tokens to more /ʃ/-like tokens) as either *Fichte* /fɪçtə/ ('spruce') or *fischte* /fɪʃtə/ (1st person sg. 'to fish') depending on the presence of a prime (names of two different neighborhoods of Berlin or no additional information). Results revealed that older listeners categorized more stimuli as *fischte* when they were primed with the name of a multiethnic neighborhood (Kreuzberg) than when primed with the name of a monoethnic neighborhood (Zehlendorf) or no prime at all. Interestingly, younger listeners rated most stimuli as *fischte* in the control condition with no added information. From that, we suggested a potential sound change in progress in terms of the loss of the phoneme contrast between /ç/ and /ʃ/ in Hood German.

Labov's Martha's Vineyard study ([14]; [15]) illustrated that the centralization of the diphthongs /aɪ/ as in 'right' and 'light' and /aʊ/ as in 'cow' and 'loud' serves as a linguistic marker of social and geographical identity. He describes this alternation as regional in character and as a feature of the speech of the people of Martha's Vineyard. He found that this linguistic marker spread from the community of fishermen to the general population of the island and was used by the islanders as a social marker to set themselves off from the economically more powerful tourists and visitors coming to the island for summer vacations.

In addition to the variable realizations of /ç/ as [ʃ] or [ɕ], we also noticed auditory striking diphthong realizations in the spontaneous speech of the Hood German speakers in our ZAS Corpus. Standard German has three diphthongs /aɪ/, /aʊ/ and /ɔɪ/ of which two seem to be realized differently in Hood German. Thus, we have now started to investigate the diphthong realizations of Hood German speakers. In a recent study we have analyzed the F2 patterns in the diphthongs /ɔɪ/ and /aɪ/ to detect potential measurable differences in the spectral patterns ([7]).

1.1. Diphthong Characteristics

In our ongoing analysis, so far, we have investigated F2 patterns from 18 female mono- and multiethnic speakers. From self-identification and the use of other Hood German features speakers in our corpus were categorized in Berlin German speakers and Hood German speakers (note that also monoethnic monolingual German speakers can use Hood German). Approximately 2750 tokens of /ɔɪ/ and /aɪ/ realizations extracted from our spontaneous speech data base have been labeled and analyzed. Formant measurements were taken at 5 equi-distant points throughout the diphthong. The onset and offset of each diphthong was marked off in Praat ([16]). A third value was logged in the middle of the vowel and two more points were logged in between the onset and the middle of the diphthong, as well as between the middle and the offset of the glide. Thus, as the green lines in Figure 1 show, measurements were taken at 0% (start), 25% (early), 50% (mid), 75% (late) and 100% (end) throughout the diphthong.

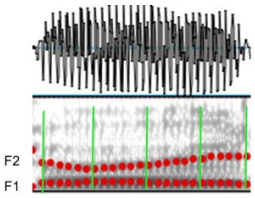

Figure 1: *Formant measurement points during the diphthong /ɔɪ/.*

Results revealed significantly higher F2 values for the Hood German speakers than for the Berlin German speakers at the positions start, early and mid of the diphthong. No such differences were found for /aɪ/ (cf. Figure 2). The centralization of /ɔɪ/ (in terms of a higher F2 in the nucleus of the diphthong) was independent of the speakers' other strong language (Turkish, Arabic, none) and thus, we suggest that it is a phonetic feature of Hood German which serves to express group membership in the multiethnic youth community. Descriptions of the regional Berlin standard ([17]) do not mention such a difference.

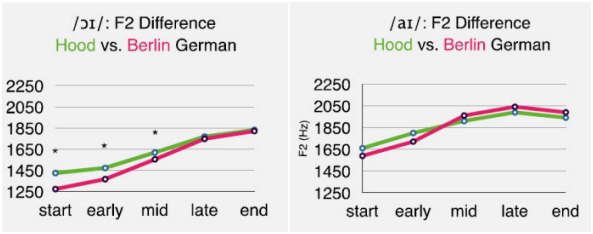

Figure 2: *Average formant patterns during the diphthongs of Hood German (green) and Berlin German (red) speakers.*

In addition, we have been trying to track some linguistic influences on the centralization of /ɔɪ/ in Hood German. Currently, we are investigating the impact of the preceeding and following segmental environment. Preliminary results are in line with the findings obtained by Labov for Martha's Vineyard: obstruents and voicelessness favor centralization ([18]).

For our analysis of the interaction of sentence accent and stress on centralization we were not able to conduct a reliable statistical analysis because only very few words exist that contain the /ɔɪ/ diphthong in a lexically unstressed syllable.

However, in our investigation of the diphthong characteristics of /ɔɪ/, we have been noticing that some speakers of Hood German produce a very different variant of this /ɔɪ/ diphthong. While it sounds centralized to trained ears, there is something else - possibly a hiatic tendency - setting some tokens produced by some speakers off from their other tokens, and from tokens produced by speakers that do not show this variant. A hiatus changes the prosodic structure of the word, adding another syllable nucleus by breaking up a diphthong into its two individual components.

To investigate this more deeply and in a more controlled way, additional recordings were made at a school in Kreuzberg with students, most of them having a multiethnic background and showing features of Hood German. While we also find it desirable to quantify our data and correlate the occurrence of hiatus with social variables, the aim of this first study is not to quantify and parameterize the general spectral and temporal patterns of the diphthong realization in Hood German, but rather to spot auditory salient variants of these diphthongs (and possibly other sounds contained in the speech material) shown by some individual speakers. Of course, individual differences might be due to speaker specific characteristics independent of the speech style within this community. However, we know that individual speakers can act as leaders in their speech community and the once individual features may spread (especially when these features are found in more than one speaker and in several tokens).

2. Method

A set of 33 adolescents from a school in Kreuzberg (Grade 8 and 9; age 13 through 16; 14 male, 19 female) participated in this experiment. Kreuzberg is one of the multiethnic neighborhoods of Berlin where Hood German is spoken by many adolescents. In contrast to our corpus study we used read speech. In this way, the recorded speech data is more controlled. Furthermore, it is well established that there is a register difference between spontaneous and read speech with the latter being more formal and pronounced ([19]). For this reason, we elicited read items containing the diphthong /ɔɪ/, hoping to get more exaggerated versions of the auditory salient, potentially hiatic alternations.

2.1. Speech material

Speakers were asked to read a list of words in the order given on a piece of paper and then repeat the list with the order of words reversed (from bottom to top). Included within this list were five words containing the diphthong /ɔɪ/. In this way 330 tokens of /ɔɪ/ realizations (33 speakers * 5 words * 2 repetitions) were recorded. The word list contained the following tokens:

1. Deutschland (Germany) /dɔɪt͡ʃland/
2. Euro (Euro) /ɔɪʁo/
3. heute (today) /hɔɪtə/
4. Kräuter (herbs) /kʁɔɪtɐ/
5. Kreuzberg (district of Berlin) /kʁɔɪt͡sbɛːɐ̯g/

The selection of words was done so that there is high familiarity for the readers in their daily language use. The words were also selected to allow for comparison with renditions of these lemmas in our spontaneous speech corpus. We deliberately elicited word lists rather than carrier phrases which may have seemed like a larger reading task to the students.

2.2. Analyses

First, both authors conducted an auditory analysis independently of each other. This was done to spot salient realizations of individual tokens. Second, representative items of these perceptually salient tokens were then investigated in more detail in spectral and temporal terms to look for quantifiable acoustic features that characterize these tokens.

3. Results

At this point, we are in the process of describing this youth style variety. We are taking inventory of the differences between Hood German (HG) and the regional standard German (RSG) as spoken in Berlin and we will not provide quantitative analyses of the items containing diphthongs that sound

different to trained ears. At a later point we plan to establish which features are due to individual variation and speaking styles and which may have a wider distribution within the speech community. This will be done by quantifying our observations through corpus studies on data drawn from our spontaneous speech database of Hood German and standard regional Berlin German.

Here, we will concentrate on several speakers which were rated as showing diphthong realizations particularly interesting to the authors. In addition, these speakers also revealed other audibly very salient prosodic features such as tensing of the final unstressed schwa vowel in the orthographic sequence <-er> but also fronting of coronal stops, final stop deletion or dark /ɬ/ coloring as expressions of their individual speaking styles. It is noteworthy, that not every speaker reveals all features but that speakers use this repertoire of features to draw from.

3.1. Diphthong realizations

3.1.1. Speakers HGm1 and HGm2

The four renditions of the /ɔɪ/ diphthong in the word *heute* 'today' shown in Figure 3 were produced by two 16 year old male Hood German speakers HGm1 (upper panel) and HGm2 (lower panel).

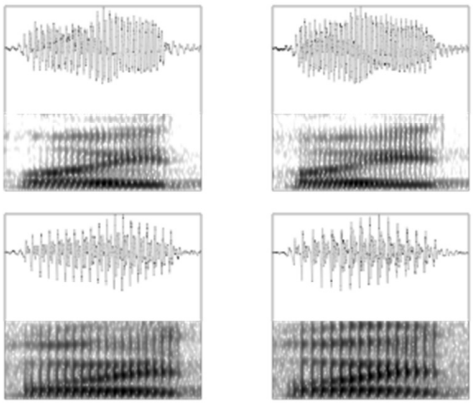

Figure 3: *Spectrograms of the diphthong /ɔɪ/ in the word heute 'today' by two 16 year old male speakers HGm1 (upper panel) and HGm2 (lower panel).*

The boys have very similar multiethnic backgrounds, yet, their /ɔɪ/ diphthong sounds rather different. The speaker whose speech is depicted on the top panel sounds to the authors, as if there are differences in timing compared to the regional standard variety spoken in Berlin.

The bottom panel shows a spectrogram by a speaker where we did not get these auditory impressions and who we believe adheres to the regional standard with regard to this feature.

There seem to be two spectrally observable differences between these productions of /ɔɪ/ for these two speakers: 1. Speaker HGm1 (top panel) produces a much greater discontinuity between the nucleus and the offglide compared to HGm2. There is spectral evidence for this in the waveform and in the spectrogram accompanied by an amplitude change visible in the waveform. Moreover, for HGm2, the F2 rises more steadily and gradual whereas for the first speaker, the F2 remains somewhat low for about one third of the diphthong and then rises.

Secondly, speaker HGm1 reaches the maximum F2 earlier within the diphthong than speaker HGm2. For most tokens of these speakers that we have in our data, these qualitative observations seem to hold.

3.1.2. Speakers HGf1 and HGf2

The diphthongs in Figure 4 were also excised from the word *heute* as produced by two 14 year old female Hood German speakers (HGf). Both renditions produced by speaker HGf1 (upper panel) resemble each other acoustically and leave the auditory impression of almost two syllables being produced rather than a monosyllabic diphthong. This is very similar to HGm1 (upper panel Fig. 3) who also showed hiatic tendencies. Just as the diphthongs by speaker HGm1 , the renditions on the top left of Fig. 4 also reveal some discontinuities. In addition, both tokens by HGf1 reach a high F2 at an early stage throughout the diphthong.

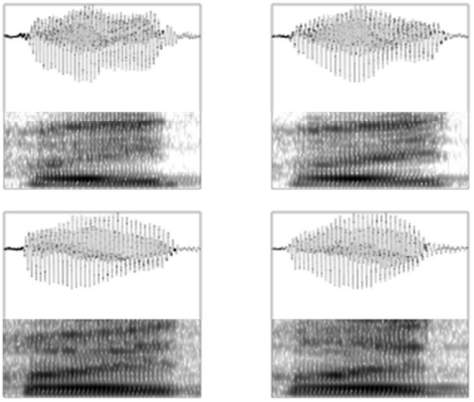

Figure 4: *Spectrograms of the diphthong /ɔɪ/ in the word heute 'today' by two 14 year old female speakers HGf1 (upper panel) and HGf2 (lower panel).*

Note that for HGf1, the energy distribution in the diphthong is different compared to that of the boys (Fig. 3). There is more energy in the initial nucleus part compared to the offglide. It is also evident through the initially raised F2 that the diphthong is strongly centralized compared to the regional standard variety ([7], [18]). Here, too, the discontinuity in the amplitude of the waveform can be observed; however, F2 seems to rise more continuously in the right panel compared to the left.

The spectrograms on the bottom of Fig. 4 show renditions of the diphthong /ɔɪ/ by HGf2 who seems to have a more equal distribution of energy throughout the diphthong. While her first iteration sounds rather hiatic, the second one sounds like regional standard German. A possible explanation is that the F2 maximum is reached somewhat earlier in the diphthong in rendition on the left which then leads to a noticeable difference in the realization of the diphthongs, best described as semi-hiatic.

3.2. Other features

There are several other features in the speech of these adolescents that are worth exploring further to establish an inven-

tory of differences between regional standard German and Hood German.

3.2.1. Tensing of final <-er>

While some features are rather segmental in nature, pertaining to the quality of the segment, one prosodic difference that we found to be rather salient was the tensing and change of quality and duration of the word final unstressed syllable as orthographically represented by <-ter> in words such as *Kräuter* (herbs) /kʁɔɪtɐ/ [kʁɔɪta]. The displays in Fig. 6 show examples of this observation by the two 14 year old female Hood German speakers HGf1 and HGf2.

HGf1 on the left emphasizes the final syllable which is untypical for regional standard German. The exact nature of this emphasis is neither well described nor well understood yet. However, perceptually, it is rather salient. It resembles what is expressed in US-American English as ´gansta´ for *ganster* and may as well originate from musical rap culture or possibly from Turkish language influence. HGf2 on the right uses the regional standard pronunciation.

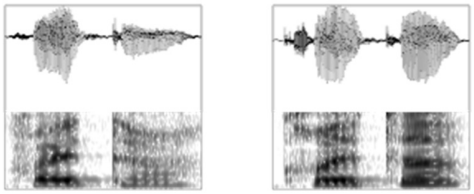

Figure 5: *Spectrograms of the word Kräuter (herbs) by the female speakers HGf1 (left) and HGf2 (right).*

Also notable here is that HGf2 on the right has a much stronger onset of the /kʁ/ sequence which we also perceive as rather typical for Hood German and which we observed with other speakers, too. The perceived quality of the uvular/velar German /ʁ/ strongly resembles that of a velar fricative /x/.

3.2.2. Dental release of /t/

The frontal release of word medial /t/ in *heute* 'today', we also observe to be perceptually very salient. This may be spectrally evidenced, too, by a higher mean burst frequency ([20]) that is indicative of a more frontal release.

Figure 6 shows two renditions of the final syllable /tə/ of *heute* by the 14 year old female speaker HGf1. The one on the left is realized more alveolar while the one on the right is produced more dental.

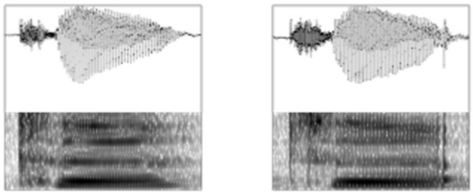

Figure 6: *Spectrograms of the final syllable /tə/ in the word heute 'today' by the 14 year old female speaker of Hood German HGf1.*

This is not only audible but also reflected in the different energy distribution of the /t/ burst. Notable also is the glottal stop at the end of the final unstressed schwa in the second panel. This, however, seems to be an idiosyncrasy of the speaker more so than a general pattern observable across different speakers.

3.2.3. Coloring of /l/

The regional standard variety of German spoken in Berlin does not usually have a dark /ɬ/ quality. However, several adolescent speakers realize the /l/ as [ɬ] in our word lists, in the onset of a syllable before a back vowel. The auditory dark lateral is produced with a more retracted tongue position and therefore spectrally reflected by a lowered F2 value and a higher F1 formant configuration.

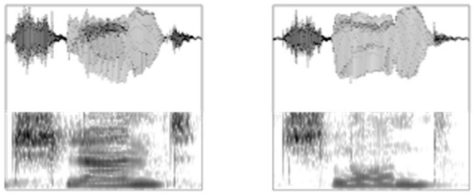

Figure 7: *Spectrograms of the sequence /t͡ʃland/ excised from the word Deutschland (country) by the female speakers RSGf1 (left) and HGf2 (right).*

The velarization of /ɬ/ is visible in the right spectrogram, compared to that seen in the left display of Fig. 7 with a light /l/ which has a relatively high F2 and low F1 ([21]). The spectrogram on the left is based on the speech of a regional standard speaker (RSGf1) who does not have this /l/ coloring. While this feature may originate from speakers with a Turkish cultural and ethnic heritage born in Germany, it is also being used by monolingual monoethnic Hood German speakers.

4. Discussion

In Hood German, we noticed prosodic and segmental deviations from the regional standard of Berlin German. They include the timing patterns of the diphthong /ɔɪ/ and the tensing and lengthening of phonologically unstressed final orthographic <-er> which in German goes along with changes in duration. We also observed the dental release of /t/ and the realization of a dark /ɬ/ in Hood German in syllable onset position before low back vowels. While none of our speakers displayed all features, some speakers show several idiosyncrasies at the same time. Thus, it seems that adolescent speakers of Hood German chose from an inventory of markers and features to create their own individual speaking style within this urban variety of German.

If however, these are reliable features of Hood German or markers of individual speaking styles remains to be seen as we are now at a stage taking inventory of the phonetic/phonological alternations evident in this youth style multiethnolect. We will take our results from the reading task (word lists as a more formal register) and compare it to iterations found in our spontaneous speech data base.

Nevertheless, the differences in realizations of the diphthong ranging from a hiatus like /ɔ.ɪ/ to the diphthong /ɔɪ/ (which is canonical in the regional standard) are variable within speakers and also across speakers. At this point, we are still investigating the acoustic properties that can best account for this observation and which may as well be individual expressions of speaking style.

We suspect that this is a new feature of Hood German as spoken in Berlin which will eventually spread through the community as already now, it is one of the most prevalent markers of the as of yet under described phonetic/phonological features.

5. Acknowledgements

This work was supported by the Federal German Ministry for Education and Research under Grant No. 01UG1411. Much gratitude is due to our research assistants Iona Gessinger, Luisa Helmeke und Sophie Arndt.

Automatic extraction of the general tendency of F0 patterns Cross linguistic study on laboratory data

Katarina Bartkova, Mathilde Dargnat

University of Lorraine, ATILF, France
katarina.bartkova@atilf.fr, mathilde.dargnat@atilf.fr

Abstract

The goal of our study is to use an automatic approach to extract the general prosodic tendencies of the speech signal conveyed by the F0 pattern. The speech signal is prosodically annotated by an automatic prosodic transcriber and then prosodic patterns are extracted from this annotation. The pertinence of the pattern extraction is tested here on laboratory data containing isolated sentences in French and English uttered by native and non-native speakers. An analysis of the extracted parameters shows how the prosody of the sentences is defined by their shared syntactic structures and also indicates to what extent the prosodic features used by the two languages are similar or different. It appears from the analyzed data that the extraction of parameters via automatic processing can yield relevant information for a cross-linguistic study of prosody.

Index Terms: prosodic annotation, automatic pattern extraction, native & non-native prosody

1. Introduction

The use of an automatic approach for prosodic annotation of speech is useful, especially as agreement on manually annotated prosodic events (boundary levels, disfluences and hesitation, perceptual prominences) between expert annotators is quite low [15]. When manual coding of pitch level is carried out, there is the risk that human annotators can be influenced by the meaning of the speech. Moreover a human transcriber may be also influenced by what he considers to be the norm, thereby standardizing the transcription of prosodic phenomena and ignoring the reality of the speech signal.

A further advantage of automatic processing is that, once the values of the parameters are normalized, they are then compared to the same threshold value. This is difficult to achieve with manual annotation because of the inherent subjectivity of this approach.

The goal of the present study is to extract relevant prosodic tendencies of the F0 pattern. This approach is then tested in a cross-linguistic study of speech prosody in French and English.

2. French & English prosody

Many studies have described the specificities of French and English prosody. According to these studies, French uses a combination of segmental and tonal cues to signal prosodic phrases, and differs in this respect from a language like English, which relies almost exclusively on tonal boundaries [7] [14]. In French, lexical stress is mostly quantitative [8], and the final syllable is the one which undergoes a potential lengthening. However, lengthening of the last syllable of the word corresponds also in French to final (pre-boundary) lengthening, which concerns rhythm, and is not an accentual lengthening as in English [6

French is generally considered as a language with mostly 'rising' F0 patterns [12] accompanied by a lengthening of final syllables [20]. French prosodic phrasing was described by Delattre's functionalist approach [9] Though extended by more recent studies [11], [13], [10]. Delattre's work still remains seminal for studies on French prosody. In French spontaneous speech data, a melodic rise is generally produced at the end of the clause. It indicates that the clause is an unfinished constituent at the discourse level, and that it can be associated with the term of "**major**" or "**minor**" **continuation contour**, according to Delattre's approach.

French and English intonation are sometimes described by a set of contours. Delattre [9] considers that 10 basic contours can describe the most frequent intonation patterns in French; [18] also distinguish 10 contours though their contours differ from those proposed by Delattre. As far as English is concerned, 22 pertinent intonation contours are proposed by [17] to describe English intonation.

It is common to use the term of *assertion intonation* or *question intonation* to refer to falling or rising contours: falling contours are associated with assertion or assertiveness (Bartels 1999), whereas rising contours are associated with questions or aspects of questioning (uncertainty, ignorance, call for a response or feedback from the addressee, etc.). Although prototypical assertions are uttered with a falling contour and prototypical confirmation or verifying questions are uttered with a rising contour, occurrences of assertions with a rising contour and occurrences of confirmation or verifying questions with a falling contour are far from rare in everyday conversations [4].

In the following paragraphs F0 contours in French and English sentences spoken by native and non-native speakers are measured and compared and their differences are statistically evaluated.

3. Prosodic annotation

Prosodic parameters are subject to parameter values governing prosodic coherence along the prosodic group. It was observed in automatic speech processing (in diphone and data driven speech synthesis) that a sudden unjustified change in F0 or sound duration (beyond stressed syllables or prosodic junctures), is perceived either as a corruption of the speech signal or as an occurrence of a misplaced contrastive stress [5]. Most of the time researchers focus on the transcription of parameter values of syllables considered as linguistically prominent, carrying pertinent linguistic information. The other linguistically non prominent syllables, remain generally uncoded although their prosody contributes to an overall perception of a correct pattern. Therefore we believe that in order to keep a faithful prosodic transcription of the speech signal, all the parameters of the syllables should be annotated.

3.1. Prosodic labelling

Speech data processing was carried out in several stages. First, prosodic parameters were extracted from the speech signal. In order to segment the speech data, a text-to-speech forced alignment was carried out using the CMU sphinx speech recognition toolkit [16] yielding an automatic segmentation of the speech signal at the phoneme level. This automatic segmentation of the speech signal was then manually checked by an expert phonetician.

For the F0 pattern analysis, F0 values in semitones were estimated every 10 ms by the software Aurora [19]. A simple F0 parameter smoothing was carried out by our annotation software to eliminate corrupted F0 values.

Prosodic annotations were yielded by the language independent automatic annotation tool PROSOTRAN [2]. This tool requires no specific linguistic knowledge, therefore it is well-adapted for cross-linguistic studies. PROSOTRAN yields various numeric and symbolic prosodic annotations for each syllable of the speech signal; however, from this data, only F0 range values and sound durations are used in this study. Sound duration is normalized and transformed to a symbolic duration annotation. For the representation of F0 patterns, a melodic range is calculated between the maximum and the minimum values of the F0 in semi-tones. All speech material for each speaker is used to build a histogram of the distribution of the F0 values. To avoid extreme, often wrongly detected F0 values, 6% of the extreme F0 values (3% of the highest and 3% of the lowest ones) are discarded. The resulting range is then divided into several zones (9 in our case) and is coded into levels (from 0 to 9). By calculating FO in this way, value normalization is enabled and also inter-speaker comparison of FO patterns.

3.2. Corpus

The corpus used in this study was recorded as part of the Intonal project, focusing on the study of intonation in French and English. The recorded corpus contains 40 short sentences belonging to 8 syntactic categories using 20 French and 20 English native speakers. The French speakers uttered French and English sentences, and constitute our non-native English speaker group.

The corpus sentences contain sentences with two kinds of non-conclusive F0 slope configurations as well as interrogative and declarative sentence final configurations. Our study analyses mainly the F0 contours on discourse level (the F0 value of the final segment of declarative clauses connected by a discourse relation, marked or not by a conjunction) and on syntactic level (F0 pattern on the final segment of declarative and interrogative sentences).

3.2.1.1 F0 tendency extraction

The goal of the F0 pattern extraction is to get the most representative F0 pattern(s) for a given sentence for a group of speakers keeping one or, if necessary, several F0 values per syllable (Figure 1).

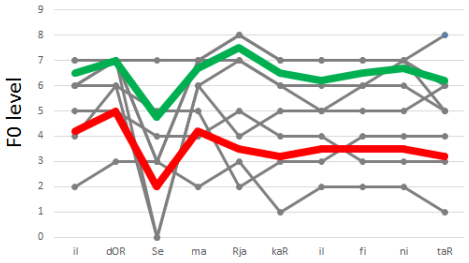

Figure 1: *Representative patterns (in green and red) of F0 levels for a sentence uttered by 8 speakers (in grey)*

The symbolic annotation yielded by PROSOTRAN is used for each syllable and for the whole speaker group of each language to identify the values that represent the general tendency of the F0 pattern. An empirical approach was adopted allowing the emergence of maximally two F0 values per syllable (as the number of speakers is relatively small in each group – maximally 18 for English native speakers). The F0 values coded by their range level are split into two groups using an adjusted median value keeping F0 values belonging to the same symbolic code in the same group. This way the division of the following symbolic F0 values [10 9 9 8 8 8 7 7 5 6] occurs after the last "8" (the 6th F0 value and not after the 5th value as expected). Each grouping obtained is represented by a mean value (V1 & V2, cf. Figure 2) and the two F0 values per syllable are maintained only if their difference is higher than 3 semi tones and when the number of F0 values in a group is higher than 2. If not, the groups are merged and a general mean value (V(1,2)) is calculated using the values of all the speakers for a given syllable.

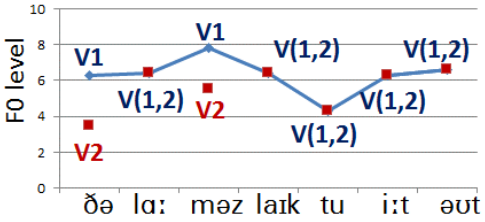

Figure 2: *F0 pattern general tendency: V1 first F0 value, V2 second F0 value, V(1,2) first and second F0 values merged*

The number of merged values was 70% for the French native speakers, 74% for English natives but only 50% for non-native speakers. The F0 patterns of non-native speakers were less consistent and have more variability in their pronunciation.

For the different sentences, the succession of the F0 values is recovered and the preferred F0 pattern tendency observed. For example, for the sentence in figure 2, the preferred tendency as to the succession of the F0 values is represented on Figure 3.

3.3. Analysis of results

Our approach of automatic extraction of F0 tendency is tested on 4 sentence types from our laboratory data; that is on continuative, paratactic, interrogative and declarative sentences. Each sentence group contains 5 different sentences

of the same syntactic structure uttered by a group of at least 8 speakers - that is a corpus of about 160 sentences. In the following paragraphs only results obtained for one sentence (containing about 8 utterances) per sentence type will be discussed, however the results obtained for the remaining sentences of the same sentence type obtained very similar results.

Continuative sentences: *(two clause sentence, with coordinating conjunction, ("He has seen **Maria** because he has come" "Il va voir **Maria** car il en a envie").* (cf. Figure 4).

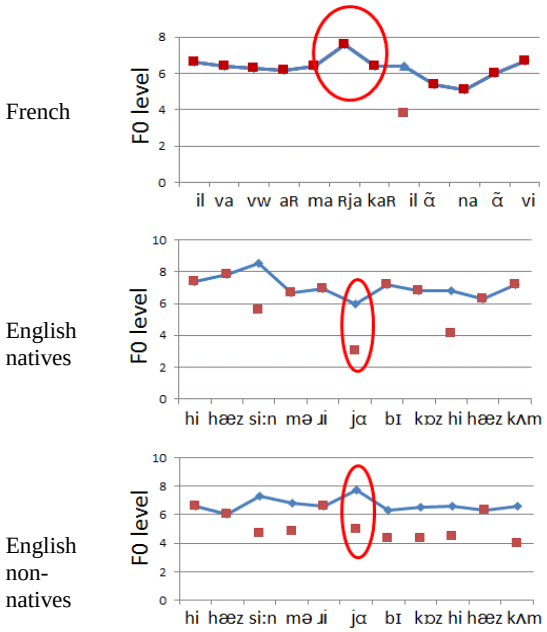

Figure 4: *F0 pattern in a continuative sentence ("He has seen **Maria** because he has come" "Il va voir **Maria** car il en a envie"); red circle: major prosodic boundary*

French speakers marked the continuation (red circle on the figure) with a rising F0 while English speakers prosodically coded the same syntactic boundary with a lowering F0. Non-native English speakers use more rising patterns than falling ones. In French, the general rising tendency of the F0 is not very high but the prosodic boundary is also indicated with lengthened vowel duration. On the other hand, the downwards movement of the F0 in English was more important but there is no vowel lengthening in the final syllable. A high prosodic agreement in these sentences is in the realization of the major prosodic boundaries: the rising tendency on the NP boundaries is respected by the majority of the French speakers and the falling F0 pattern by the majority of English speakers. In the non-native group there is little agreement as to the F0 pattern on major prosodic boundaries; in fact most of the time two F0 values are extracted: a high value indicating a rising F0 movement and a low value indicating a falling F0 movement.

Paratactic sentences: *(two clause sentence, without coordinating conjunction, "Il dort chez **Maria**, il va finir tard. / He'll sleep at **Maria's**, he'll finish late.")* (cf. Figure 5)

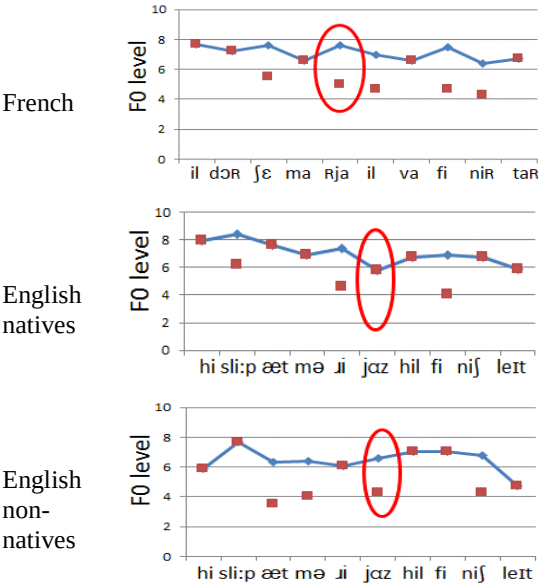

Figure 5: *F0 pattern in a paratactic sentences ("He slips at **Maria's** he'll finish late" "Il dort chez **Maria**, il va finir tard"); red circle: major prosodic boundary*

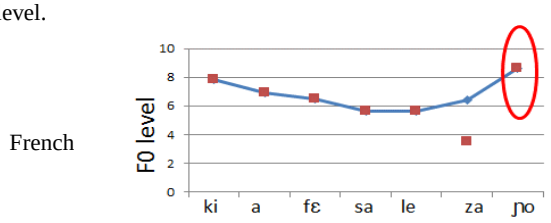
In French little prosodic agreement is found on the major non-final prosodic boundary (red circle on the figure): the F0 level fluctuated and most of the time two F0 level values are extracted. In these sentences the speaker's prosodic production of the first clause is similar to a final prosody signaling the end of the first clause in a sentence and its syntactic independence from the second clause. However, a strong agreement in the F0 values is observed in English native data where all the clause final F0 values are falling. As far as the non-native English group is concerned, their F0 realizations are again closer to the French group than to the English group.

Interrogative configuration *(simple subject NP: "Qui a fait ça? **Les agneaux**? / Who did this? **The lambs**?")* (Figure 6)

In French interrogative sentences, generally, a huge level rise is preceded by a rather flat F0 level. The F0 pattern in English interrogative sentences contains a more moderate F0 upward movement or (Figure 6) a lowering F0 movement (despite the interrogative character of the sentence). As the interrogative character of the sentence is also expressed by question words ("who" in this example), there is probably no real need for prosodic marking. Again, the French speakers of English are closer with their F0 pattern realizations to French prosody, (rising F0 values) than to English prosody. Other noteworthy findings for this sentence type: the interrogative character is prepared from the beginning (onset) of the sentence: for the 3 speaker groups the interrogative sentences start at a high F0 level.



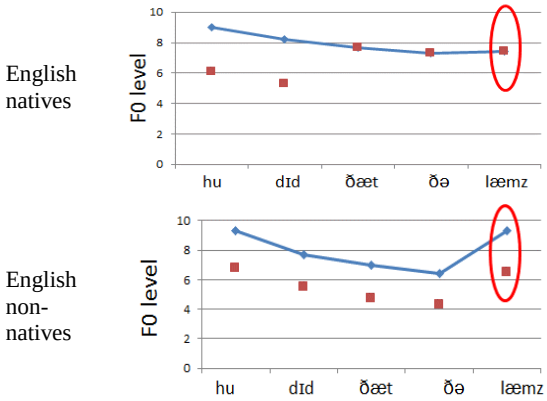


Figure 6: *Interrogative sentence types ("**The lamas** like to eat oats" "**Les lamas** aiment bien l'avoine"; red circle: interrogative sentence final boundary*

Declarative sentences *(Longer declarative sentence: "Il dort chez **Maria**. /He'll sleep at **Maria's**")* (cf. Figure 7)

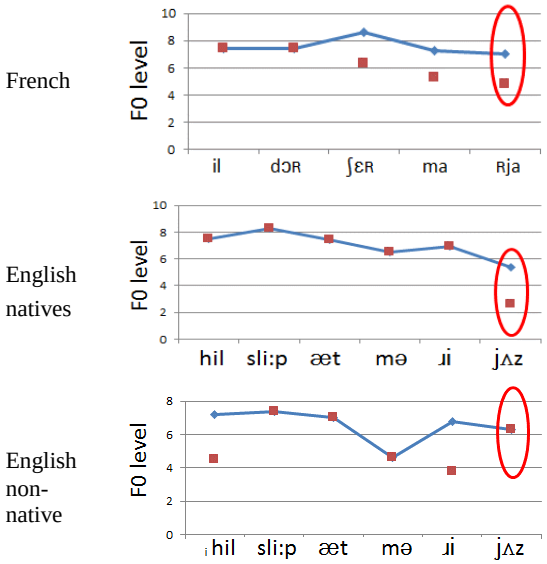

Figure 7: *F0 pattern in a sentence with continuative configuration on a subject NP ("**The lamas** like to eat oats" "**Les lamas** aiment bien l'avoine"); red circle: final declarative boundary*

In French the preferred F0 pattern at the end of the declarative sentence types is only slightly falling or it remains flat. This finding can be partly explained by the fact that, in French, the final pattern of a declarative sentence is also marked by the last syllable duration lengthening which is more moderate than the syllable duration lengthening on major continuation prosodic boundaries [1]. In English, on the other hand, the end of the declarative sentences is marked by a systematically falling F0 pattern. As for the non-native speaker group, their F0 pattern is also either slightly falling or remains flat i.e. they are closer to the native French group F0 patterns than to the native English group patterns.

3.4. General discussion

From the previous analysis some general tendencies can be identified as to the differences between French and English F0 patterns. In the phrases studied here French speakers gave preference to more rising F0 patterns on prosodic boundaries while English native speakers uttered the English version of the sentences with a preferential falling F0 pattern. The final F0 movement in the sentence is falling in both languages (cf. Table I), however the slope of the F0 level change is steeper in English than in French.

The English non-native speaker's prosody remains somehow influenced by both French and English prosody: for example in interrogative sentences their F0 pattern is clearly similar to French, while in continuative sentences the non-native's F0 pattern is more similar to English (cf. Table I).

Table I: *Amount of F0 levels in rising (+) or falling (-) patterns on major prosodic boundaries for the 4 sentence types*

Sentence type	French	English native	English non-native
Continuative	+2.6	-1.5	-1.5
Paratactic	+1.1	-1.5	-0.5
Interrogative	+3	+0.5	+2.5
Declarative	-1.8	-3	-1.5

The intra-speaker variability of the F0 levels (2 F0 level values per syllable) of the native (French & English) groups occurs more often in linguistically less important syllables. So in French only 1.7 syllables/sentence type (or 35% of linguistically pertinent syllables), and in English 1.5 syllables/sentence type (or 30% of linguistically pertinent syllables) are coded by two F0 levels on the linguistically pertinent prosodic boundaries. On the other hand, non-native speakers are less consistent in their prosodic production with more variability in F0 values: 2.8 syllables/sentence type (or 55% of linguistically pertinent syllables) are captured by 2 F0 level values.

Finally, variability is observed also with respect to the number of F0 levels used by the speakers of the 3 groups: the French and English native speakers used up to 6 F0 levels for their F0 patterns while the non-native speakers used only 4 F0 levels. That means that the F0 patterns of non-native speakers are more monotonous than the F0 patterns of the native speakers.

4. Conclusions

The goal of our study was to use an appropriate coding schema for prosody representation in a cross linguistic study of French and English prosody. The data used for testing the proposed method were laboratory data produced by a group of French and English native speakers and they contained sentences sharing the same syntactic structures in both languages. This syntactic specificity of the data base was well adapted to a cross-linguistic study as it allowed for comparison of prosodic phenomena relatively easily.

The methodological problem addressed here was how to represent prosodic parameters in such a way that comparison of the occurrences of these parameters in different sentences and languages would be pertinent. The aim of the study was to represent the general tendency of the F0 pattern by extracting one, or maximum two, F0 values per syllable, coded in terms of 9 F0 levels calculated from the voice range of each speaker. In the present study for each syllable one or maximum two F0 values were kept to capture the prosodic tendency of the sentence. However, in future, a more general automatic decision algorithm should be used to make the decision of the number of representative values of the F0 more data driven.

Abstract

Using the structural priming paradigm, the present study explores predictions made by the Implicit Prosody Hypothesis by testing whether an implicit prosodic boundary generated from a silently-read sentence influences attachment preference for a novel, subsequently read sentence. Results indicate that such priming does occur, although the patterns are highly dependent on individual differences in listeners' "autistic" traits.

Index Terms: Implicit Prosody, non-restrictive RC, autistic traits, prosodic disambiguation, AQ

1. Introduction

1.1 Implicit Prosody in Relative Clause Attachment

In a sentence such as (1), it is ambiguous whether the relative clause (RC) modifies NP1 *the servant* (high attachment) or NP2 *the actress* (low attachment):

(1) *Someone shot the servant of the actress who was on the balcony*. ([1])

Although the details of attachment preference are language-specific ([2],[3]), it is known that, cross-linguistically, attachment decisions are sensitive to the sentence's prosodic characteristics, including the location of a prosodic boundary ([4], [5], [6], [7], [8]). This fact has been used to support the Implicit Prosody Hypothesis (IPH; [2], [9]), which states that, in silent reading, a default prosodic contour is projected onto the sentence, influencing syntactic ambiguity resolution. Other things being equal, the parser favors the syntactic analysis associated with the most natural (default) prosodic contour for the construction. Fodor and colleagues claimed that speakers interpret a prosodic break before an RC as a marker of a stronger syntactic boundary, which prompts high attachment. This suggests that the human sentence parser would favor low attachment when the RC forms a single prosodic phrase with NP2, but favors high attachment when a prosodic break directly precedes the RC.

1.2 Accessing Implicit Prosody

An important question is how implicitly-generated prosody can be investigated. Fodor and colleagues (e.g., [10],[6],[11],[7]) assumed that implicit prosody is equal to explicit, or overt, prosody such as that associated with an out-of-the-blue reading. However, recent production studies ([12],[13],[14]) suggest that this is not necessarily the case. These studies found that a majority of English speakers produced a large prosodic boundary directly before the RC, despite English's status as a language with a low-attachment bias. Thus it appears that implicit prosody is not easily accessible via the investigation of overt prosody.

If implicit prosody is not reliably studied by way of overt prosody, it may be possible to study it more directly, by influencing implicit prosody itself and observing the effects on processing. One possible way to accomplish this is to manipulate visual cues that impose implicit boundaries in reading materials. For example, recent studies examining individual differences in attachment preference show working memory capacity to be positively (e.g., [15], [16] for on-line data) or negatively (e.g., [17] for off-line data) correlated with high attachment responses when the target sentence is presented on a single line. However, when the sentence is displayed on two lines, i.e., visually chunked so that the RC is separated from the two head nouns (i.e., …NP1 NP2 // RC...), working memory plays a weaker role and subjects prefer high attachment, regardless of their working memory capacity. This suggests that visual cues, such as visual discontinuity, may influence attachment by imposing implicit prosodic juncture in reading.

Another approach to the manipulation of implicit prosody would be to try to "prime" it using overt prosody. In recent work ([18]), we carried out an experiment intended to do just this, using a novel prosodic adaptation of the structural priming paradigm ([20], [21], [22]). In particular, listeners were auditorily presented with ambiguous RC-sentences that contained a prosodic boundary either before or after NP2, and then had to read another, also ambiguous RC target sentence. Subjects then made attachment decisions about the silently read target. If the overt prosody in the prime sentence influenced the implicit prosody generated during the reading of the target sentence—and implicit prosody influences attachment—this would be observable in attachment decisions.

In fact, a certain subset of listeners were influenced by the primes as predicted by the IPH; after hearing sentences with a boundary after NP2, these subjects were more likely to interpret the silently read target as having a high-attaching RC. Interestingly, this group of subjects consisted of those with prominent "autistic" traits along the "communication" dimension (indicating poorer, more autistic-like communication skills), as measured by the Autism Spectrum Quotient ([23]). At present it is unclear why these individuals should be especially sensitive to prosodic boundaries in this way, although high scores on this dimension (indicating poorer, more

autistic-like communication skills) have been shown inversely related to the use of pragmatic information in sentence processing (e.g., [23], [24]), and, similarly, to the accentual patterns that typically encode such information ([25]). (For further discussion of the individual sensitivity to prosodic structure, and its consequences for sentence parsing, see [19]).

The results of the experiment just described indicate a correlation between the use of a prosodic boundary and attachment of an RC in a way that supports the basic prediction of the IPH. A question remains, however: what was the mechanism? That is, although a boundary separating the RC and the two head nouns was (for subjects with more prominent autistic traits) associated with high attachment, it is unclear whether this happened as a result of syntactic structure priming or prosodic structure priming. In the first case, the overt prosody of the primes would have influenced the syntax assigned to the primes themselves, at which point that syntactic structure could be re-used to parse the target sentence. This is syntactic priming in the typical sense ([20]). In the second case, however, the overt prosody would have influenced the targets more directly, by influencing the implicit prosody generated for those targets. However, both of these scenarios are possible in the experiment just described, it is unclear which is the correct one.

This is the matter that we attempt to better understand in the present study. In the experiment presented below, native English speakers took part in a more traditional (i.e., reading only) structural priming task, involving targets containing an RC with ambiguous attachment, such as in (1) above. However, prime sentences were designed not to have RCs with one or the other attachment possibilities, but to have RCs that modified a head noun restrictively or non-restrictively. The reason for this was that this contrast—orthogonal to the attachment ambiguity—is distinguished primarily by the presence versus absence of a prosodic boundary before the RC in speech; it is represented visually by the presence versus absence of a comma in orthography. An example of the contrast is shown in (2a) and (2b):

(2) a. Restrictive RC in the prime sentence:
The newspaper reporter phoned the secretary who was annoyed.

b. Non-restrictive RC in the prime sentence:
The newspaper reporter phoned the secretary, who was annoyed.

If the implicit prosody (of targets) can be influenced by the implicit prosody (of primes), we expect targets like (1) to be parsed differently depending on whether they are read following a sentence with a restrictive versus non-restrictive RC. In particular, because the non-restrictive RC in the primes contains a boundary before the RC (cued by the comma), it should increase the probability that a boundary will be inserted before the RC in the targets. Based on the results of previous studies (e.g., [27], [17]), we predict that this will induce a greater likelihood of high attachment responses. Based on [18, 19], we also predict this effect to depend somewhat on autistic traits. As described above, autistic traits are measured in the neurotypical population using the AQ, a self-report questionnaire; this measure is composed of five subscales measuring *social skills*, *attention to detail*, *attention switching*, *communication skills*, and *imagination*. Rather than the entire score combined, in our own work, we have found scores on the communication subscale to be inversely related to the use of prosodic prominence in speech [26], and directly related to a sensitivity to prosodic boundaries [18, 19].

This was tested in the experiment presented below in Section 2; a discussion and conclusion based on the results follows in Section 3.

2. Experiment

2.1. Method

2.1.1. Stimuli

Sixteen sentences containing RCs of medium length (4-6 syllables) were created to serve as target sentences to be read by participants. These sentences, based on sentences used in previous studies (e.g., [28], [29], [30], [31], [32], [33]), were designed to lack any grammatical or semantic bias towards high or low attachment. An example of such a sentence is shown in (1), with some additional examples listed in Appendix I.

Prime sentences, to be presented and read immediately before the targets, were based on 30 sentences of similar length. Like the targets, primes contained RCs that were 4-6 syllables in length, but they differed from targets in two ways. First, the RCs in primes followed a single head noun, and so they had unambiguous attachment to that head noun. Second, there were two versions of each prime, one which was to be interpreted as having a restrictive RC, and the other which had a nonrestrictive RC. The non-restrictive RC was marked by the standard orthographic convention, i.e., a comma preceding the RC; the restrictive RC versions lacked any such comma. An example of each version is shown in (2); five additional examples are listed in Appendices II and III.

2.1.2. Participants

Participants were 120 native speakers of American English, mostly undergraduate students at the University of California, Los Angeles. None of the participants reported any speech or communication disorders, and all received either course credit or monetary compensation.

2.1.3. Procedures

Participants read the prime and target sentences, and answered attachment questions, at their own pace. A MATLAB script was used to present participants with the sentence materials on a computer screen. On each experimental trial, the script selected one of the 16 target sentences and three prime sentences from one of the two prime conditions; the order of presentation of primes was randomized on each trial. The subject then proceeded through these four sentences, first the three primes, then finally the target, at their own pace, pressing a computer key to remove one sentence and display the next. Following a key press after the target sentence, however, a question appeared, asking the participant the standard RC-

attachment question (e.g., Who was on the balcony? In the case of (1), above), presenting the two possible head nouns as the options "A" and "B". Whether the high attachment response (i.e., NP1) appeared on the left as "A" or on the right as "B" was counterbalanced for each participant.

Filler trials (consisting of 28 filler targets and 30 filler primes) proceeded in the same manner as experimental trials, with the following exception. On filler trials, a question appeared for one of the three prime sentences, selected at random. This was to prevent participants from knowing exactly which sentence in a trial (i.e., every fourth sentence presented to them) would be the one requiring the answering of a question.

Participants carried on through all experimental and filler trials (randomized for each participant), and the assignment of a particular target sentence to a prime condition (restrictive vs. non-restrictive RC) was counterbalanced across subjects. The task took participants approximately 15-20 minutes. Following the reading task, participants completed the AQ ([23]), a 50-item self-report questionnaire, requiring an additional 10 minutes.

2.2. Results

Two rounds of mixed-effects logistic regression modeling took place; the first was aimed at a simple, overall test of the effect of primes, without considering possible individual differences related to autistic traits. The second round of modeling included AQ scores.

Results of the first model, shown in Table 1, indicated that primes did in fact influence how participants interpreted the ambiguous targets; as predicted, participants chose high attachment significantly more often after reading sentences in the non-restrictive RC condition that contained a comma than in the restrictive RC condition that did not contain a comma (see Figure 1). That is, the implicit prosody of primes influenced the implicit prosody of the targets, which then influenced the attachment resolution, thus supporting the IPH. Additionally, the significant effect of trial indicated that, as the experiment went on, high attachment responses became more likely overall.

A second model of mixed effects logistic regression included the participants' scores on each of the subscales of the AQ (Communication, Social Skills, Attention to Detail, Attention Switching, and Imagination), in addition to the factors in the first model. The results of the model (see Table 2) showed significant interaction between Prime Type and AQ-Communication scores. As shown in Figure 2 (next page), the influence of primes was stronger for individuals with higher scores on this subscale (indicating more autistic-like communication skills).

There was also a significant main effect for scores on the AQ-Attention Switching subscale; as shown in Figure 3, higher scores in AQ-Attention scale were associated with a greater likelihood of a "high attachment" response. Finally, the significant effect of trial found in the simpler model also held here, indicating high attachment was more likely on later trials.

Table 1. *Estimates, standard errors, z- and p-values for the first model testing the effect of primes on high attachment responses. Positive estimates indicate the amount of increase in log-odds relative to the intercept.*

Fixed effects:	*β*	*SE*	*z*	*p*
(Intercept)	-.389	.213	-1.83	.068
Trial	.009	.003	2.55	**.011**
PrimeType(*nonrestrictive*)	.220	.104	2.11	**.035**

Table 2. *Estimates, standard errors, z- and p-values for the second model of high attachment responses, adding AQ subscales.*

Fixed effects:	*β*	*SE*	*z*	*p*
(Intercept)	-1.797	.933	-1.93	.054
Trial	.009	.004	2.45	**.014**
AQ-Attention Switching	.096	.036	2.70	**.007**
AQ-Communication	-.052	.036	-1.45	.147
PrimeType(*nonrestr.*)	-.932	.511	-1.82	.068
PrimeType(*nonrestr.*) × AQ-Communication	.060	.026	2.30	**.021**

3. Discussion and Conclusion

The structural priming experiment presented above was intended to test a basic prediction of the Implicit Prosody Hypothesis ([2], [9]), which says that a strong prosodic boundary generated implicitly during reading influences the attachment of a relative clause. In particular, a strong prosodic boundary directly before the RC is predicted to encourage a high attachment parsing of the RC. Our prime sentences were designed to manipulate the presence versus absence of such a boundary. In fact, results showed that, after reading primes with a boundary, participants were more likely to attach the RC high

in a novel, structurally ambiguous sentence. First, and significantly, this suggests that implicit prosodic structure, like syntactic structure, can be primed; second, in relation to our main goal, it demonstrates that silently-generated prosodic boundaries influence attachment—supporting the IPH.

The results also confirm previous findings that autistic traits in the neurotypical population are relevant to predicting sensitivity to prosody in sentence processing ([26]). In particular, the communication subscale of the AQ seems to be correlated with sensitivity to prosodic boundaries ([18, 19)]. Participants with higher AQ-communication scores (e.g., those who are not good at social chit-chat, or are slower in understanding the point of a joke), chose more high attachment responses for targets following non-restrictive RC primes than those following restrictive RC primes. Though the mechanisms underlying this tendency require further study, we hypothesize that individuals with high AQ-communication scores, rather than incorporating the prosodic boundary to attachment, might have been disrupted by the juncture, prompting closure at the location of boundary.

On the other hand, a second finding, not previously reported, is also related to autistic traits. Namely, high scores on the attention-switching subscale of the AQ (i.e., worse attention-switching abilities) were associated with higher overall rates of high attachment. The relation between attachment preference and attention-switching therefore resembles the one between attachment preference and verbal working memory capacity ([16], [17]), possibly because both of these reflect similar general processing resources. That is, those who lack attention shifting abilities and those who have lower working memory capacity might both have difficulty integrating multiple sources of information. This may be supported by the main effect of trial, which indicated that, as the experiment went on (and participants possibly became more fatigued), high attachment decisions became more likely. Again, further research is needed to understand the processing mechanism underlying the performance of individuals with more prominent autistic traits.

In sum, the present study provides crucial evidence for the Implicit Prosody Hypothesis with respect to the relation between implicit boundaries in reading and attachment preferences. Further, we have shown that implicit prosodic structure, like syntactic structure, can be primed, and that the details of this priming depend on autistic traits in the neurotypical population.

4. Acknowledgements

The authors thank Henry Tehrani for his help in writing the MATLAB script and undergraduate research assistants Katie Brown, Sewon Na, and Hannah Kim for help running the experiment. Work on this project was facilitated by a UCLA Faculty Research Grant to Sun-Ah Jun.

5. Appendices: Example Stimuli (part)

I **Example Target Sentences**

1 Jennifer blackmailed the boss of the clerk that was dishonest.
2 Susanna was dating the cousin of the artist that was a veteran.
3 The lady mended the sleeve of the shirt that had been stained.

II **Example Prime Sentences (Restrictive, without comma)**

1a The inspector photographed the boat's cover that was yellow.
2a The coach looked at the varsity players who were very happy.
3a The picky journalist hated the soldiers who were sitting down.

III **Example Prime Sentences (Non-restrictive, with comma)**

1b The inspector photographed the boat's cover, which was yellow.
2b The coach looked at the varsity players, who were very happy.
3b The picky journalist hated the soldiers, who were sitting down.

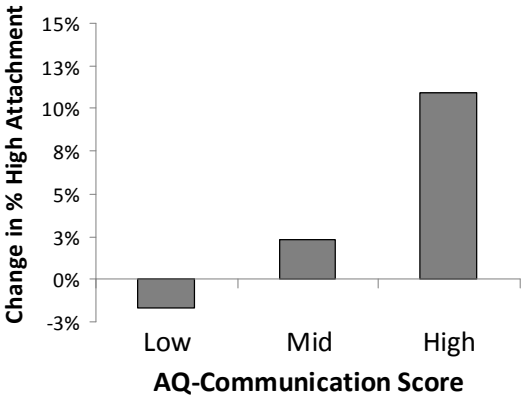

Figure 2: *Increase in high attachment responses to targets in the non-restrictive RC prime condition (relative to the restrictive RC prime condition) as a function of AQ-Communication scores. The three levels of AQ refer to the group distribution: "Mid" are subjects scoring within 1 SD of the mean, the "Low" and "High" levels below or above 1 SD.*

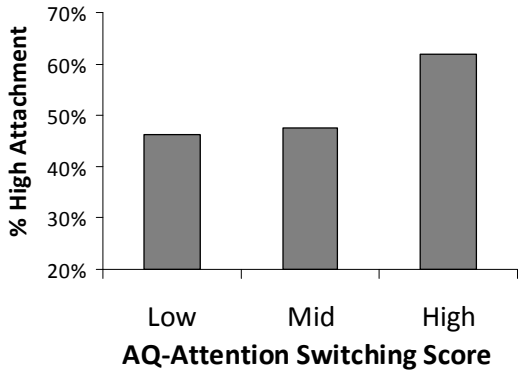

Figure 3: *High attachment responses as a function of scores on the Attention-Switching subscale of the AQ. The three levels refer to the group distribution: "Mid" are subjects scoring within 1 SD of the mean, the "Low" and "High" levels below or above 1 SD.*

Abstract

The perception of prosodic structure (phrasal prominences and boundaries) may depend in part on acoustic cues in the speech signal and in part on utterance meaning as related to syntactic structure and discourse context. In this study we ask if listeners are able to differentially weigh acoustic and meaning-based cues to prosody. We test naïve subjects' transcription of prominences and boundaries in spontaneous American English under three different conditions, all of which involve listening to audio recordings and marking prominences and boundaries on a transcript. The three conditions differ in the instructions given to transcribers. In one condition, subjects were instructed to transcribe prominence and boundaries based on meaning criteria, in a second condition they were told to transcribe based on criteria of acoustic salience, and a third condition had less specific instructions, without explicit reference to either meaning-based or acoustic cues. Our results show that subjects perform differently when focusing on meaning than when focusing on acoustics, especially for prominence marking, where partially different sets of words are selected as prominent under the two tasks. Boundary marking is more similar under the two instructions, with acoustic criteria resulting in more listeners marking a given word as pre-boundary, but with boundaries marked largely on the same words in both tasks. With non-specific instructions, performance was similar to that obtained under acoustic-based instructions. We report on agreement rates within and across conditions. This study has implications for models of prosody perception and the methodology of prosodic transcription.

Index Terms: prosody, prominence, boundaries, prosodic transcription

1. Introduction

Prosodic prominences and boundaries are assigned to utterances based on many factors related to syntactic structure and discourse context. Because of these dependencies, the acoustic cues that signal prosody also serve as cues to the linguistic context of the prosodically marked word and the utterance to which it belongs. For instance, listeners interpret syntactic structure based in part on acoustic cues that signal prosodic boundaries [1,2,3,4], and the interpretation of the focus and information status of a word is influenced by acoustic cues to prominence [5,6,7,8,9]. The influence of prosodic cues on discourse processing is such that a mismatch between the discourse context and a word's prosodic form can disrupt processing, as shown by evidence from eye-tracking [6,8,10] and ERP studies [11].

The studies cited above, and many others, demonstrate the role of prosody in communicating meaning related to the syntactic, semantic and discourse context of an utterance. While the evidence shows that listeners attend to the prosodic cues present in the acoustic speech signal, it's possible that listeners' perception of prosody is also driven by expectations about the prosodic form of an utterance given its syntactic properties and its semantic and discourse context, in the same way that expectations play a crucial role in word recognition (and in the visual domain). In this paper we examine prosody perception due to acoustic cues and due to expectations from factors related to syntactic, semantic and discourse context (hereafter *meaning-based cues*), and ask whether listeners can focus differentially on acoustic and meaning-based cues in identifying prosodic prominence and phrase boundaries in spontaneous speech. We examine listeners' perception of prosody using the method of Rapid Prosody Transcription (RPT) developed by one of the authors (JC) for investigating prosody through the analysis of judgments made by naïve native speakers of English [12]. This method and prior findings are introduced in the next section.

1.1. Rapid Prosody Transcription

Under the RPT methodology multiple listeners (between 10-20 in prior experiments) make auditory judgments about the location of prosodic phrase boundaries and prominences in an audio speech recording, based only on (the individual listener's) auditory impression and with no visual inspection of the graphical speech display. For each word of transcribed speech two continuous-valued prosody features are calculated, representing the proportion of transcribers who perceived the word as prominent (the p-score), and the proportion who perceived the word as final in a prosodic phrase (the b-score). A p-score of 0 shows agreement among all transcribers that the word is not prominent while a p-score of 1 shows agreement that the word is prominent. Values in between 0 and 1 reflect disagreement among transcribers. The prosody scores can be viewed as a measure of the probability that a random listener (from the same speech community) will perceive a given word as prominent, or as preceding a prosodic phrase boundary. Fig. 4 below shows an example of the p- and b-scores for each word in a fragment of a speech sample from this study, based on the aggregated transcriptions of 16 listeners.

Cole and her colleagues conducted two studies of prosody perception with American English spontaneous speech using RPT, testing the relative contribution of signal-based processing (from acoustic cues) and expectation-based processing (from syntactic and information-based cues) in non-expert listeners' judgments of prosodic prominence and phrase boundaries. Cole et al. [13] investigated p-scores and their relationship to various acoustic cues previously found to correlate with prosodic prominence such as increased duration, increased intensity, and the presence of a pitch accent. They found a positive correlation between these acoustic measures

and p-scores: higher values of the acoustic measures (e.g., longer duration, higher intensity) predict higher p-scores (indicating higher agreement among listeners that a word is prominent) for a given word. However, p-scores were also correlated with measures of word surprisal—non-acoustic cues such as word frequency and number previous mentions of a word in the discourse. Similarly, Cole et al. [14] found that syntactic context predicts the perception of boundaries in spontaneous speech, in addition to and partly independent of acoustic cues.

These two prior studies using RPT provide evidence that in perceiving prosodic prominences and phrase boundaries, listeners are influenced both by acoustic cues and by cues related to the syntactic role of a word and its meaning in relation to discourse context, and that these cues function at least partly independently of one another. However, these studies do not fully indicate to what extent acoustic and meaning-based cues are different and whether listeners can attune their attention to either acoustic or meaning-based cues, diminishing the other. These issues are the point of departure for the present study.

2. Methodology

2.1. Subjects and Materials

This experiment uses the Rapid Prosody Transcription method [12] to obtain prominence and boundary judgments from 15 naïve native speakers of English, all students at the University of Illinois. Sixteen short excerpts (~18 s each) from sixteen different speakers in the Buckeye corpus of spontaneous English speech [15] were used in this study. The total number of words summed over all excerpts was 925. This dataset is a subset of the dataset used in the study by [12] and comparisons with the findings of that study are included in Section 3. The transcription experiment was conducted in a quiet, computer-equipped room. Subjects proceeded through the experiment at their own pace using LMEDS, a customized software application developed by the authors.

2.2. LMEDS

A customized web interface, LMEDS, the Language Markup and Experimental Design Software, was developed to administer the experiment materials electronically. LMEDS is a generic toolset that simplifies the creation of custom experimental setups, such as those needed for an RPT experiment, as well as the aggregation of data collected during the experiment.

In this LMEDS experiment each excerpted speech sample was presented on its own page. Each of these pages presents a button for playing the audio file, a transcript where each word is clickable, and a button to progress to the next phase (Fig. 1). Each participant (hereafter, transcriber) first listened to the audio twice while clicking on individual words to mark a perceived boundary after the word. The transcribers had no training in phonetics and were not shown any visual display of the speech waveform, spectrogram or pitch track. After two passes through the file, listening and marking boundaries, transcribers then listened to the audio passage two more times, clicking on words perceived as prominent. The interface displayed the location of a selected boundary with a thick vertical line and indicated a word marked as prominent by changing the font color of the word to red. While marking prominences, transcribers were able to see, but not modify, the boundaries they had just placed. After annotating a transcript for both boundaries and prominences, subjects would progress to the next page in the experiment.

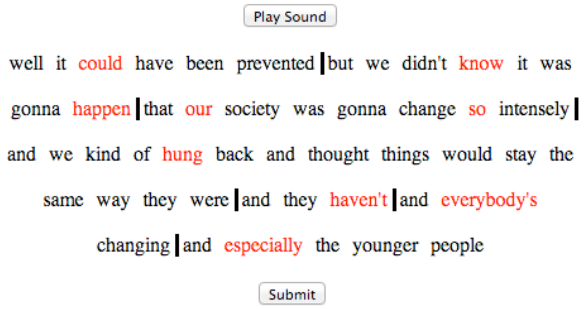

Figure 1. Example transcript and action buttons for a speech excerpt displayed in LMEDS, with prominences and boundaries as marked by an individual transcriber.

2.3. Task instructions

The experiment was divided into two blocks. Each block specified the criteria transcribers were to use in making judgments about the location of prominences and boundaries. In the *acoustics* block, subjects were asked to mark a boundary where they heard a 'break, discontinuity or disconnection in the speech stream, strong or subtle' and were asked to mark a prominence where they heard a word stand out by 'being louder, longer, more extreme in pitch, or more crisply articulated.' In the *meaning* block, subjects were asked to mark boundaries where the audio could be 'segmented with minimal disruption of the meaning of the speech' and were asked to mark the words that 'convey the main points of information as you think the speaker intended.'

3. Results

In our analysis we consider the RPT task under three different instruction sets: the explicit acoustic-based and meaning-based instruction sets that were run for the present study and the less explicit instructions used in [12,13,14].

Our first question is whether or not subjects performed differently across these three tasks. One way to assess differences due to task instructions is through inter-transcriber agreement, as reflected in p-scores and b-scores. Greater agreement would indicate stronger and more consistent cues to prosody under the stated criteria (acoustic or meaning-based). Fig. 2 shows that the distribution of b-scores and p-scores across all of the recordings are largely similar across the three transcription tasks. Most words receive a b-score of zero, indicating that no transcribers marked a boundary following the word, with a nearly flat distribution of b-scores greater than zero. The distribution of p-scores is similar, with the majority of words receiving a p-score of zero (again, indicating that no transcribers marked the word as prominent). However, there are also a significant number of words with low, non-zero p-scores (i.e, words that very few transcribers marked as prominent). Although there is some variation across tasks, the overall trend in transcriber agreement for p-scores or b-scores is the same.

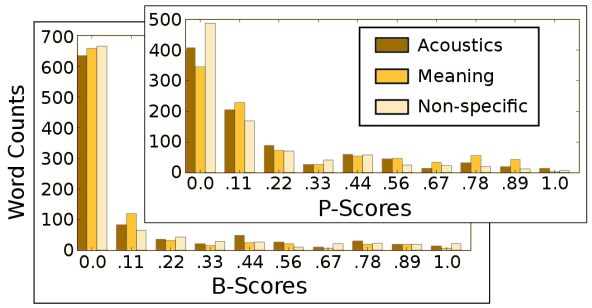

Figure 2. Distribution of b- and p-scores across the three tasks differing in transcription instruction.

The distributions of b-scores and p-scores also show that across tasks transcribers are marking a similar number of words as prominent or as preceding a boundary. For instance, looking at the histogram of b-scores we see that the number of words with a b-score of zero (indicating that no transcriber marked the word for a boundary) is very similar across the three tasks. We also observe that boundary labeling is more conservative than prominence labeling: in all tasks there are more words with a b-score of zero than there are words with a p-score of zero, which means that there are relatively fewer words being marked by transcribers as pre-boundary compared to the number of words marked as prominent. One exception to the overall similarity in prosody scores across tasks, as shown in Fig. 2, is the lower number of words with a p-score of zero under the meaning-based and acoustic criteria compared to the non-specific criteria. This finding indicates that transcribers are more likely to judge a word as prominent when attending to specific cues than when judging prominence in a non-specific way .

The distributions of p-score and b-score values for all tasks show a high agreement among transcribers on words that are not prominent (p-score=0), and on words that are not preceding a boundary (b-score=0), but it reveals little about the patterns of agreement on individual words as marked under different transcription instructions. We are interested to know if the transcribers weigh acoustic and meaning-based criteria differently on the basis of the task instructions, marking different words as prominent/important or as pre-boundary, across tasks.

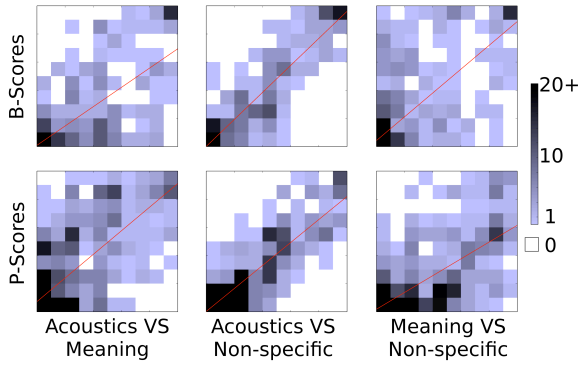

Figure 3. Linear correlations on top of density plots comparing b-scores (top) or p-scores (bottom) in one task against the corresponding score for the same word in a different task. The plots represent data density (# of datapoints in the same region of the plot) with values on the color scale as shown in the legend.

We examine task effects on transcription by comparing b-scores and p-scores for each word from one task with the scores for the same word from a different task, using correlation and linear regression analysis (Fig. 3). All correlations are significant, and r^2 values are above 0.5 for all comparisons (Table 1), indicating that the selection of words that are prominent and in pre-boundary position is similar across tasks, though not identical. The transcriptions that are most correlated (with the highest r^2) are those based on acoustic and non-specific criteria. The meaning-based transcription is less correlated to transcription under either acoustic or non-specific criteria. These findings show that transcribers are able to weigh acoustic and meaning-based cues differently when specifically instructed, but that in the absence of instructions calling for attention to meaning-based criteria, transcribers rely more on acoustic cues in marking prominences and boundaries. Thus, providing different instructions to subjects can indeed cause them to attune their attention to different types of information in speech.

	Acoustics VS Meaning	Acoustics VS Non-specific	Meaning VS Non-specific
B-scores	0.616	0.892	0.528
P-Scores	0.575	0.828	0.540

Table 1. Linear regression coefficients (r^2) for data plotted in Figure 3. ($p < 0.01$ for all reported values)

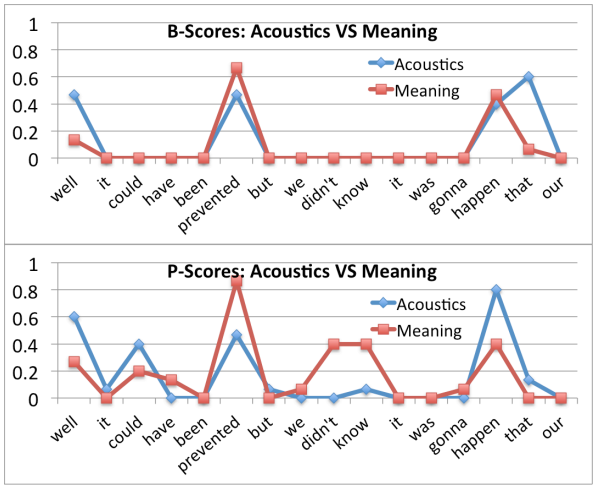

Figure 4. B-scores and p-scores for words from a fragment of a single excerpt, comparing the acoustics-based task with the meaning-based task.

The relatively lower correlation between acoustic and meaning-based prosody scores tells us that there are frequent mismatches in transcribers' marking of words in these two tasks. There are two scenarios that can explain such differences. One possibility is that transcribers in one task are marking a subset of the words that are marked in the other task. Taking p-scores as an example, it could be words that are selected as prominent under meaning-based criteria are also selected under acoustic criteria, but not vice versa. Under this scenario, (nearly) all words with p-scores greater than zero in the meaning-based transcription would also have non-zero p-scores in the acoustic transcription, but in addition, some words with non-zero p-scores in the acoustic transcription

would have a p-score of zero in the meaning-based task. The second scenario is where *different* words are marked as prominent under the two transcription criteria. This pattern of mismatch would result in words that have p-scores of zero in one task and non-zero p-scores in the other task, and vice-versa.

Fig. 4 plots b-scores and p-scores for individual words for a fragment of one speech excerpt, comparing acoustic-based with meaning-based transcription. Recall that the regression analysis (Table 1) shows substantial disparity between tasks in both b-scores and p-scores. The example in Fig. 4 suggests that task-related differences pattern differently for p-scores compared to b-scores. The b-scores under the two tasks (top panel) are similar in the selection of words that are marked as pre-boundary by any transcriber—the lines graphing b-scores nearly lie on top of one another—with b-scores in the two tasks differing mostly in the *number* of transcribers who mark a word as pre-boundary. On the other hand, the p-scores under the two tasks (bottom panel) differ substantially in which words are marked as prominent—the lines graphing the p-scores do not appear so nearly as lying on top of one another.

To further investigate the nature of the disparity between acoustic and meaning-based transcription, we compare prosody scores between the tasks after binning all scores into two values: 0 and 1. All b-score and p-score values of zero remain at zero, and values greater than zero are set to 1. This amounts to labeling a word as prominent if one or more transcriber marks it so, and otherwise labeling it as not-prominent. B-scores are similarly transformed to the labels boundary and not-boundary. Using these binned results, we can now ask how often two tasks align in their scores, which reveals the extent to which the same words are selected as prominent or as pre-boundary in both tasks, disregarding differences in the number of transcribers (>0) who agree in marking the word. In this analysis we ask whether a word that is labeled as prominent by acoustic criteria is also labeled as prominent under meaning-based criteria, and similarly for boundary labeling.

Fig. 5 shows the patterns of agreement between acoustic and meaning-based transcription for prominence and boundary labels (P/B) from the binned p-score and b-score data. Words counted in the Agree groups have the same P (or B) label in both tasks (acoustic, meaning), where 1 marks P (or B) and 0 marks not-P (or not-B). Words counted as Disagree are labeled differently in the two tasks. We observe several interesting findings. First, the vast majority of the words in the speech samples (89%) have the same boundary label across tasks (words in the 'Agree' groups), with most words assigned the not-boundary label. This meets our expectation, given that most prosodic phrases contain more than one word. However, we also note that there is high agreement across tasks for words with the boundary label, and only 11% of words are assigned different boundary labels in the two tasks. Turning to the prominence labels, we again note that overall more words are marked as prominent than are marked as (pre-)boundary, but there is also a lower overall level of agreement between tasks in prominence labeling, with only 76% of words assigned the same prominence label (the Agree groups). In other words, 24% of the words in this sample are marked as prominent in one task but not in the other. Words with disagreeing labels include those marked as prominent under acoustic criteria but not under meaning-based criteria, and vice-versa. These findings confirm the patterns shown in Fig. 4, that differences in p-scores between the tasks reflect the selection of different words marked as prominent, where differences in b-scores tended to reflect differences in the number of transcribers marking a word as pre-boundary more than differences in which words are marked.

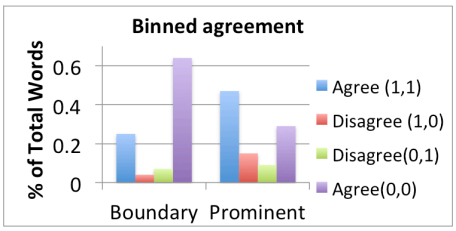

Figure 5. Number of words (% of total) that agree or disagree in prominence and boundary labels across acoustic and meaning-based tasks.

In both the histograms (Fig. 2) and the agreement ratings (Fig. 5) we see that there are more words have a b-score of 0 than there are words having a p-score of zero. For the p-scores, that mass is mostly redistributed to the low, non-zero p-scores (between 0.1-0.3). One reason for this discrepancy between prominence and boundary marking might be the number and variety of factors that condition the placement of prosodic prominence vs. boundaries. Thus, a boundary may be placed at a major syntactic juncture and also preceding disfluency. Prominence, on the other hand, seems to be conditioned by a greater variety of factors. Importantly, words that are acoustically salient do not necessarily convey new or pragmatically important information [16]. There may be differences among transcribers and/or across tasks in the weighting of these factors in the perception of prominence, resulting in greater variability in prominence marking. Another consideration is that the acoustic correlates of prominence seem to be more variable across speakers and utterances compared to the acoustic correlates of boundaries [17], and it's possible that transcribers vary in their sensitivity to individual cues.

4. Conclusions

This study compared prosody transcription under task conditions that focus listeners' attention on acoustic vs. meaning-based criteria. Transcription of prominence and boundaries in spontaneous American English was conducted by non-expert listeners. The findings show similar frequency of boundary and prominence marking across tasks, a lower frequency of boundaries than prominences, and higher agreement among transcribers in the location of boundaries. Task-related differences were also observed: more frequent prominence marking under meaning-based criteria, and a greater disparity between tasks in the individual words that are marked as prominent than there is for words marked as preceding a boundary. Overall there is more uniformity across transcribers and across tasks in boundary marking, parallel to results on inter-transcriber reliability for the ToBI prosodic transcription system [18,19]. This finding calls for future work on the status of prominence in speech production and perception, and on the criteria for prominence transcription. Our ongoing work investigates acoustic cues and also compares p-scores and b-scores gathered in a text-only condition with those obtained under the conditions described in this paper.

Abstract

When we address speaker states like sleepiness, two partly competing interests can be observed: both within applications and engineering approaches, we aim at utmost performance in terms of classification or regression accuracy – which normally means using a very large feature vector and a brute force approach. The other interest is interpretation: we want to know what tells apart atypical (here: sleepy) speech from typical (here: non-sleepy) speech, i.e., their respective feature characteristics. Both interests cannot be served at the same time. In this paper, we preselect a small number of easily interpretable acoustic-prosodic features modelling spectrum and prosody, based on the literature and on the general idea of sleepiness being characterised by relaxation. Performance obtained with these single features and this small feature vector is compared with the performance obtained with a very large feature vector; moreover, we discuss to which extent the features chosen model relaxation as sleepiness characteristic.

Index Terms: paralinguistics, sleepiness, prosody, brute forcing, interpretation

1. Introduction

Sleepiness is definitely an interesting research topic, both for practical reasons – the detection of sleepiness is highly relevant in scenarios where sleepiness can cause accidents (driving, flying, operating of machines), and for general reasons – it is ubiquitous, we face it several times a day. As a multi-modal phenomenon, it can be perceived/measured within all modalities, be this speech, facial gestures, eye movements, gait, body posture, or biosignals. Each of these modalities has its pros and cons, as far as processing is concerned: for video processing, light conditions should be favourable; biosensors are intrusive; audio recordings are non-intrusive and possible even under less favourable noise conditions. In this paper, we will concentrate on audio. Moreover, we concentrate on one specific research problem which might not be formulated that often explicitly but sort of gets into our way very often: do we want to get better, or do we want to get any wiser? For getting better, i.e., for obtaining the highest accuracy in classification or regression, we normally employ a very large feature vector (with or without subsequent feature selection): the baseline result for the Interspeech 2011 sleepiness challenge [1] was obtained using the openSMILE tool and 4368 features. Finding features that are most relevant for performance and at the same time easily interpretable is not an easy task [2]. For getting any wiser, so far, we are confined to the rather 'traditional' way of doing research: we employ a small set of promising features and, if possible, formulate a working (alternate) hypothesis on what we expect to find. These promising features are at the same time easily interpretable such as *F0 mean*, in contrast to complex and at the same time opaque features such as the *75% quantile of the 10th MFCC coefficient on consonantal frames* which will turn out as the 2nd most important feature obtained in our data-driven feature selection, cf. Section 4. However, we will definitely not get the highest possible classification/regression performance when using the 'traditional' approach. Here, we try to combine these two different approaches. After presenting the database in Section 2, we sketch in Section 3 the feature sets employed. The experiments reported in Section 4 are discussed in Section 5.

2. Data and Annotation

We employ the Sleepy Language Corpus (SLC) from the Interspeech 2011 Speaker State Challenge [1, 3]. Ninety-nine German speakers took part in six partial sleep deprivation studies (mean age 24.9 years, standard deviation 4.2 and a range of 20–52 years; recordings in a realistic car environment or in lecture-rooms; microphone-to-mouth distance 0.3 m, sampling rate 16 kHz, quantisation 16 bit). We disregard the isolated vowels and use the remaining five subsets (7745 speech files ("turns", units of analysis in our regression approach), about 20 hours of speech): read speech: the story of "Die Sonne und der Nordwind" ('the North Wind and the Sun'); commands/requests: simulated driver assistance system commands/requests, e. g. "Ich suche die Friesenstraße" ('I am looking for the Friesen street'); simulated pilot-air traffic controller communication statements (non-native English); descriptions of pictures; a PowerPoint guided, but non-scripted 20 minutes presentation in front of 50 listeners. A well established, standardised subjective sleepiness questionnaire, the Karolinska Sleepiness Scale (KSS, [4]), was used by the subjects (self-assessment) and by the three assistants who had supervised the experiments, using all available information (audio/video/context); they had been formally trained to apply a standardised set of judging criteria. Scores range from 1 to 10: extremely alert (1), very alert (2), alert (3), rather alert (4), neither alert nor sleepy (5), some signs of sleepiness (6), sleepy, but no effort to stay awake (7), sleepy, some effort to stay awake (8), very sleepy, great effort to stay awake, strug-

gling against sleep (9), extremely sleepy, cannot stay awake (10). The labels were given not to single turns but to 'recording units' consisting of up to 20 turns (9.4 on average) such as stories or sequences of commands. This constitutes an optimal and smooth reference; accordingly, mean pairwise Pearson correlation between self-assessment and observers is very high: 0.89 (0.88 between two observers). The scores from self-assessment and observers are averaged to form the reference sleepiness values (mean/standard dev.: 6.1 ± 2.3 for females, 5.9 ± 2.5 for males). A more detailed description of the data is given in [5, 6]. For the 2011 Challenge, a subdivision of the data into three speaker-disjunct sets for training, development and test was defined. Here, we always report the results on the test set (*TEST*, 19 females, 14 males, 2466 turns, 6.6 hours), estimating parameters on the union of the original training and development set (henceforth *TRAIN*, 37 females, 29 males, 5279 turns, 13.2 hours). Gender is a bit imbalanced: 73% and 64% of the utterances of TRAIN and TEST, respectively, are from female speakers.

3. Features

We employ 3705 acoustic-prosodic features described in [7]; here, we only can give the general idea. For segmenting pauses, vowels, consonants, and speaker noise, we use the phoneme recognizer of the Brno Univ. of Technology [8]. Then, pseudo-syllables are derived in four different ways, taking: (1) the nucleus (i. e. consecutive vowels), (2) nucleus + coda (consecutive vowels plus trailing consecutive consonants), (3) onset + nucleus (leading consonants plus consecutive vowels), and (4) onset + nucleus + coda (leading consonants plus consecutive vowels plus trailing consonants – these syllables overlap). We compute four low-level descriptors on a frame-by-frame basis: F0, formants, formant bandwidths, and Mel frequency cepstral coefficients (MFCC) as a more fine-grained and robust, yet less explicit representation of articulators. For each syllable, we compute micro-structural prosodic descriptors such as loudness [9]. F0 is suitably interpolated, normalized per utterance, and perceptually transformed. Normalized versions of energy and duration remove phoneme-intrinsic influences. To obtain a fixed number of features per utterance, we compute twelve functionals that characterise the statistical and temporal properties of these local descriptors: mean, standard deviation, minimum, maximum, median, quantiles 5%, 25%, 75%, 95%, average absolute local change (similar to Grabe's raw pairwise variability index rPVI [10]), root average squared local change, and slope of the regression line. Depending on the type of descriptor, these functionals are computed across syllables and vocalic/consonantal frames. Additionally, we compute features developed for describing speech rhythm [10, 11, 12]. From this brute-force set, we now manually select and combine the following features suitable to capture the acoustic correlates of sleepiness that can be expected according to the pertinent literature (see e. g. [3] for an overview). The expected sign given in parentheses indicates falling/lower ('$-$') or rising/higher ('$+$') values for sleepy speech; an appended question mark indicates ambiguous tendencies.

spectral features: formants

(1) g-mean(F1–4)_V_mean ($-$): the ***geometric mean of formants F1–F4*** per frame, averaged across vocalic frames. The circadian rhythm includes body core temperature variation [13]; we can assume some decrease with sleepiness. With that, the temperature of the exhaled air drops, too. Therefore, formant frequencies should be shifted slightly downwards [14, 15].

(2) mean(FBW1–4)_V_mean ($+$): the ***arithmetic mean of the formant bandwidths FBW1–FBW4 per frame***, averaged across vocalic frames. Reduced body temperature and muscular relaxation might lead to vocal tract softening and stronger dampening of the signal due to yielding walls [16]. We expect glottal loss and cavity-wall loss for the lower formants, and radiation, viscous and heat-conduction loss for the higher formants [17]. Consistent with that is the increased time of high values for Formant 1 bandwidth in [6].

(3) F1_V_std * F2_V_std ($-$): the ***product of the standard deviations of F1 and F2*** across vocalic frames. The reduced cognitive processing speed going along with sleepiness might lead to impaired neuromuscular motor coordination processes, slowing down the transduction of neuromuscular commands into articulator movement and affecting the feedback of articulator positions [18, 19], possibly leading to aversion of spending compensatory effort [20]. Thus, sleepy speech could exhibit slurred, less crisp pronunciation, mispronunciations, abrupt articulatory changes, speech errors, or hesitations. A less crisp pronunciation might result in vowel centralization and a reduced area covered by the first two formant frequencies, which account for most of the discriminability across vowels.

(4) F1_V_mean ($-?$): the ***average of F1 across vocalic frames***. Sleepy speech is also expected to exhibit changes in speech quality such as tensed, nasal, or breathy speech due to, e. g. impaired coordination of velum closure [21]. The effects of increased nasality are complex: the first formant (F1) gets weaker, and its position moves higher, because nasals are usually pronounced more open. Yet, F1 is likely to be masked by the appearance of the lower and louder first nasal formant, resulting in an opposite tendency. Thus, nasality seems to be difficult to quantify with a simple acoustic parameter. The decrease in F1 for sleepy speech reported in [6] thus cannot be readily assessed: most likely, the decrease is due to the first nasal formant showing up more, and possibly also to reduced body temperature as shown above, these two effects outweighing the opposite tendency due to the expected more open pronunciation.

spectral features: MFCC

(5) MFCC2_V_mean ($+?$): the ***average of the second MFCC coefficient*** across vocalic frames as an estimate of the negative spectral tilt; we expect the spectral tilt to fall with sleepiness, and thus a rise of this feature. Increased breathiness in sleepy speech – see feature (4) – should lead to a negative spectral tilt for high frequencies [22], which seems to be confirmed by [23] where a decrease of the slope of the long term average spectrum is reported. An opposite effect could be caused, however, by a stronger high-pass effected by a more closed mouth position (centralisation) compatible with reduced muscular tension.

(6) MFCC1_V_mean / MFCC1_C_mean ($-$): the ***ratio of the first MFCC coefficient averaged across vocalic frames to its average over consonantal frames.*** The abovementioned losses in resonance (muscular relaxation and reduced body temperature) could lead to a reduced energy in vocalic segments compared to consonantal segments; the first MFCC coefficient is a measure of energy.

(7-10) MFCC2_V_std, MFCC3_V_std, MFCC2_C_std, MFCC3_C_std ($-$): the ***standard deviations of the second and third MFCC computed separately across vocalic and consonantal segments.*** These features describe coarsely the spectrum of the vowels (F1, F2) and of the consonants and can capture less diligent pronunciation (centralisation) [7].

prosody: F0

(11) F0_V_mean ($-?$): the ***average of pitch estimates across vocalic frames.*** The muscular relaxation going along with

sleepiness might lead to a reduced fundamental frequency (F0) as reported in [6, 24, 25], although [26] report the opposite. Since increased breathiness should also go along with reduced F0, there is one more reason to assume a decrease.

(12) F0_V_std / F0_V_mean ($-?$): the ***standard deviation of F0, normalized to the mean F0***, across vocalic frames. For sleepy speech, we anticipate monotonic and flattened intonation [3]: [27, 25] report a decreased standard deviation of F0 although an opposite result has been published in [28]. The standard deviation of pitch is correlated with the absolute pitch level of a speaker; this effect is removed by the normalization.

(13) syl-F0-mean_std ($-?$): the ***standard deviation of the syllables' average F0***; here and in the following, we use the 'nucleus + coda' pseudo-syllables. Now we apply our microstructural prosodic features, where F0 undergoes a different normalization, and perceptual scaling.

(14) syl-F0-max_mean ($-?$): the ***syllables' F0 maxima*** averaged across syllables. Flattened intonation should lead to less pronounced F0 maxima.

(15) syl-F0-min_mean ($+?$): the ***syllables' F0 minima*** averaged across syllables which should rise.

(16) syl-F0-slope_mean ($-$): the ***F0 slope within syllables***, averaged across syllables, expected to fall with sleepiness because of flattened intonation.

prosody: energy

(17) syl-energy-mean-norm_std ($+?$): the ***standard deviation of the syllables' normalized mean energy.*** According to [6], the average absolute deviation of intensity increases with sleepiness. This could be explained as a less diligent or controlled pronunciation, although a flattened intonation might also have the opposite effect.

(18) syl-rel-energy_mean ($-$): a ***medium-term estimate of the relative energy*** (computed for energy normalization purposes [9] from up to 15 neighbouring syllables, taking into account phoneme-intrinsic properties), averaged across syllables. Muscular relaxation might also lead to reduced loudness.

(19) syl-energy-slope_mean ($-$): the ***average energy slope within syllables*** which we expect to fall with sleepiness, due to flattened intonation.

prosody: duration

(20) syl-rel-duration_mean ($+$): ***medium-term estimates of the syllables' relative durations***, averaged across syllables. Slowed cognitive processing reduces speech planning, which might lead to a reduced speech rate [29, 27, 28] and thus to increased durations.

(21-22) syl-pauses_mean, syl-filled-pauses_mean ($+$): the ***average duration of silent and of filled pauses between syllables.*** Along with segment durations, pause length is expected to increase with sleepiness, too [28].

prosody: rhythm

(23) %V ($-$): ***Ramus' %V, the percentage of vocalic intervals*** [11] is expected to fall because the relative frequency of voicing decreases with sleepiness [30].

(24-25) nPVI_V, nPVI_C ($-?$): ***Grabe's normalized pairwise variability index nPVI*** [10], a rate-of-speech-normalized measure of local durational variability, computed separately for vocalic and consonantal segments, is expected to fall with monotonicity (although more disfluencies could also lead to a rise).

(26-27) varco_V, varco_C ($-?$): ***Dellwo's variation coefficients*** [12] are a measure of global durational variability (rate-of-speech-normalized standard deviations of the duration of vocalic and consonantal segments). Again, we expect a decrease, although disfluencies could have the opposite effect.

4. Experiments and Results

4.1. Analysis of single Features

We compute Pearson's correlation coefficient r between the reference sleepiness values and the individual features of each utterance only for TEST; this guarantees strict comparability with the regression results of Section 4.2. Spearman's ρ did not differ much, so we skip it. The results are given in Table 1. These individual correlations are mostly weak; for the weakest correlations, contra-intuitive effects can arise. For instance, feature (3) is negatively correlated to sleepiness for female and male speakers separately, but positively for all speakers together – this can be due to slightly different distributions of feature range and sleepiness score for female vs. male speakers. For males, correlations are mostly stronger (average $|r|$: 0.14 vs. 0.09). Using the same database, we showed in [7] that this can mainly be attributed to females showing their sleepiness less than males do. If we disregard very weak correlations – arbitrarily defined as $|r| < 0.1$ – which might well be caused by noise, given the limited number of speakers – then only 9 out of 81 cases with 'unexpected' sign remain (typeset in italics in Table 1); thus, our predictions of Section 3 are generally corroborated. The correlations of feature (5) are negative, contradicting our expectation; a more relaxed and thus closed mouth position might outweigh the effects of breathiness. Feature (19) displays highly contradicting signs as well. Our conjecture was that flattened intonation would result in negative slopes, for both F0 and energy within syllables. This did turn out right for F0, see feature (16), but not for energy. Feature (2), an estimate of the bandwidth of formants, unexpectedly falls with increased sleepiness for male speakers. One conjecture would be interactions between changes in F0 and formant extraction; but then, these interactions should be stronger for females due to the higher distance between harmonics. Another explanation could be a stronger volitional effort to fight against sleepiness in women, which might lead to muscular tension and vocal tract hardening.

Feature (6), the ratio of the energy of voiced and unvoiced segments, unexpectedly rises with sleepiness for male speakers. An explanation could be a less diligent control of the air stream, possibly resulting in louder vowels for males who tend to show the effects of sleepiness to a higher extent than females [7]. Feature (18) unexpectedly rises for female speakers: the tendency of females to show sleepiness to a lesser extent might lead to overcompensation, resulting in louder speech with clearly articulated consonants (because of the negative sign for (6)).

4.2. Regression Experiments

For robust estimation, ridge regression [31] is used. Parameters are estimated on TRAIN, results are computed on TEST; details are given in [7]. Again, Spearman's ρ is similar to Pearson's r between predicted and reference sleepiness values, so we use only the latter. The results are given in Table 2. If all 3705 features are used, the best result is 0.41 for all speakers. Also here we see higher correlations for male speakers (0.50 vs. 0.34), consistent with the single correlations above.

For the 27 manually selected features, correlations are lower, e. g. 0.33 vs. 0.41 for all speakers, but much better than a pure random selection of 27 features, which results in a correlation of 0.15 for all speakers on average (not displayed in Table 2). When looking at spectral and prosodic features separately, there is another interesting gender effect: for men, spectral features seem to be more suited than prosodic features (0.43 vs. 0.21). It is the other way around for female speakers: here, prosodic features yield better results than spectral features (0.33

Table 1: *Manually selected features and their Pearson correlation r to sleepiness: for all speakers, females (f), and males (m). The absolute value of the correlations is illustrated by the grey level of each cell's background. Grossly unexpected correlations (different sign and $|r| \geq 0.1$) are set in italics.*

vs. 0.20). As for the non-ambiguous features ('−' or '+' without '?' in Table 1), results for all speakers suffer only a little by this restriction (0.30 vs. 0.33). However, now there is hardly a difference between the performance on female and male speakers (0.29 and 0.30). This is quite different when looking at the features we just removed: Training only with the 12 ambiguous features ('−?' or '+?' in Table 1), the performance difference between male and female speakers is more pronounced than ever (0.42 vs. 0.19). A possible explanation for this could be the following: the non-ambiguous features generally model sleepiness changes based on 'physiological primitives' that cannot be controlled very well by the speaker. The ambiguous features, where we identified possible antagonistic influences, however, represent parameters where the speakers do have some choice.

For a data-driven feature selection, we use a so-called wrapper approach, together with a greedy forward search: each time that feature is added which yields the best performance when training and testing the regression system with TRAIN. Here, we discuss the comparable numbers of selected features, namely 27 and 15, respectively. Intriguingly, these yield similar performance compared to the manual feature selection: for 27 features and all speakers, 0.33; for females and males separately, correlations decrease slightly (0.30 vs. 31, and 0.35 vs. 0.40, respectively). The first 15 automatically selected features are slightly better than the 15 manual non-ambiguous features (0.32/0.30/0.35 vs. 0.30/0.29/0.30). One would normally expect data-driven selection to outperform manual selection; however, it has to cope with weak sleepiness effects, facing noisy data from a limited number of speakers, and thus the unavoidable train-test mismatch. In fact, the 9th and the 21th selected feature are our manual features (6) and (10) – a very nice outcome because the probability for this to happen by chance is very low. Generally, the data-driven and manual features are not very similar, at least when compared individually: mean pairwise Pearson correlation between data-driven and manual features is 0.04, mean absolute 0.14. Minimal correlation is -0.53; maximal correlation (apart from the two identical features) is 0.91: between the 95%-quantile of pitch estimates across vocalic frames and our manual feature (11).

Table 2: *Performance when predicting sleepiness from different features. Both male and female speakers were used in training; Pearson correlation on test is reported for all, female (f), and male speakers (m). Higher absolute correlation = darker.*

Features	all	f	m
all (3705)	0.41	0.34	0.50
manually selected (27)	0.33	0.31	0.40
– spectral (10)	0.29	0.20	0.43
– prosodic (17)	0.22	0.33	0.21
manually selected – non-ambig. (15)	0.30	0.29	0.30
– spectral (8)	0.21	0.17	0.26
– prosodic (7)	0.30	0.32	0.21
manually selected – ambiguous (12)	0.16	0.19	0.42
– spectral (2)	0.19	0.16	0.40
– prosodic (10)	0.03	0.15	0.16
data-driven selection of 27	0.33	0.30	0.35
data-driven selection of 15	0.32	0.30	0.35

5. Discussion and Concluding Remarks

Expectably, brute forcing with many features beats knowledge-based selection of features (overall performance not being too high, obviously because sleepiness can only be partly modelled by speech alone, and its indication is partly speaker-dependent/idiosyncratic). However, our knowledge-based vector is on par – and in a few cases, overlapping – with the same number of automatically selected most important features, corroborating our general hypothesis of sleepiness being a relaxation phenomenon. However, females and males display interesting and partly antagonistic tendencies: male sleepiness is mainly reflected by spectral changes towards less canonical pronunciation (centralisation, cf. the MFCC features in Table 1) whereas female sleepiness primarily implies prosodic changes such as lowered pitch (feature 11). All this is in line with our explanation in [7], cf. [32, p. 130] and [33], that women tend towards more canonical speech. Generally, the non-ambiguous 15 features seem to be more 'stable' and more uniformly used by both males and females; in contrast, the 12 ambiguous features (esp. the spectral ones) obviously offer more degrees of freedom, e.g. for females, to 'hide', and for males, to 'express' their sleepiness. Of course, these explanations are tentative and have to be corroborated with future studies and additional data.

Abstract

Over the last century researchers collected a considerable amount of data reflecting the properties of Lombard speech, i.e., speech in a loud environment. The documented phenomena include effects on intensity, fundamental frequency, spectral tilt, speech rate and articulation. Relatively little attention has been paid to the effects on relative extent of movement of individual articulators. In an attempt to fill in this gap we present a preliminary analysis of EMA data collected in increasing levels of babble noise. We introduce HH-index as a measure of overall relative activity of articulators. Our results indicate a non-linearity of the effect of noise on articulatory movement and quantitatively different effects on the movement extent for different groups of articulators. The effects of noise are compared with those brought out by other techniques for eliciting articulatory variation. We also discuss possible application of Lombard speech as an elicitation paradigm for studies of hyperarticulation.

Index Terms: Lombard speech, hyperarticulation, articulatory variation, Slovak, EMA recordings

1. Introduction

Speakers raise their voice when they speak in environmental noise. This adaptation of speech to noise in order to increase the signal-to-noise ratio is called the Lombard effect [1] and is realized by physiological means that have different consequences on speech acoustics. Typically, the speakers increase intensity and f_0, adjust intonational contours [2, 3, 4], and their mode of vocal fold vibration is more pressed decreasing the slope of the glottal voice-source spectrum. The loud environment also affects the duration and spectral characteristics of vowels, shifting the positions of the formants [5, 6].

Compared to the vast body of research focused on acoustic and perceptual correlates of the Lombard effect, experimental articulatory investigations are relatively sparse. Studies primarily focusing on the jaw and lip movements have confirmed that Lombard speech is realized with amplification of articulatory patterns identified in "normal" speech in silent environment, and that the extent of amplification is linked to the type of noise, its loudness and the degree to which speaker's self-monitoring feedback is compromised [7]. The amplification has been shown to involve complex, non-linear reorganization of articulatory movement patterns [8].

In this preliminary study we report the results of analysis of articulatory recording including the lip, jaw and tongue movement. We focus on relative expansion of movement trajectories induced by increasing volume of babble noise as well as on global durational correlates of the Lombard effect. Furthermore, we evaluate the relative sensitivity of individual articulators on the increasing level of noise.

In articulatory terms, the Lombard effect can be interpreted as hyperarticulation. Hyperarticulation – an increase of the extent of articulatory movement – and its hypoarticulation counterpart have been widely studied as the general source of phonetic variation (H&H variation) [9] and as an important factor underlying prosodic phenomena [10]. One of the aims of this work is to assess a possibility of eliciting hyperarticulation using the Lombard effect in a controlled, quantifiable fashion. We also include two additional conditions in our recordings – a hypospeech and a non-native speaker targeting speech – and compare the effects elicited by these paradigms with those brought up by environmental noise.

In order to evaluate the effects of elicitation conditions quantitatively, we introduce a measure of relative articulatory variation, *HH-index*, capturing a proportional increase/decrease of articulatory movement in terms of articulator trajectory.

2. Methods

This study is a part of a larger investigation of the effects of prosody on articulation and inter-articulator timing. Four Slovak stimuli sentences, each containing 17 syllables, were created for a three-way manipulation of utterance-internal boundary strength, resulting in a total of 12 stimuli. With a minimum 5 intended repetitions, each block thus contained at least 60 tokens with the order of stimuli randomised within each block. Non-linguistic manipulation of prosody included the elicitation of hyper- and hypo-articulation in the following way. A reference stimulus block (subsequently referred to as condition *0dB*) was recorded in silence and the speaker was instructed to speak naturally. Three stimuli blocks were produced with three levels of babble noise at the level of 60, 70, and 80 dB – conditions *60dB*, *70dB* and *80dB*, respectively – played over the subject's headphones. Additionally, another block was elicited with no noise, where the speaker was explicitly instructed to use relaxed, hypo-articulated speech (*0dB-r* condition). Finally, the assumed highest level of hyper-articulation was elicited with 80 dB babble noise simulating a communication with a non-native interlocutor (cf. [11]) who was present and visually interacted with the subject (condition *80dB-nn*). The blocks were recorded in the following order: *70dB*, *80dB*, *0dB*, *0dB-r*, *60dB*, *80dB-nn*. Overall, we obtained 365 sentences from one subject, a native Slovak speaker with no speech or hearing impairment.

The articulatory data come from kinematic trajectories of sensors attached to 6 active articulators – lower and upper lip (LL, UL), jaw, tongue tip (TT), tongue body (TB) and tongue dorsum (TD) – obtained using electro-magnetic articulography

(EMA, AG500, Carstens Medizinelektronik, IBS, University of Helsinki). The EMA data were post-processed using TAPAD routines [12]. Audio signal was used for automatic forced alignment using the SPHINX toolkit adjusted for Slovak [13] and the time points of speech initiation and cessation were subsequently manually corrected based on the initial amplitude increase at the beginning, and the cessation of formant structure (for vowels) or voicing (for sonorants), at the end of each sentence.

To assess the quantitative articulatory characteristics for each token we calculated the approximate length of trajectory of each sensor during the utterance. That is, for each time step (determined by sampling rate of the articulatograph, 200 Hz) we calculated the Euclidean distance between subsequent positions of the given sensor in midsagittal plane. The entire trajectory of the sensor during the utterance was then calculated as a sum of these small transitions. This measure of the articulatory activity closely corresponds to the definition of Bounded Variation norm used in [4] for investigating effects of noise on fundamental frequency in Lombard speech.

Naturally, even when no global articulatory variation is elicited, the distance covered by individual articulators varies with their anatomical properties and the segmental characteristics of the stimulus. In our data, for example, the TB sensor moved on average over approx. 340 mm per token, while the UL sensor covered on average less than 70 mm. Consequently, absolute hyperarticulation effects on the distance travelled are considerably greater for "livelier" articulators than for the more restricted ones. As we are primarily interested in relative and stimulus-independent effects on articulation we have normalized the measure defined above in the following way.

The *0dB* condition – the stimuli uttered with no background noise in a natural fashion – was used as a reference. First, for each sensor we computed the mean trajectory length of the recordings of the same stimulus in this condition. Then, in order to factor out the influence of segmental and prosodic structure of different stimuli, we divided the trajectory length of every sensor for every recording in the data-set by this *0dB*-mean value of the corresponding sensor-stimulus combination. We will call the resulting measure of relative hypo-/hyper-articutation the *HH-index* for the given articulator and token. For each token, the mean of *HH-indeces* for 5 out of 6 recorded sensors, excluding UL sensor[1], is referred to as the *overall HH-index* for the token.

Naturally, the mean values of all *HH-indeces* for *0dB* condition are all equal to 1. Greater values indicate proportionally greater articulatory movement; *HH-index* value 2 means that the given articulator (or the group thereof) covered twice the distance than in the reference condition – speaker hyperarticulated. Similarly, values less than 1 correspond to hypoarticulation.

To eliminate the influence of different segmental and prosodic structure of the 12 stimuli, analogous normalization was performed for durations: again, the duration of each token was divided by the mean duration of *0dB* tokens of the same stimulus, yielding the *normalized duration* measure.

As we only have one subject and the normalizations described above removed the influence of speech material, we used a simple ANOVA-based Tukey multiple comparisons of means (with corrected p-values) implemented in R for evaluation of the effects of noise levels as well as the other two manipulations.

[1]We had to skip this sensor as we failed to recover its correct movement for multiple tokens in *70dB*-condition during the post-processing.

3. Results

3.1. Durations

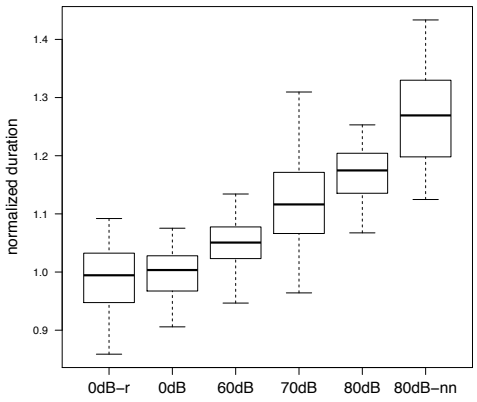

Figure 1: *Normalized durations* per condition.

Fig. 1 summarizes the effects of various conditions on duration of utterances as rendered by the subject. Tukey multiple comparisons of means showed that all differences among mean values for individual conditions are significant ($p < 0.001$), except the *0dB-r–0dB* pair ($p = 0.77$). Moreover, the pattern shown in the boxplot suggests approximately linear dependence of (non-linearly scaled) noise on the normalized duration. The differences between subsequent means, in the order captured in Fig. 1, are: 0.014, 0.050, 0.070, 0.051 and 0.096.

3.2. Overall articulatory variation

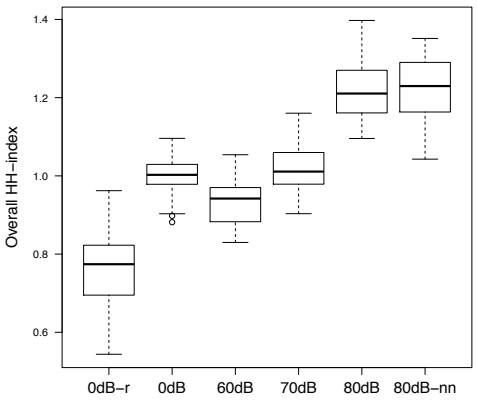

Figure 2: Overall *HH-indeces* per condition.

Fig. 2 shows the distributions of *overall HH-indeces* for individual tokens grouped by conditions. Again, most of the depicted differences are robustly significant ($p < 0.001$). The very strong effect of explicitly induced hypospeech indicates that the articulator trajectory measure as adopted in this work is a viable estimate of the magnitude of HH-variance. The difference of means between *0dB* and *0dB-r* is 0.238, the greatest among all the neighboring pairs; it means that during the "relaxed" speech the selected articulators covered almost one-quarter shorter distance than in the normal reference condition.

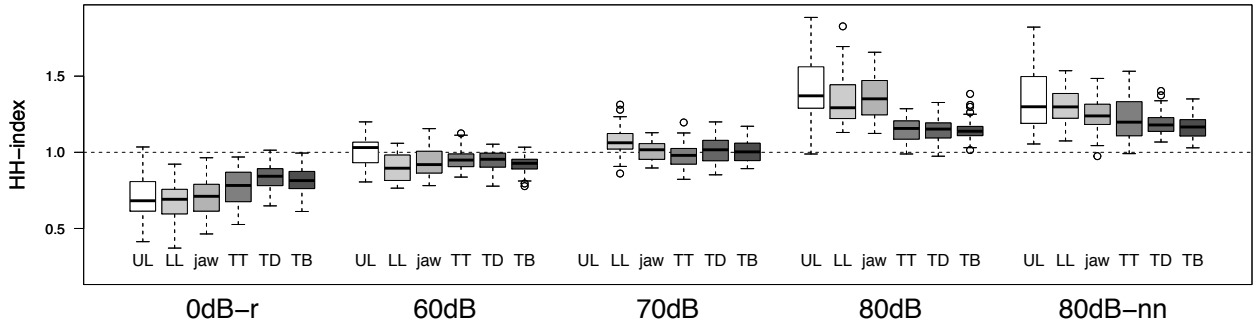

Figure 3: Sensor specific *HH-indeces* per condition.

The difference between means is not significant only in two cases. First is the difference between conditions *80dB* and *80dB-nn* ($p = 0.999$): the non-native speaker directed speech failed to elicit significantly greater articulatory movement, at least in our relatively small data-set.

Second case is the pair *0dB–70dB* ($p = 0.84$). This fact seems to be a consequence of a slightly surprising patterns present in our data. While for the three conditions with noise the mean value of *overall HH-index* significantly increases with the noise intensity, the mean value is actually significantly *lower* for *60dB* condition than for the reference quiet condition.

3.3. Sensitivity of individual articulators

We assessed the behavior of individual articulators – depicted by sensors UL, LL, jaw, TT, TD and TB – with respect to different recording conditions in two steps. First, we analyzed the effect of the conditions on each sensor separately, in a manner analogous to that in Section 3.2. Then, we compared the extents to which different sensors reacted to the influence of noise and the other two recording conditions.

Fig. 3 depicts the distributions of *HH-indeces* for individual sensors (shown in different shades of grey) and different conditions. Due to space restrictions, data for condition *0dB* are not plotted (the means for all sensors were by definition equal to 1 indicated by the dashed line). Also, the values for sensor UL are missing for *70dB*-condition for technical reasons, see Section 2.

The distributions of sensor-specific *HH-indeces* per individual conditions show, by and large, patterns very similar to that identified for the overall *HH-index* (Fig. 3.2). In general, the mean values significantly ($p < 0.001$) increase with increasing level of noise, and the comparison of *60dB* and *70dB* conditions with the quiet condition *0dB* in many cases fail to reveal a significant difference. For all sensors, the mean of *HH-indeces* for *0dB-r*-condition are significantly lower than for every other condition, and for *80dB* and *80dB-nn* conditions the means are significantly higher than for every condition with lower (or no) noise level ($p < 0.001$ in all cases).

Here we list all condition pairs for each sensor for which the difference of means of *HH-indeces* are not significantly different from 0 at $p < 0.001$ in our data set (Tukey multiple comparisons of means test).

For UL, the difference between the means for *60dB* and *0dB* is not significant ($p = 0.99$). For LL, the mean for *70dB* is significantly greater than that for *0dB* at $p < 0.01$. For both lip sensors the difference between *80dB* and *80dB-nn* is not significant ($p = 0.99, 0.86$, for UL and LL respectively).

For the jaw, the difference between *0dB* and *70dB* is not significant ($p = 0.99$), while the means for both *60dB* and *70dB* are both significantly smaller than that for *0dB* ($p < 0.05, 0.01$, respectively). The mean for *80dB* is significantly greater than that for *80dB-nn* ($p < 0.001$).

Interestingly, for TT and TD the relationship between *80dB* and *80dB-nn* is reversed compared to the jaw, the former being significantly lower that the latter ($p < 0.001, 0.05$, respectively). For TB sensor, the *80dB–80dB-nn* difference is also not significant ($p = 0.47$). For all three tongue sensors, the difference between *0dB* and *70dB* is not significant ($p = 0.63, 0.84, 0.84$, for TT, TD, TB, respectively). For TT sensor, neither are the differences between the means for *0dB* and *60dB* ($p = 0.06$) and *60dB* and *70dB* ($p = 0.83$).

Next we looked at differences in articulatory variability between individual articulators in different conditions. Table 1 summarizes the differences between the means of *HH-indeces* for all pairs of articulators (rows) organized by conditions (columns; the p-values are corrected for individual conditions). Figure 3 depicts the general trends.

First, note the very small differences between relative trajectory expansion/shrinking among tongue sensors TT, TB and

Table 1: Differences between mean values of *HH-indeces* for pairs of articulators for different conditions. Asterisks indicate significance of the difference being different from 0: ***:$p < 0.001$, **:$p < 0.01$,*:$p < 0.05$.

TB-LL	0.13^{***}	0.02	-0.07^{***}	-0.19^{***}	-0.14^{*}
TT-jaw	0.07^{*}	0.02	-0.03	-0.21^{***}	-0.02
TD-jaw	0.13^{***}	0.01	0.01	-0.21^{***}	-0.06
TB-jaw	0.11^{***}	-0.02	0.00	-0.21^{***}	-0.09
TD-TT	0.06^{*}	-0.01	0.04	0.00	-0.04
TB-TT	0.04	-0.03	0.03	-0.01	-0.07
TB-TD	-0.03	-0.03	-0.01	0.00	-0.02

TT. The maximal difference is approximately 7 % between TT and TB for *80dB-nn* condition. Only one difference is significant (TD–TT for *0dB-r*, $p < 0.05$) in our data set.

On the other hand, there are relatively robust and in many cases significant differences between reaction of the tongue and lip-jaw articulatory systems on most conditions. The greatest differences between articulators from these groups can be seen in condition *80dB*. In this case, the lips and the jaw expanded their trajectory compared to the reference condition (*0dB*) by some 20–30 % more than the tongue articulators; all increases were significant. Smaller effect is present for *60dB* and *70dB* conditions. Interestingly, while in condition *70dB* LL trajectory expanded significantly more than tongue sensor's ones, it expanded significantly *less* than TT and TD trajectories in *60dB* condition. In the latter condition, however, UL trajectory shows significantly greater expansion of UL sensor relative to the tongue (unfortunately, data for UL in *70dB* are missing in our analysis). The jaw has not shown any significant differences compared to the tongue articulators in these two conditions.

The trend reversal suggested by LL sensor continues for the hypoarticulated condition *0dB-r*: with one exception (TT–LL), the effect is significantly greater for the tongue than for the lip-jaw articulators.

Within the lips-jaw system the results generally support the above observation of the greatest sensitivity of UL sensor compared to the LL and the jaw. The mean *HH-index* for UL is greater than both for LL (significantly so for *60dB* and *80dB*) and for the jaw (significantly for *60dB*, *80dB* and *80dB-nn*). Comparison between LL and the jaw reveals significant difference only in *70dB* condition.

Finally, for *80dB-nn* condition, the relative articulator sensitivity shows similar patterns to that of *80dB*, however, (with an exception of the UL sensor) the observed differences are generally not significant.

4. Discussion and conclusions

In the presence of a loud background noise, the utterances expand in duration and, at least in the case of 80 dB babble noise, also in the extent of articulatory movement. While temporal expansion seems to be approximately linear with logarithmic increase of the noise level, our results suggest a non-linear effect on articulatory trajectories. The overall effect on articulation seems to be negligible (or even, counterintuitively, negative) for lower noise levels, however, at the level of 80 dB the lengthening of trajectories is robust for all articulators.

Admittedly, the reported non-linearity can arise from various sources, predominantly the relatively small size of our data set limited to a single speaker. A possible source can also be the order in which the analyzed tokens were recorded: the reference, *0dB* stimuli were recorded right after the loudest *80dB* block, while *60dB* block followed the hypoarticulated *0dB-r* condition; clearly, some carryover effect could have influenced our measurements. At the same time, the lack of effect for the lower noise levels is intriguing as the subject was immersed in the noise through headphones with no self-monitoring feedback while he was wearing no headphones in quiet conditions: attenuating the external auditory feedback is to be expected to elicit a Lombard effect on its own even without the noise [14]. In any case, these initial findings warrant further investigation with additional speakers, randomized elicitation order and different ways of presenting/blocking self-monitoring feedback.

The robust effect of explicitly induced hypoarticulation (*0dB-r*) on both overall and articulatory specific *HH-indeces* in an expected direction justifies this measure as a way of quantitatively evaluating articulatory variation along HH dimension. As *HH-index* evaluates purely spatial extent of articulation and not articulatory velocity and/or duration, it can be used in a complementary fashion to other measures like the (normalized) duration used here. (Note the apparent "orthogonality" of the two measures for *0dB–0dB*-r and *80dB–80dB-nn* condition pairs.)

Furthermore, our results show that the Lombard effect is a viable methodology for eliciting global articulatory variation (more precisely, hyperarticulation) in a controlled manner: at least the loudest noise condition resulted in significant global and sensor-specific hyperarticulation patterns. In our limited data set, the other method intended to produce extra hyperarticulation – addressing non-native speaker (*80dB-nn*) – resulted in considerably longer durations but failed to elicit more overall articulatory movement compared to its nearest counterpart (*80dB*). To further evaluate and compare these two methods of triggering hyperarticulation, a condition when the subject speaks to non-native listener in quiet condition will be included in the follow up experiments.

The data analysis revealed interesting – albeit not altogether unexpected – patterns regarding relative sensitivity of articulators to conditions. Behavior of the articulators follows a plausible division to three anatomically meaningful groups: the tongue articulators, the lower lip-jaw system and the upper lip. In general, the sensors placed on the tongue exhibited mutually similar behavior as did the LL-jaw articulators, although the latter were more sensitive to noise-induced variations (at least for louder noise levels). The upper lip was still more sensitive. The greater sensitivity of the lips and the jaw is shown also for hypospeech, where the movement extent attenuated more for these articulators than for those of the tongue.

Two slightly different explanations can account for this phenomenon. It is possible that the greater extent of hyperarticulation for the lips and the jaw is specific to Lombard speech, in line with the other known correlates of the Lombard effect. Greater opening of the mouth simply contributes to better "audibility", salience in a loud environment, alongside increased loudness, pitch and spectral adjustments. The increase in motion of the visible articulators can also assist the interlocutor in parsing what has been said [15]. The observed effects on the tongue can be just a straightforward consequence of the more extensive movement of the anatomically connected jaw. Alternatively, the greater effect on the lips and the jaw compared to the tongue can be a consequence of greater freedom of the former in terms of physiological constraints and acoustic consequences of increased variation. In both aspects the tongue is more restricted than the jaw and the lips. In this case, the different sensitivity could be a hallmark of H&H variation in general, and has to be taken in consideration in research involving articulatory variation, for example, coarticulatory effects of bilabials and vowels in stressed vs. unstressed syllables. Our results provide a tentative support to both these interpretations: the differences in articulator sensitivity between *80dB* and *80db-nn* conditions for the former and the consistency of the *0dB-r* patterns with the general trend for the latter. More data and further research are required to shed more light on this issue.

A Study of Human Perception of Intonation in Domestic Cat Meows

Susanne Schötz and Joost van de Weijer

Lund University Humanities Lab, Centre for Languages & Literature, Sweden

susanne.schotz@ling.lu.se, vdweijer@ling.lu.se

Abstract

This study examined human listeners' ability to classify domestic cat vocalisations (meows) recorded in two different contexts; during feeding time (food related meows) and while waiting to visit a veterinarian (vet related meows). A pitch analysis showed a tendency for food related meows to have rising F_0 contours, while vet related meows tended to have more falling F_0 contours. 30 listeners judged twelve meows (six of each context) in a perception test. Classification accuracy was significantly above chance, and listeners who had reported previous experience with cats performed significantly better than inexperienced listeners. Moreover, the two food related meows with the highest classification accuracy showed clear rising F_0 contours, while clear falling F_0 contours characterised the two vet related meows that received the highest classification accuracy. Listeners also reported that some meows were very easy to classify, while others were more difficult. Taken together, these results suggest that cats may use different intonation patterns in their vocal interaction with humans, and that humans are able to identify the vocalisations based on intonation.

Index Terms: Animal–Human Communication, Human Perception of Pet Prosody, Prosody of Domestic Cat Vocalisations

1. Introduction

There is much anecdotal evidence of pets – especially cats and dogs – imitating speech when interacting with humans. This is probably a learned skill used to elicit certain responses or rewards, e.g. food, from their human caretakers. Because of the position of their larynx, nonhuman mammals are able to articulate only a limited number of the vowel and consonant sounds of human language (see e.g. [1]). However, many animals can produce extensive vocal variation in duration, F_0 and sound pressure level (intensity), and should be able to adopt prosodic patterns similar to those used in human speech. Ohala [2] describes several prosodic features related to the *frequency code*, which are used in animal communication, e.g. low F_0 and resonances to signal large size and dominance.

Despite a recent increase in mammal vocalisation studies (see e.g. [3]), phonetic studies of pet vocalisations are fairly scarce, and very little is known about the prosodic aspects of pet vocalisations in pet–human communication. To what extent do pets use the frequency code when interacting with humans? Do pets learn to adopt human-like prosodic patterns, such as rising and falling intonation, when signalling different vocal messages to humans? How are prosodic patterns in pet vocalisations perceived by human listeners? Phoneticians who are pet owners can hardly avoid noticing the varied and often human-like prosodic patterns used in human-directed pet vocalisations. This study is an attempt to shed some light on these issues by examining human perception of different intonational patterns in cat vocalisations.

1.1. Cat vocalisations

The cat (Felis catus, Linneaus 1758) was domesticated 10,000 years ago, and has become one of the most popular pets of the world with more than 600 million individuals [5, 6]. Cats are social animals [4], and their interaction with humans has over a long time of living together resulted in cross-species communication that includes visual as well as vocal signals. Although there are several descriptions of the communicative social behaviour of the domestic cat (see e.g. [5, 4, 7]), the ones concerning vocalisations are scarce and often fragmented. It is still unclear how cats combine different sounds, and how they vary intonation, duration and intensity to convey or modulate a certain vocal message.

The vocal repertoire of the cat is characterised by "an indefinitely wide variation of sound and of patterning". Cat vocalisations are generally divided into three major categories: (1) sounds produced with the mouth closed (murmurs), such as the purr, the trill and the chirrup, (2) sounds produced with the mouth open(ing) and gradually closing, comprising a large variety of meows with similar [ɑːou] vowel patterns, and (3) sounds produced with the mouth held tensely open in the same position, i.e. sounds often uttered in aggressive situations, including growls, yowls, snarls, hisses, spits, and shrieks [8, 4].

1.2. The meow

In cat–human communication, the most common vocalisation is said to be the *meow* or *miaow* [9]. Nicastro [10] defines the meow as a quasi-periodic sound with at least one formant and with diphthong-like formant transitions. The duration ranges from a fraction of a second to several seconds, and the F_0 contour is generally arch-shaped with the tonal peak marking the maximum mouth opening of the opening-closing gesture. Meows can include atonal features and may be garnished with an initial or final trill or growl.

McKinley [11] divided the meow type vocalisation into four sub-patterns based on the pitch and vowels included in the sound: the mew, a high-pitched call with [i], [ɪ] or [e] quality; the squeak, a raspy nasal high-pitched mew-like call; the moan, an [o]- or [u]-like opening-closing sound; and the meow, a combination of vowels resulting in a characteristic [iau] sequence.

Cats learn to produce different meows for different purposes, e.g. to solicit feeding, to gain access to desired locations and other resources provided by humans. Each meow is believed to be "an arbitrary, learned, attention-seeking sound rather than some universal cat–human 'language'" [7]. If each cat and owner develop their own arbitrary vocal communication codes, other humans would be less able to identify meows uttered by unfamiliar cats. However, if cat vocalisations contain some kind of functional referentiality (cf. [9, 12]), i.e. that each vocalisation strongly correlates with a certain referent and also that perceiver responses correlate with the vocalisation, then ex-

perienced humans should be able to classify meows produced by unfamiliar cats fairly well.

Nicastro & Owren [9] asked naïve and experienced listeners to judge meow calls from twelve cats recorded in five different behavioural contexts (food-related, agonistic, affiliative, obstacle, and distress). Classification accuracy was modestly (but significantly) above chance, and it was suggested that meows are unspecific, negatively toned sounds that attract the attention of humans, but that humans can learn to appreciate meows as they become more experienced.

Schötz [13, 14] made a duration and F_0 analysis of 795 cat vocalisations and found that within each vocalisation type (including the meow) durations were fairly similar, but the overall F_0 variability was high, partly due to the large number of different intonation patterns.

1.3. Purpose, aims and hypotheses

The purpose of this study was to investigate human listeners' perception of domestic cat vocalisations of the same type (the meow), with similar durations, but with different intonation patterns. By asking listeners to classify a number of meows as belonging to one of two contexts: food related or vet related, our aim was to find out which intonation patterns are more often associated with food related vocalisations and which are more vet related. A larger goal was to learn more about how humans perceive prosodic cues in cat vocalisations and to increase our understanding of cat–human vocal communication.

Based on our own previous experience of these types of meows, as well as on pitch patterns used in human speech and also related to the *frequency code*, we expected the meows of both contexts to be of similar duration and mean F_0, but we expected a higher number of rising pitch patterns in the food related meows than in the vet related meows. We also hypothesised that experienced human listeners would judge the meows more often correctly than inexperienced listeners and also be more confident in their responses. Moreover, we hypothesised that meows with rising intonation patterns would more often be judged as food related meows than vet related meows.

2. Method

2.1. Material

Three young domestic cats: Donna, Rocky and Turbo (D, R and T; 1 female, 2 males, all three year old siblings from the same litter) were recorded in two different contexts: 1) in a familiar environment, i.e. in their home kitchen while waiting to be fed and 2) in an unfamiliar environment, i.e. in the waiting room (or in a car outside) of a veterinary clinic. The equipment consisted of a Sony digital HD video camera HDR-CX730 with an external shotgun microphone Sony ECM-CG50. Audio files (wav, 44.1 kHz, 16 bit, mono) were extracted with Extract Movie Soundtrack, and the vocalisations segmented, extracted and normalised for amplitude in Praat [16]. Six meows from each context produced by two of the cats (D and T) were selected as material, based on the overall recording quality and on judgements of the owner (one of the authors) of how representative the vocalisations were for each context. As one cat (R) was quiet during the recordings made in the vet context, no meows from this cat were used in the experiment. An auditive analysis of the material by one of the authors revealed that the food related meows tended to have rising tonal patterns, while veterinary related meows had slightly arched or falling intonation. In addition, we noticed slight variations in the background noise, including a few instances of background human speech, but this was judged to have a neglectable influence on the perception task.

Measures of duration and F_0 were obtained with a Praat script and manually checked. One meow was significantly shorter than the other vocalisations, but we decided to keep it in order to get a first impression of how stimulus duration would influence the perception results. The other stimuli ranged between 0.58 and 1.13 seconds in duration. All stimuli contained vowels belonging to the meow type, as described by McKinley [11], and were judged as clearly distinguishable from other common cat vocalisation types, including the purr (cf. [15]), the murmur (cf. [13]) and the chirp (cf. [14]). The longer meows were often garnished by short initial trills. Table 1 shows the duration, and the mean, minimum, and maximum F_0 values for the twelve meow stimuli. Figure 1 displays F_0 contours of the meows of the two contexts.

Table 1: *Duration (sec.) and F_0 (Hz) values for the 12 meows in two contexts (Food, Vet) by two cats (D, T).*

meow	duration	mean F_0	min F_0	max F_0	F_0 range
Food D 1	0.78	739	528	939	411
Food D 2	0.91	888	541	1003	462
Food D 3	0.27	797	782	816	34
Food T 1	1.06	532	418	582	164
Food T 2	0.85	539	423	653	230
Food T 3	1.03	567	433	640	207
Vet D 1	1.10	790	715	887	172
Vet D 2	0.80	838	764	924	160
Vet D 3	0.58	915	885	947	62
Vet T 1	1.13	510	451	589	138
Vet T 2	0.87	697	639	737	98
Vet T 3	1.02	540	487	570	83

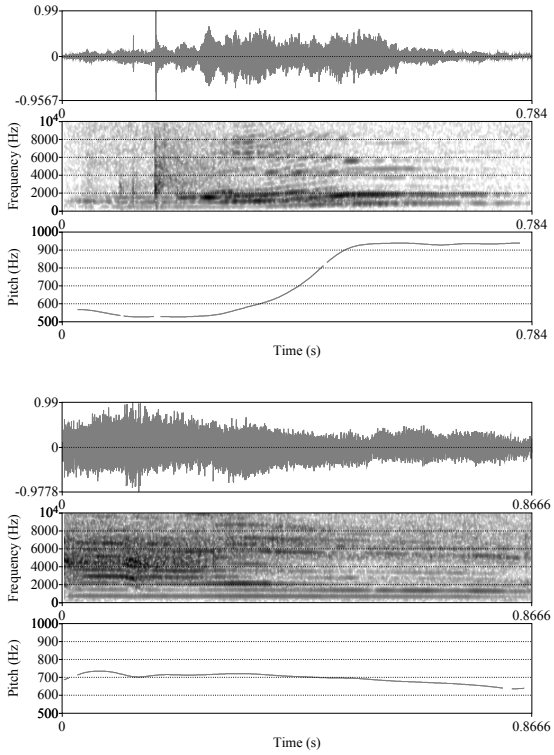

Figure 2: *Waveforms, broadband (300 Hz) spectrograms and F_0 contours of a typical food related meow (top) and a typical vet related meow (bottom).*

2.2. Procedure

The experiment was designed as a multiple forced choice identification test using the ExperimentMFC function in Praat. A group of 15 men and 15 women volunteered as participants. Their average age was 44 years (range 23 to 69 years). Of the participants, 21 reported being familiar with cats, that is, they either owned a cat at the time of testing, or they had owned a cat prior to the experiment. The time that these participants had owned a cat varied from less than one year to a maximum of 55 years (median 2.5 years). Oral and written instructions were given before the experiment, in which the task was to classify each meow as belonging to either the food context or to the vet context by clicking on the appropriate box on a computer screen. The experiment ran on an MacBook Pro computer in a quiet room. Each of the twelve meow recordings were presented three times in a randomised order through HUMP NF22A speakers or AKG K270 studio headphones at a comfortable sound level. A replay option allowed the participants to listen to each stimulus up to three times. After the test, the participants were asked to make a single judgement of the degree of certainty of their responses on a 5-point scale. Each session lasted about 3-4 minutes.

3. Results

Of all 1080 responses in the experiment 529 were food related and 551 veterinary related. In total, there were 699 correct responses (65%). The participants who reported familiarity with cats were more often correct (70%) than the participants who did not (54%).

Table 2 displays the proportions correct as well as the average reaction time for every meow stimulus. As shown in the table, there was one meow (Food D 3) that was classified incorrectly considerably more often than the other meows. This meow was exceptionally short compared to the other stimuli (cf. Table 1), and presumably contained too little information for the participants to make good judgements.

Table 2: *Percentage of correct responses and average response time (RT) for the 12 meow stimuli in the two contexts (Food, Vet) by two cats (D, T).*

meow	correct	RT (ms)
Food D 1	0.83	2342
Food D 2	0.80	2419
Food D 3	0.37	2635
Food T 1	0.54	2944
Food T 2	0.66	2673
Food T 3	0.62	2706
Vet D 1	0.63	3012
Vet D 2	0.57	2904
Vet D 3	0.68	2544
Vet T 1	0.71	2658
Vet T 2	0.71	3127
Vet T 3	0.64	3044

The F_0 contours of the two stimuli of each context category that received the highest proportion of correct classifications are the ones drawn in black in Figure 1. For the food related meows, these contours show clear rising intonation patterns, while the vet related meows that received the highest number of correct classifications generally display more falling contours.

We performed a multilevel logistic regression (with random stimulus and subject intercepts) on the results in two steps. In the first step we did not include any predictors of interest other than the intercept. The results of this analysis indicated that the overall intercept differed significantly from zero ($B = 0.7615$, $SE = 0.2529$, $z = 3.011$, $p = 0.0026$), which suggests that the overall number of correct responses was significantly above chance.

In the second step, we added the familiarity predictor to the first model. This predictor had a significant effect ($B = 0.8908$, $SE = 0.3611$, $z = 2.467$, $p = 0.0136$) and overall the second model was significantly better than the first ($\chi^2 = 5.5767$, $df = 1$, $p = 0.0182$). This suggests that the participants who were familiar with cats performed significantly better than those who were not.

We also tested whether the number of years that the participants had owned a cat was a better predictor than the familiarity, but this turned out not to be the case. In fact, number of years had a non-significant effect on the dependent variable, suggesting that participants who owned a cat for a longer period of time did not score better than those who owned a cat for a relatively short time.

The participants who were familiar with cats were not only more often correct in their answers, they were also more confident in their answers. The average confidence rating given by participants familiar with cats was 2.86, whereas that given by the other participants was 1.78. This difference was tested in a linear regression analysis, which showed that it was significant ($B = 1.0794$, $SE = 0.4133$, $t = 2.612$, $p = 0.0143$).

Finally, we examined the relation between the acoustic measurements of the stimuli shown in Table 1 and the judgements made by the participants. Given the high degree of correlation between the different F_0 variables, we used only F_0 standard deviation in combination with duration as predictors of the participant choices in a multilevel logistic regression analysis. The results showed that F_0 standard deviation was a significant predictor ($B = -0.0069$, $SE = 0.0008$, $z = -8.705$, $p = 0.0000$), while duration was not ($B = 0.3969$, $SE = 0.3502$, $z = 1.133$, $p = 0.2571$). The relation between F_0 standard deviation and the listener's judgements is visualised in Figure 3. The lower the F_0 standard deviation of the stimulus, the more often it was classified as a vet related vocalisation.

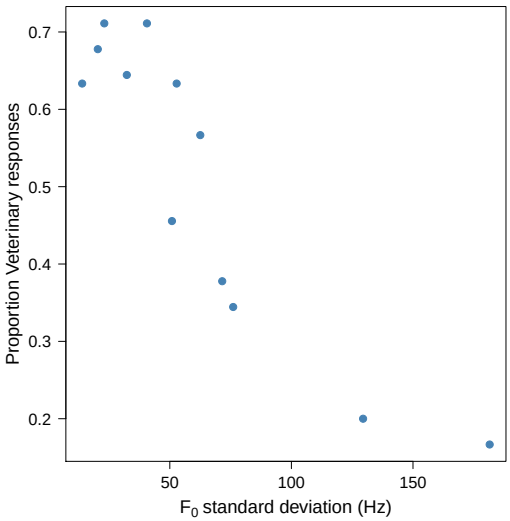

Figure 3: *Relation between F_0 standard deviation and participant choice.*

4. Discussion and future work

The results of the experiment showed that listeners were able to identify domestic cat meows from two different contexts significantly better than chance, and that experienced listeners were better judges than inexperienced ones. Moreover, there was a tendency to judge meows with rising intonation as food related, and falling intonation as vet related. Our acoustic analysis showed that the food related meows tended to have rising F_0 contours often in combination with high F_0 range, while the vet related meows often had slightly falling F_0 patterns, often accompanied by a low F_0 range. It is also possible that the listeners were influenced by these differences in F_0 range and interpreted them as expressions of different emotions; food related stimuli as happy with high F_0 range, and vet related stimuli as sad with low F_0 range.

A majority of the participants made the additional comment that some meows were quite easy to judge, while others were much more difficult. The meow with the shortest duration was often found extremely difficult to classify. Some of the listeners reported that they recognised some of the meows as similar to those of their own cats. This may suggest that different cats produce similar vocalisations in the contexts used in this study. In a future study, we will ask listeners to judge the difficulty of each individual stimulus, and also investigate the phonetic differences between vocalisations that were easy and more difficult to classify.

Several participants reported that they quickly adopted a classification strategy which they used consistently throughout the rest of the experiment even when uncertain of the success rate of this strategy. One strategy would be to listen to the intonational contours of the meows, and judge all rising patterns as belonging to one context, and all falling patterns to the other context. Another possible strategy would be to listen to the vowel quality of the meows. In this study, we did not measure formant frequencies of the vowels included in the stimuli. However, we will examine vowel quality of the cat vocalisations more carefully in future studies, and also systematically study the sound pressure level contours – including the timing of the intensity peaks – of the different meows. It is possible that we will find differences between different types or context meows.

Our study suggests that cats can learn to manipulate prosodic patterns in their vocalisations in order to better elicit the desired response from their human companions. Similarly, many humans adapt their speech or speaking style to their pets by using some kind of "pet talk" (see e.g. [17]). It is not unlikely that pets and their owners together develop a set of different prosodic patterns to improve inter-species communication. We hope to investigate this further in a future phonetic study of pet–human dialogues.

As far as we know this is one of the first phonetic studies of intonation in human-directed cat vocalisations, and there are numerous questions yet to be answered in order to better understand how cats and other pets use prosody in their vocal interaction with humans. Although this study examined a very limited number of meows from only two cats, our hypotheses that humans can judge similar cat vocalisations that differ in intonation patterns significantly better than chance and that experienced listeners perform better than inexperienced ones were confirmed. In future studies, we intend to investigate other parameters, including F_0 direction and movement, vowel quality and dynamics (diphthongisation) as well as intensity. We will also examine sounds produced to gain access to desired locations behind an obstacle (cf. [9]), and additional vocalisation types, such as the murmur and the trill, which are common in cat–human communication [13]. We will also try to include cats of a variety of breeds and cats from different countries in order to learn more about the geographical and dialectal variation in cat vocalisations.

5. Acknowledgements

The authors gratefully acknowledge support from the Linnaeus environment Thinking in Time: Cognition, Communication and Learning, financed by the Swedish Research Council, grant no. 349-2007-8695. A warm thanks to the cats Donna, Rocky and Turbo for their patience during the recordings of the material for this study. We are also very grateful to all the participants in our experiment.

Observation of so-called "pursed-lip" and "curled-lip" utterances in Japanese, using video and MRI images

Chunyue ZHU [1], *Toshiyuki SADANOBU*[2]

Abstract

The Japanese language includes utterances described by the idioms "speaking with pursed lips" and "speaking with curled lips." This study employs video and MRI imaging to examine the articulatory characteristics of these utterances ("utterances P" and "utterances C", respectively) by comparing their articulation with that of "unmarked" utterances ("utterances U"). Through doing so, we arrive at the following four conclusions: (1) For the articulation of utterance P, the lips are projected outward, and rounded by expanding in the vertical direction and narrowing in the horizontal direction. (2) For the articulation of utterance C, curling the lips is not an absolute requirement. The articulation of utterance C is similar with that of utterance P in that the lips are projected outward and rounded. (3) Utterances P and C differ in two points: (a) Lips projection accompanies the lower jaw projection only in utterances P; (b) Lips in utterance P is wider than those in utterance C. (4) The shapes the lips make in utterance P, utterance C, and utterance U can be described as a circle, a horizontal rectangle, and a horizontal oval, respectively. (5) There are many facts that contradict the accepted theory that "Rounding the lips causes both lips to project outward. In reaction to this movement, the surface of the tongue is pushed toward the rear" (Koizumi 1989).

Index Terms: "pursed-lip utterances", "curled-lip utterances", video images, MRI images

1. Introduction

Although there has been considerable research on fundamental frequency, amplitude, and timing of speech, it was not until the 21st century that researchers began to conduct close investigation into voice-quality of speech ([1]). Previous studies on various voice qualities in Japanese everyday speech adopt either quantitative approach ([1]) or qualitative approach ([2][3]). This study is a first step toward the comprehensive description of Japanese voice qualities by using qualitative and quantitative approaches both.

The specific topic of study consists of three types of articulation in contemporary Japanese communication. These three types of articulation can be described in approximate terms as the articulation of speech described in the Japanese idiom "*kuchi o togarasete mono o iu"* (*"*to speak with pursed lips"), the articulation of speech described in the idiom "*kuchi o yugamete hinan suru"* (*"*to criticize with curled lips"), and the articulation of "unmarked" common speech. However, strictly speaking these descriptions differ a little from the actual facts of the matter.

The Japanese idiom "to speak with pursed lips" refers to a childish way of speaking that expresses displeasure or dissatisfaction ([4]). However, there is another way of speaking that is highly similar to this one, used by adults to express timidity. While the intuition of native speakers tells us that these differ, for purposes of describing them in print they will be treated together here. This paper will attempt to make clear the features of these articulations of "speaking with pursed lips". We will refer to these ways of speaking as "utterance P" hereinafter.

Another Japanese idiom, "to criticize with curled lips," refers to a way of speaking that expresses a feeling of contempt. For example, the phrase "'*Ore wa ee nen kedo na,' tte, ano hito konna koto iun da yo"* (*"*He says, 'I don't care'") spoken with curled lips expresses contempt for the object. However, the intuition of a native speaker tells us that the part spoken with curled lips is not the criticism portion ("*ano hito konna koto iun da yo"*) but the speech repeated as the object of contempt ("*Ore wa ee nen kedo na"*). This paper will attempt to make clear the features of this articulation. We will refer to utterance spoken in this way as "utterance C" hereinafter.

In contrast to utterance P and utterance C, we will identify as utterance U speech that contains no feeling of displeasure, dissatisfaction, timidity, or contempt.

This study will attempt to elucidate, through empirical methods, the actual state of the articulations of these three types of utterances. We used two high-definition video cameras positioned on the front and the side of the face to record the movements of the entire face, including the speech organs, in order to examine the external properties of the speech organs and MRI imaging to record the movements of articulation in order to examine the internal properties of the speech organs, such as the shape of the vocal tract, and we analyzed the results.

2. Methods

2.1. Experiment participant

At this stage, the experiment participant is one speaker of standard Japanese who resides in the Kansai region. This is because it was not easy to find speakers who could clear the strict requirements of MRI imaging.

2.2. Spoken text

As the spoken text, we chose the following three sentences, for which the style of speaking would be easy to recall when speaking them.

a. Iyaa, chotto sorewa muzukashiisu nee. (VIDEO, MRI)
'That's hard!' (utterance P, utterance U)
b. Orewa eenenkedo na. (VIDEO, MRI)
'I don't care.' (utterance C, utterance U)
c. Sonnano muzukashii yo. (VIDEO)
'That's hard!' (utterance P, utterance C, utterance U)

2.3. Equipment used

Video camera: CANON ivis HF M32 × 2

MRI: Siemens MAGNETOM Verio (3T)

2.4. Methods of imaging

2.4.1. MRI imaging

Instead of recording video images in real time, it is possible to construct video data by repeating the same utterance 96 times, using recording that synchronizes the timing of imaging and speech using two types of trigger signals: a scan signal and a noise burst ([5][6]). In this experiment, we used this video imaging method to record images of a median sagittal plane at a resolution of 1 mm × 1 mm per pixel and a thickness of 3 mm per slice, creating a video image at 60 frames per second. We recorded the speech spoken during the experiment simultaneously.

2.4.2. Video imaging

We used two high-definition video cameras with resolutions of 1920 × 1080 pixels, one positioned in front of the speaker and one to the side of the speaker, to record speech simultaneously.

3. Qualitative analysis of the data

3.1. Qualitative analysis of the video images

Figures 1 and 2 superimpose tracings of utterance P, utterance C, and utterance U from the images recorded using the front and side video cameras, respectively. (Solid lines: utterance U, dotted lines: utterance P, dashed lines: utterance C.)

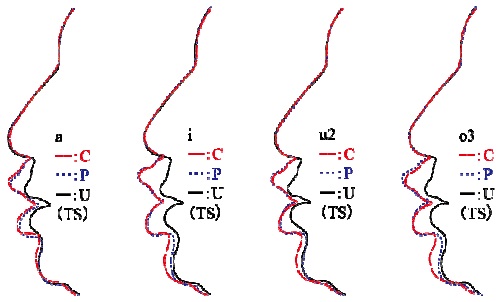

Figure 1: *Lip formations (side) of utterance P, C, and U*

Compared with utterance U, utterance P is characterized as prominent projection of lips, and utterance C of lower jaw.

From Figure 1, one can see the degree to which the lips project in comparison to utterance U and the changes in the position of the lower jaw when pronouncing each vowel /a//i//u//o/. Observation of vowels were conducted on their constant and steady region, and this is also the case with quantitative analysis.

We were able to confirm that while the lips project further in utterance P than in utterance U, the lower jaw projects only slightly. For this reason, the articulation of utterance P can be said to come mainly from projecting the lips.

While in utterance C the lips project to about the same degree as in utterance P, the lower jaw projects markedly forward.

Figure 2 is one example of a tracing of the outline of the lips during the steady-state parts of vowels in each utterance, recorded from the video camera set up in front of the speaker. The shaded area in the center of each image represents the opening of the lips as seen from the front (the narrowest part of the vocal tract opening), while the second line from the outside is the boundary between the lips and the mucous membranes inside the oral cavity that can be seen when the mouth is shut at rest. The properties of the lip formation when pronouncing each of the vowel sounds /a//i//u//o/ observed from these images are outlined below.

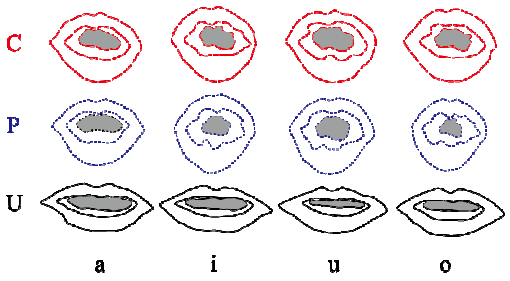

Figure 2: *Lip formations (front) of utterances P, C, and U*

The lips form, respectively, a circle, a horizontal rectangle, and a horizontal oval.

For utterance U, the lips cannot be described as being opened very wide in the vertical direction and the opening in the horizontal direction is unchanged from when the mouth is shut at rest. Using utterance U as the basis for articulation, in both utterance P and utterance C both the narrowness of the lips in the horizontal direction and the large opening in the vertical direction are prominent.

A look at the shape of the lip opening shows that in general the property of the lips rounding to form a circle is pronounced in the case of utterance P, while in utterance C the lips both round and extend in the horizontal direction.

In sum, for utterance P, utterance C, and utterance U the lips form, respectively, a circle, a horizontal rectangle, and a horizontal oval.

3.2. Qualitative analysis of the MRI images

Figure 3 uses MRI images to compare U and P pronunciation. It overlaps two tracings based on the part that

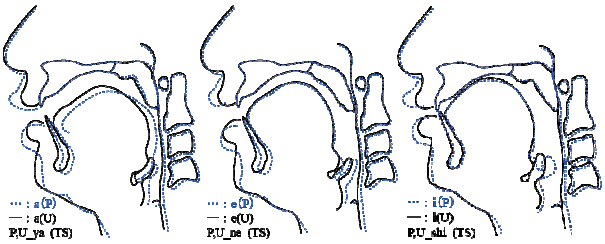

Figure 3: *Form of vocal tract in utterances U and P (MRI)*

Compared with utterance U and P is characterized as the forward projection of the lips. The mouth is openes in the vertical direction in the left and middle drawings, but not in right drawing. In utterance P, the lower jaw also often opens. The tongue doesnot show any movement toward the read in the middle and right drawings.

does not move during pronunciation (the front palate, including the upper jawbone).

From this figure, the following three points are clear.

(1) While the forward projection of the lips stands out more in utterance P than in utterance U, in some cases this accompanies the opening of the mouth in the vertical direction (as in the left and middle drawings) while in other cases it is due to projection alone (as in the right drawing).

(2) In utterance P, in many cases the lower jaw also opens. In such cases, the jaw-opening method basically is through a hinged movement with the temporomandibular joint serving as the axis.

(3) While the accepted theory holds that "Rounding the lips causes both lips to project outward. In reaction to this movement, the surface of the tongue is pushed toward the rear" ([7]), actually many facts contradict this accepted theory, since as seen in the middle and right pictures of Figure 3 in many cases the tongue itself does not show any movement.

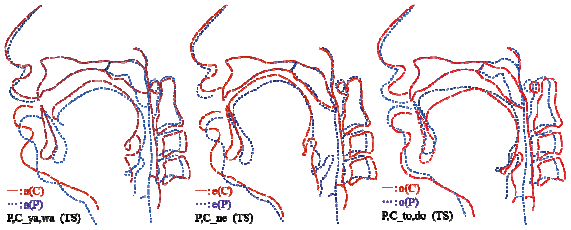

Figure 4: *Shapes of the vocal tract during utterances P and C (MRI)*
Utterances P and C have the projection of the lips in common. In utterance P the lower jaw mainly simply opens through a hinged movement of the temporomandibular joint (change in angle). In utterance C the jaw lowering involves projection of the lower joint forward. In utterance C the lips often appear to thin.

Figure 4 compares P and C pronunciation by overlapping their MRI tracings in the same way as Figure 3. As we saw in Figure 1, while utterance P and utterance C have the projection of the lips in common, they differ considerably in the way the lower jaw moves. While in the former case the lower jaw mainly simply opens through a hinged movement of the temporomandibular joint (change in angle), the latter case involves projection of the lower joint forward. In addition, in many cases in utterance C the lips appear to thin. This probably is because in the case of utterance C the lips not only project forward but also elongate in the horizontal direction. (Also see Figure 2.) Tongue back of vowels /a/ and /e/ is raised much higher in utterance C than in utterance P.

4. Quantitative analysis of the data

We measured the angles and vertical and horizontal widths of the lips in the video images taken from the front and side views and compared and analyzed the findings.

4.1. Measurement method

In our quantitative analysis of the video data filmed from the front, we measured and recorded the figures for the following five points.

(1) Horizontal width of the outer perimeter of the lips (AB in Figure 5)

(2) Height of the outer perimeter of the lips (CD in Figure 5)

(3) Horizontal width of the lip opening (narrowest part) (EF in Figure 5)

(4) Height of the lip opening (narrowest part) (GH in Figure 5)

(5) Horizontal angle of the lips (JK in Figure 5)

We also measured the following point from the video filmed from the side.

(6) Projection of lips from the face surface (MN in Figure 5)

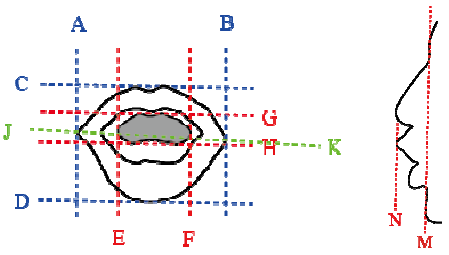

Figure 5: *Measurement of each part of the lips*

4.2. Measurement results and analysis

Selecting still images (144 in total) of the four vowel sounds /a//i//u//o/ from the video recorded from two cameras, one in front and one on the side, of the phrase *sonnano muzukashii yo* ("that's hard!") spoken six times each as utterance P, utterance C, and utterance U, we measured the six items listed under 4.1 above and recorded the resulting values. We took the average values for each of the four vowels in the three groups utterance P, utterance C, and utterance U and studied each parameter as described below.

4.2.1. Projection of lips

Identifying a line connecting the two points of the forehead and the jaw (M in Figure 5) to be the surface of the face, we measured the shortest distance from that line to the tip of the projected lips (N in Figure 5) as the projection of the lips. As shown in Figure 6, for each vowel sound the ranking from highest to lowest, of the extent of projection of the lips was as follows: utterance P > utterance C > utterance U. Since as we saw in Figures 1 and 4 the jaw moves forward in a horizontal direction in utterance C, its figure for pure projection is slightly lower than that for utterance P.

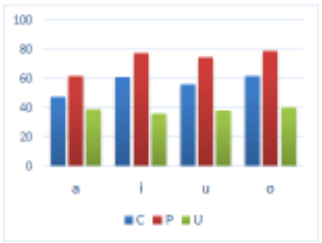

Figure 6: *Projection of lips*
The extent of projection of the lips was: utterance P > utterance C > utterance U.

4.2.2. Lip height and horizontal width

Figure 7 shows the ratio of the width of the lips' outer perimeter ((1) under 4.1) to the height ((2) under 4.1), while Figure 8 shows the ratio of the width of the lip opening at its narrowest spot ((3) under 4.1) to its height ((4) under 4.1), Since the scale on the horizontal axis shows the size of the figure for the horizontal width as a multiple of the height, the higher this number the more the lips will have a wide shape, and likewise the closer this number is to 1 the more the lips will have a rounded shape.

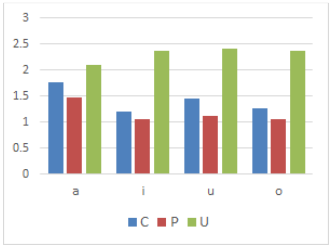

Figure 7: *W/H ratio of lip outer perimeter*

Utterance U shows the flattest shape and utterance P the closest to a circle. Although the shape for utterance C is close to that of a circle, the lips are wider than they are for utterance P.

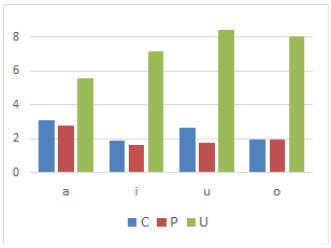

Figure 8: *W/H ratio of lip opening*

As well as Figure 7, utterance U shows the flattest shape and utterance P the closest to a circle. Although Utterance C is close to utterance P, the lips are wider than they are for utterance P.

As shown in Figures 7 and 8, it is clear that to one degree or another the vowels all show similar tendencies. That is, the shapes the lips form are similar in both outer perimeter and opening, with utterance U showing the flattest shape and utterance P the closest to a circle. Although the shape for utterance C is close to that of a circle, the lips are wider than they are for utterance P.

4.2.3. Lip angle

Figure 9 shows the average angle of the lips ((5) under 4.1) for each utterance. The scale on the horizontal axis is degree of inclination, and the fact that this value is negative for all utterances in each group means that the lips are inclined downward by 3° or more for each utterance.

As seen in Figure 9, in a so-called curled-lip utterance (utterance C), the lips actually are more curled than the others only for the vowel /a/, while for each of the vowels /i//u//o/ the lips are more curled in a pursed-lip utterance (utterance P). This suggests that curling the angle of the mouth is not an absolute requirement of utterance C.

5. Conclusions

From the studies described under Section 3 and Section 4, we reached the following five conclusions.

(1) For the articulation of utterance P, the lips are projected outward, and rounded by expanding in the vertical direction and narrowing in the horizontal direction.

(2) For the articulation of utterance C, curling the lips is not an absolute requirement. The articulation of utterance C is similar with that of utterance P in that the lips are projected outward and rounded.

(3) Utterances P and C differ in two points: (a) Lips projection accompanies the lower jaw projection only in utterances P; (b) Lips in utterance P is wider than those in utterance C.

(4) The shapes the lips make in utterance P, utterance C, and utterance U can be described as a circle, a horizontal rectangle, and a horizontal oval, respectively.

(5) There are many facts that contradict the accepted theory that "Rounding the lips causes both lips to project outward. In reaction to this movement, the surface of the tongue is pushed toward the rear" ([7]).

6. Future considerations

While there are two types of utterance P —child and adult — in natural conversation this study has not taken into consideration the differences between the two. Although we have recorded video and MRI images of all four utterances of utterance P (children), utterance P (adult), utterance C, and utterance U, the measurement process for these recordings still is underway and could not be completed in time for this paper. We would like to address the results at the next opportunity.

7. Acknowledgements

We thank our "Onsei Bunpou Kenkyukai" colleagues, especially late Miyoko Sugito for extensive advice and for helping in many other ways.

This work was partially supported by the Ministry of Education, Culture, Sports, Science and Technology, Grant-in-Aid for Scientific Research (A), 23320087.

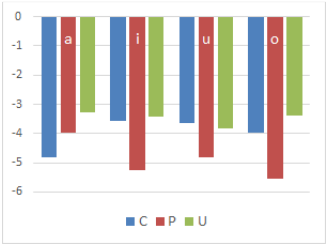

Figure 9: *Lip angle*

The lips of uutterance C are more curled than the others only for the vowel /a/, while for each of the vowels /i//u//o/ the lips are more curled in utterance P.

Prosodic Cues to Monolingual versus Code-switching Sentences in English and Spanish

Abstract

Code-switching offers an interesting methodology to examine what happens when two linguistic systems come into contact. In the present study, two experiments were conducted to see if (1) listeners were able to anticipate code-switches in speech-in-noise, and (2) prosodic cues were present in the signal as potential cues to an upcoming code-switch. A speech-in-noise perception experiment with early Spanish-English bilinguals found that listeners were indeed able to accurately identify words in code-switching sentences with the same accuracy as in monolingual sentences, even in highly-degraded listening conditions. We then analyzed the stimuli used in the perception experiment, and found that the speaker used different prosodic contours for code-switching productions compared to monolingual productions. We propose that listeners use specific code-switching prosody to anticipate code-switches, and thus ease processing costs in word identification.

Index Terms: prosodic contours, bilingualism, code-switching

1. Introduction

Code-switching – where two languages are used in a single utterance, sometimes switching mid sentences – is a common practice among high-proficiency bilinguals [1]. Code-switching is well documented with regards to sociolinguistic practices [2, 3, 4] and its syntactic and morphological aspects for several language pairings [5, 6, 7, 8, 9].

Psycholinguists have also studied code-switching, by examining how bilinguals deal with processing one language directly after another. Most switching studies have used an artificial form of switching, namely picture naming – where bilinguals had to switch the language in which they named a picture. [10, 11, 12, among others]. One consistent result across these studies is that bilinguals take longer to name pictures in switch trials compared to non-switch trials, regardless of the direction of the switch. A cost has also been found for processing code-switches in electrophysiological studies, both for single lexical items [13] and when comparing utterances that are either monolingual or code-switching [14, 15]. Given these costs, it seems odd that code-switching would be such a productive practice for bilinguals.

However, most of this work examined processing of words in isolation. Further, in studies that did provide full sentences, the stimuli were presented orthographically. Yet, it is possible that acoustic correlates to code-switches exist in the speech stream, and that listeners use them as cues to an upcoming switch; these cues may then reduce some of these processing costs. For example, it is well documented that English and Spanish, besides having different phonetic inventories, also have different intonation patterns. Notably, English declaratives typically have shallow-rise prenuclear and nuclear pitch accents (e.g., H* in the ToBI labeling conventions), whereas (Mexican) Spanish uses scooping rises with delayed peaks (L+>H*) in prenuclear position, but usually low-f0 targets (L*) as its nuclear pitch accent. [16, 17, 18]. In code-switching, it is possible that speakers will produce intonation patterns that do not directly map on to either language. Listeners could use this information to their advantage to anticipate upcoming language switches. For example, work on Spanish-English code-switching and narrow focus has found that while code-switching cues narrow focus, it is not enough for the sentence to include a code-switch; the sentence must also have the correct prosody for the sentence to be consistently understood as signaling narrow focus [19].

The present study asks two main questions. First, do Spanish-English bilinguals have trouble identifying words in code-switches sentences because code-switching induces high processing demands? To examine this question, we conduced a speech-in-noise study using both monolingual and code-switching utterances. If there truly is a processing deficit due to code-switches' being unexpected, then listeners should preform worse on the code-switching sentences compared to the monolingual sentences. However, if they perform equally well on code-switching and monolingual sentences, then it is possible that there are phonetic cues that allow listeners to anticipate a code-switch. As already discussed, one known difference between English and Spanish is pitch accent realization. Thus the second question of the study is, are there systematic prosodic differences between English, Spanish, and code-switching (both English to Spanish and Spanish to English) sentences? This will be investigated by examining the F0 contours of the full sentences used as stimuli in the speech-in-noise study, as well as the F0 realization of the pitch-accented words in each utterance.

2. Part 1: Perception experiment

2.1. Methods

2.1.1. Listeners

Eight early Spanish-English bilinguals (seven female, one male) of Mexican-American heritage participated in the perception experiment. The average age was 19.6 (standard deviation 1 year). Average age of acquisition of Spanish was 1.3 years (standard deviation 1.1 years); that of English was 3.1 years (standard deviation 1.8 years). We administered the Bilingual Dominance Scale [20] to all participants. The scale computes a score for how dominant the participant is in one language or another: a score of 0 means that the participant is a balanced bilingual; a high positive score mean the participant is heavily

English dominant; a high negative score means heavily Spanish dominant. The average score for the participants was 6.9 (standard deviation 7.7), suggesting that listeners were English dominant, despite the fact that their first language was Spanish. All participants were undergraduates at the University of California, San Diego, and received course credit in exchange for their participation in the study.

2.1.2. Stimuli

Sentences were modified versions of the Bamford-Kowal-Bench (BKB) sentences [21], which have been used in several past speech-in-noise studies [22, 23, 24]. The sentences were produced by a bilingual female speaker of American English and Mexican Spanish for use as English, Spanish, and code-switching sentences (code-switching English to Spanish (henceforth, **CS-ES**) and code-switching Spanish to English (**CS-SE**)). More information about the speaker's language background is provided in 3.1.1. Sentences were translated for use in the Spanish and code-switching sentences. The original BKB sentence list was created to include short sentences with vocabulary commonly used by partially-hearing children ages eight to 15. Similarly, the Spanish translations were modified as needed to include high-frequency words in Spanish, as well as be culturally appropriate for the dialect of Spanish spoken by the bilingual participants (viz., Mexican Spanish). Similar sentence structures were maintained for both the Spanish translations and the code-switching sentences. Code-switch location within a sentence was counterbalanced for syntactic position. This was done to reflect the grammatical rules of code-switching as discussed in previous research on Spanish-English code-switching [5, 6, 7]. A native Spanish-English bilingual reviewed the code-switching sentences for grammaticality and naturalness. The BKB sentences are blocked into lists of 16 sentences, each containing 50 keywords. Keywords were salient words in the sentence, generally nouns and verbs. Eight lists were used for the experiment, and half of an additional list was used for an initial practice session. Thus, there was a total of 32 test items per language context. Sentences were mixed with white noise at four signal-to-noise ratios (SNRs), -6, -3, +0, and +3 dB in Praat. There were two lists per SNR.

2.1.3. Procedure

Listeners completed a speech-in-noise task, during which they wrote down as many words as possible for each sentence presented. Listeners began with a practice session consisting of eight sentences (two from each language context) with feedback. After the practice session, listeners were presented with two blocks of four lists of sentences, one list per SNR per block. Within a given list, there was an equal number of sentences from each language context (four English, four Spanish, four CS-ES, four CS-SE). Stimuli were randomized within list and the list order was randomized within block.

2.2. Results

Regarding SNR, listeners do well in all four contexts, and perform above chance (50% correct) even at the lowest SNR of -6 dB. A logistic mixed-effects regression model was run to test for the effect of SNR on keyword identification. Keyword identification ('correct' or 'incorrect') was the dependent variable, SNR was the independent variable, and participant was included as a random slope by SNR. As expected, listeners identified words significantly better as the SNR increased [-6 vs -3: β = 0.26, z = 1.66, p = 0.10; -6 vs +0: β = 0.84, z = 4.66, $p < 0.001$; -6 vs +3: β = 1.81, z = 6.32, $p < 0.001$]. Since listeners were largely at ceiling for the higher SNR levels, a model was also run on the -6 SNR ('high noise') data alone, in order to examine more closely the effects of language context. Keyword identification ('correct' or 'incorrect') was the dependent variable, language context was the independent variable, and participant was included as a random slope by language context. These results are presented in Figure 1. Listeners were significantly better at Spanish than the three other language contexts [Spanish vs English: β = -1.53, z = -4.16, $p < 0.001$; Spanish vs CS-ES: β = -1.12, z = -3.17, $p < 0.01$; Spanish vs CS-SE: β = -1.03, z = -2.42, $p < 0.05$]; there were no significant differences among any of the other contexts.

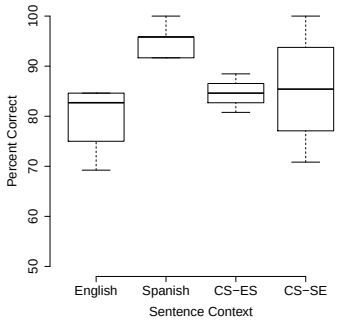

Figure 1: *Percent correct for keywords identified in each context at an SNR of -6 dB (the 'high noise' context).*

2.3. Interim discussion

The results of the perception experiment demonstrate that listeners are good at identifying words in code-switching sentences, even in listening conditions with high noise. Listeners performed best at the Spanish context. This is an interesting finding given that they are English dominant. However, this may be an effect of Spanish being their L1, thus demonstrating that current dominance is not always the most important factor. Listeners performed equally well on code-switching sentences as English sentences (their dominant language). This result seems to run counter to previous research which found a processing deficit in code-switching. This may be because previous experiments used only orthographic or pictorial switches and did not provide audio. If indeed phonetic cues in the signal can be used by listeners to anticipate a code-switch, then it is understandable that processing code-switches becomes difficult in the absence of audio information, which should result in longer processing times. It should also be noted that past studies that found a processing deficit for code-switching tested online processing, while the present study does not. However, this study does provide at least initial data suggesting that there is ***not*** a processing deficit for code-switching. To test if listeners in Part 1 performed well on code-switching stimuli because of potential phonetic cues to code-switching, in Part 2 we examine the prosodic structure of the stimuli. We hypothesize that prosodic differences – namely, differences in F0 contours over the utterance and in pitch accent realizations – may be present in code-switching contexts.

3. Part 2: F0 analysis of stimuli in Part 1

3.1. Methods

3.1.1. Speaker

One speaker produced all stimuli. She is a 22 year-old early Spanish-English bilingual having learned first Spanish at home and then English around age 6. She is a speaker of both Mexican and Peninsular Spanish, although she was instructed to produce the Spanish and code-switching sentences with a Mexican Spanish accent. She is a native speaker of Southern Californian English. She had a score of 1 on the Bilingual Dominance Scale suggesting she is a balanced bilingual. At the time of recording, she was naive to goals of the experiment. A larger-scale analysis with more bilingual speakers is underway.

3.1.2. Stimuli

Sentences were the test stimuli used in Experiment 1.

3.1.3. Method of analysis

For each sentence type (English, Spanish, CS-ES, and CS-SE), the F0 contours were analyzed both across the entire sentence and at specific points in the sentence. For the entire sentence, F0 values were extracted at 1% increments, starting at 0% into the sentence up to 100% into the sentence, resulting in a total of 101 measurements per sentence. Because content words always bore pitch accents, we also segmented each content word's stressed vowel and any adjacent sonorants to the stressed vowel within the syllable. Each sentence was uttered as one Intonation Phrase, with no IP-medial intermediate phrase break. F0 values were taken at 5% increments, starting at 0% into the stressed syllable up to 100%, resulting in a total of 21 measurements per stressed syllable. Syllables were coded as being the first stressed syllable (and thus, first pitch accent) in the Intonation Phrase, an Intonation Phrase-medial stressed syllable (sometimes there were up to three medial stressed syllables for a given Intonation Phrase), or the final stressed syllable (i.e., the nuclear-pitch-accent syllable) in an intermediate phrase (and thus, also the Intonation Phrase). Once the F0 values were obtained, outliers (based on visual inspection of the F0 tracks) were manually removed.

3.2. Results

The F0 contours across the entire sentence for the four contexts are shown in Figure 2. Visual inspection suggests that there are only two contours in use. One contour type, with a more extreme but delayed initial rise, is used in the English and CS-SE contexts. A second contour type, with a shallower and earlier initial rise, is used in the Spanish and CS-ES contexts. Towards the end of the code-switching sentences, the F0 generally maps onto the target language for the end of the sentence (i.e. CS-ES maps onto the contour for the Spanish sentence), with some deviation.

Figures 3, 4, and 5 present the contours for the first, middle, and final stressed syllables (which were also pitch-accented) in each context. To test for differences between contours, ANOVAs were conducted at 0%, 50%, and 100% for each syllable grouping. The dependent variable was F0 (in Hz) at the given time point, and the independent variable was language context. For the first stressed syllables in the sentence, there were significant effects of context at all three time points [0%: $F(3, 110) = 3.29$, $p < 0.05$; 50%: $F(3, 120) = 6.22$, $p < 0.001$; 100%: $F(3, 121) = 9.39$, $p < 0.001$]. Post-hoc Tukey tests were conducted to determine which specific contexts differed significantly from each other. English and Spanish pitch-accented vowels significantly differed from each other at the vowel's midpoint [$p < 0.001$] and end [$p < 0.001$], with F0 being higher at both time points in the English context. The F0 of CS-ES was significantly lower than that of English at the beginning of pitch-accented vowels [$p < 0.05$], but was significantly higher than that of Spanish at the vowels' end points [$p < 0.001$]. CS-SE had a significantly lower F0 than that of English midway through the vowels [$p < 0.05$].

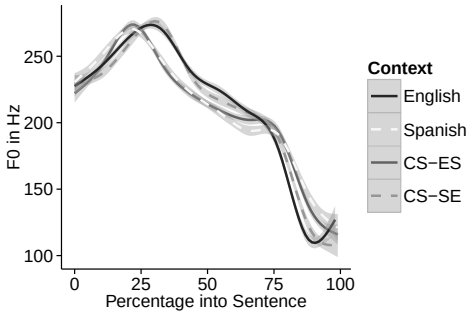

Figure 2: *Normalized F0 contour for full sentence by context. Error bars indicate one standard error.*

For the middle stressed syllables, there were significant effects of context at all three time points [0%: $F(3, 176) = 7.35$, $p < 0.001$; 50%: $F(3, 188) = 5.34$, $p < 0.01$; $F(3, 184) = 9.03$, $p < 0.001$]. Post-hoc Tukey tests were conducted to check which contexts differed from each other. English and Spanish significantly differed from each other at all three time points [0%: $p < 0.001$; 50%: $p < 0.001$; 100%: $p < 0.001$], with English having a consistently higher F0 than Spanish. CS-ES had a significantly lower F0 than English at the beginning of the vowels [$p < 0.05$], and a significantly higher F0 than Spanish at the end points [$p < 0.05$]. CS-SE also significantly differed from English at the vowel end points [$p < 0.01$], where it had a lower F0 than English.

For the final stressed syllables, there were significant effects of context at 0% and 100% [0%: $F(3, 105) = 4.32$, $p < 0.01$; 100%: $F(3, 99) = 7.65$, $p < 0.001$]. Post-hoc Tukey tests were conducted to determine which contexts differed from each other. English had a significantly higher F0 than Spanish at both beginnings and ends of vowels [0%: $p < 0.05$; 100%: $p < 0.001$]. CS-ES significantly differed from English at the end points [$p < 0.05$], where it had a lower F0 than English. CS-SE has a significantly higher F0 than Spanish at the beginning and end points [0%: $p < 0.05$; 100%: $p < 0.01$].

In sum, the stressed (and pitch-accented) syllables in the utterance differed depending on the language context. English stressed syllables generally had a higher F0 than Spanish ones. On the other hand, stressed syllables in the code-switching contexts usually had an intermediate F0 – not as high as English, but higher than Spanish.

4. General discussion

The goals of the present study were to see if (1) listeners are able to anticipate code-switches in speech-in-noise, and (2) prosodic cues are present in the signal to warn of an upcoming code-switch. The results of the perception experiment suggest

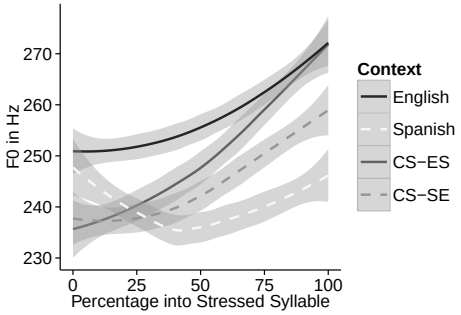

Figure 3: *Normalized F0 contour for first stressed syllable in sentence by context. Error bars indicate one standard error.*

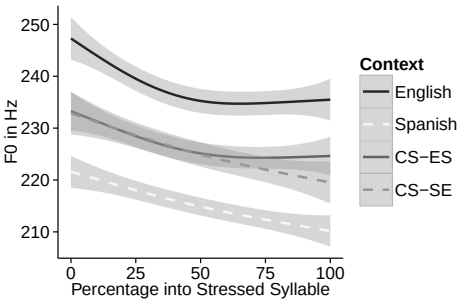

Figure 4: *Normalized F0 contour for middle stressed syllables in sentence by context. Error bars indicate one standard error.*

that listeners are able to easily process code-switches, even in a detrimental environment such as high noise. Listeners performed equally well at code-switches compared to monolingual sentences in English. This suggests that there could be something in the signal that cues listeners of an upcoming switch, which eases processing costs later on. One possibility is that listeners use syntactic and semantic information to anticipate a code-switch. This conclusion is unlikely here, as all sentences were derived from English monolingual sentences and thus could be completed in either language. Conversely, there may well be phonetic cues, either segmental or suprasegmental. The aim of Part 2 was to determine if there were prosodic cues (in the form of F0 differences) that listeners may use to anticipate a code-switch.

The results of Part 2 found that the speaker who produced the stimuli in Part 1 did in fact produce different F0 contours for code-switching sentences compared to monolingual sentences. English stressed syllables had an overall higher F0 than Spanish ones, consistent with the fact that Spanish has low nuclear pitch accents and scooping rises (with delayed high F0) in prenuclear position [17, 18]. On the other hand, English pitch accents tend to be high-toned, even in the nuclear-pitch-accented position [16]. However, in the English-to-Spanish code-switch, the speaker does not simply use English-like tone realization for the first half of the sentence and then immediately switch to Spanish-like tones for the second half of the sentence. Instead, the speaker used intonational patterns from both languages throughout her code-switching sentences. When examining the contours for the entire sentence, the speaker produced the beginning of code-switching sentences with F0 patterns that

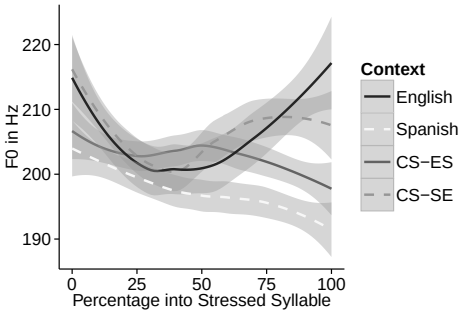

Figure 5: *Normalized F0 contour for final stressed syllable in sentence by context. Error bars indicate one standard error.*

were more similar to the post-switch language: e.g., English-to-Spanish code-switching sentences began with more Spanish-like intonation, rather with English-like intonation that became progressively more Spanish-like. This may serve as a cue to the listener of an impending code-switch. When stressed syllables of content words were examined, results were generally mixed: the speaker produced code-switching contours that never fully mapped on to either language. This can be seen most clearly in Figure 4. This is in contrast to the monolingual contours, which were consistently different from each other at almost all time points analyzed. Thus, while the speaker maintains different prosodic patterns for English and Spanish, this does not necessarily map directly onto her code-switching contours. Instead, code-switching F0 contours are in a category of their own, regardless of the direction of the switch (English-to-Spanish vs Spanish-to-English). However, another possible explanation for the differences in F0 is the segmental make-up of the words in each context, particularly the segmental make-up of stressed syllables, which could affect the timing and maximum of F0 peaks. To address this possibility, future analyses will include a phonological analysis of the sentences, to see how contexts differ in terms of tone realization and alignment. Future work will also expand upon the production study by recording additional speakers, to see if the effects shown here hold for the population at large.

5. Conclusion

The present study demonstrated that listeners are able to anticipate code-switches and thus ease processing costs in speech-in-noise word identification. An analysis of the stimuli suggested that this anticipation may in part be due to the F0 contours of the sentences as a whole, as well as those of pitch-accented words, which differ in code-switching contexts compared to monolingual contexts. Additional work on the intonation patterns of naturalistic code-switching, both in production and perception, will test whether code-switching utterances generally differ prosodically from monolingual ones in the ways found here, and whether these differences are used as cues in real-life language processing.

6. Acknowledgements

We thank our speaker for volunteering to record the stimuli and the members of the Phonetics Lab for comments and advice on this project.

Speakers modulate noise-induced pitch according to intonational context

Simon Ritter, Timo B. Roettger

I*f*L Phonetik, University of Cologne

{simon.ritter; timo.roettger}@uni-koeln.de

Abstract

Recent studies have shown that speakers systematically modulate properties of voiceless segments according to intonational context. More specifically, in the absence of fundamental frequency (F0), speakers appear to adjust the Center of Gravity (CoG) and the intensity of voiceless fricatives to convey the impression of pitch. In line with these findings, the present production study extends earlier work and investigates noise-induced properties of fricatives, modulated by the intonational context. It is shown for German that the mean CoG and intensity of intended contours with a high boundary tone are higher than those produced for intended contours with a low boundary tone. Furthermore, looking at the development of CoG and intensity over the time course of the fricative, the trajectories corresponding to the boundary tones differ in intercept (CoG and intensity) and slope (intensity), i.e. reveal a steeper fall in case of a corresponding falling tone.

Index Terms: noise-induced pitch, intonation, boundary tone, truncation

1. Introduction

Segmental and suprasegmental properties of the speech signal have traditionally been described as two separate levels. More specifically, intonation has been mainly associated with the acoustic parameter of fundamental frequency (F0), which is superimposed on the segmental string to bear different communicative functions. In intonation research, segments themselves are traditionally considered to constitute a potential perturbation of F0. In particular, voiceless parts of the signal have been regarded as communicatively irrelevant for the interpretation of the meaning conveyed by the F0 contour. However, intonation contours are frequently interrupted by the lack of voiced segments. As a consequence, speakers realize F0 movements on the segmental material available, i.e. they might truncate the contour (e.g. [1]). In the case of truncation, the contour simply ends earlier. Work on German phrase-final intonation patterns provides evidence for truncation in nuclear contours consisting of a high peak followed by a fall [2]: If the voiced material available at the end of the phrase was limited (e.g. in words like "Schiff" /ʃɪf/), the falling intonation movement is not realized completely (truncated). In some cases, the fall is entirely absent. Despite missing F0 information, speakers appear to have no problem with understanding each other's communicative intentions. In fact, [2] notes that even if the final fall is missing in the F0, German listeners perceive the "word as having 'falling pitch'" [2:140].

So why can speakers understand each other even though communicative relevant F0 movements may be entirely absent? One possible answer to this question is that the signal is over specified: acoustically different parts of the signal can serve as cues for certain meanings. In particular, other parts of the signal might function as acoustic cues which correspond to the intended meanings.

Experiments with whispered speech have shown that segmental cues can be used to convey meanings that would otherwise be encoded in the F0. Listeners of Mandarin compensate for the lack of F0 in whispered speech e.g. by using duration of the syllable as an auditory cue for the contrast between lexical tones [3]. Such a usage of acoustic substitutes for F0 is not restricted to whispered speech: Recent experiments have shown that speakers consistently adjust noise-induced differences to intonational contexts in normal speech. Several experiments demonstrated that frication and aspiration noise of phrase medial and final voiceless obstruents corresponds to the expected modulation of F0 [4,5,6,7]. In particular, voiceless parts of the signal corresponding to high/rising tones exhibit higher mean Center of Gravity (CoG) and higher mean intensity values than their counterparts corresponding to low/falling tones.

Niebuhr [7] investigated polar questions and statements in German. German polar questions typically end in a rise, whereas statements typically end in a fall (in Autosegmental-Metrical terms H-% and L-%, respectively [8]). In his study, target words ending in voiceless fricatives were placed at the end of the utterance. Acoustic measurements revealed that fricatives obtained higher CoG and intensity means at the end of questions than at the end of statements. Niebuhr interpreted these differences as noise-induced correlates of the intended boundary tone. This conclusion, however, is limited to some degree: The contours not only differ in their boundary tones, they are characterized by the combination of a boundary tone and a particular pitch accent type preceding the boundary tone. In the case of the question it is a low pitch accent (L*), in the case of the statement it is either a high (H*), a rising (L+H*) or a falling (H+L*, H+!H*) pitch accent. Thus, the factor boundary tone is confounded with the pitch accent type, making a conclusion towards a direct causal link between missing F0 information and spectral differences difficult.

This is important because a considerable amount of the global contour differences between statements and questions is manifested through the pitch accent preceding the boundary tone, i.e. the F0 movement of the pitch accent is realized within the vowel. This leaves the listeners with relevant information of the tonal movement encoded directly in the F0 to distinguish sentence modalities. In turn, modulation of spectral characteristics of the fricatives might be less required to signal the contrast. To shed further light on the relation between boundary tone and noise-induced characteristics of voiceless sounds, we report on a production study on German boundary tones extending Niebuhr's findings. In this study, we keep the pitch accent type constant and vary only the boundary tone.

A further contribution of this paper is the nature of our dependent variable. Tonal events are inherently dynamic, i.e. a function of F0 developing over time. Previous work only looked at summary measures, which reflect the averages over the whole segment, i.e. mean CoG and intensity. However, CoG and intensity may change dynamically throughout the duration of a segment. Any differences of CoG or intensity found for the arithmetic mean may reflect (a) a baseline

difference of CoG (an overall difference with a similar trajectory), (b) a trajectory difference starting at the same intercept or (c) a combination of an intercept difference and a trajectory difference. A first indication of dynamic differences of such noise-induced cues was reported by [4]. CoG and intensity were measured at the beginning and the end of the aspiration of /t/. The results showed that intonational contexts with a final F0 fall exhibited steeper slopes of the highest spectral energy in the aspiration. In the present study, we explore the development of CoG and intensity over the time course of the fricative in addition to the static mean.

2. Methodology

2.1 Reading material

Six monosyllabic nouns with CVC structures served as target words with three words for each of the target fricatives (listed in table 1). The target sounds were the postalveolar and uvular voiceless fricatives (/ʃ/ and /χ/). Following [7]'s findings, those sounds were chosen in order to elicit the strongest segmental pitch effects.

/ʃ/	Fisch ('fish')	/fɪʃ/
	Tisch ('table')	/tɪʃ/
	Busch ('bush')	/bʊʃ/
/χ/	Koch ('cook')	/kɔχ/
	Loch ('hole')	/lɔχ/
	Bach ('stream')	/baχ/

Table 1: *Target words sorted by fricative*

The vowels in syllable nucleus position were phonologically short. Short vowels were chosen in order to reduce the voiced material available to realize the F0 movements before the voiceless fricatives at the end of the target words.

In addition to the six target words, we used two control words. Both contained voiced segments only. One was monosyllabic (*See* 'lake' /zeː/) and one was trisyllabic (*Brombeere* 'blackberry' /ˈbʀɔmbeːʀə/). We included these control words to elicit undisturbed F0 contours for the contexts under scrutiny.

The target words were embedded in short dialogues on everyday topics. The dialogues comprised two to three turns per speaker. Each target word occurred in two different contexts: In context A, the target word was the first noun in an *enumeration* of three or more nouns. In context B, the target word was utterance final in a *contrastive focus* statement (corrective contrast: "is it X?" "No it is *Y."*).

The syntactic structures of the critical utterances as well as the semantic-pragmatic context frames set by the preceding utterances were designed in such a way that they elicited fundamentally different types of edge contours: Context A mainly elicited a high nuclear pitch accent (L+H* or H*) on the target followed by a high boundary (H- or H-%) resulting in a plateau. Context B mainly elicited a high nuclear pitch accent (L+H* or H*) on the target with a terminal falling utterance-final movement (L-%). This contour is typical for a contrastive focus statement in German.

2.2 Participants and recording procedure

Twelve Participants (mean age = 22; 6 men; 6 women) were seated in front of a computer screen together with one of the experimenters and read aloud the mini-dialogues at a time. They were instructed to read each dialog silently first. After the silent reading they read the dialog together with the experimenter. They were instructed to read the contexts as naturally as possible.

2.3 Analyses

The recordings were digitized at a sampling rate of 44.1 kHz (16bit). All acoustic material was manually annotated. For the acoustic analysis of the segments, we identified segmental boundaries of the target word using a waveform and a wide-band spectrogram. All segmental boundaries of vowels and consonants were labeled at abrupt changes in the spectra. Intonation contours were labeled according to the GToBI annotation system [8]. Those productions of the target utterances that could not be counted as instances of one of the two contours described in §2.1 were excluded from the analysis (n = 29).

Based on the labels for the acoustic boundaries, we measured the fricative *Center of Gravity* (CoG) and *intensity*. The CoG measurements were taken on the basis of spectral slices in Praat [9]. The slices resulted from a 20 ms Hamming window and were shifted in 5 ms steps across the fricative. Of each interval, CoG measurements were taken within a frequency range of 0.5-10 kHz. The frequency range covers the main spectral characteristics of /ʃ/ and /χ/ and excludes potential F0 residuals as well as high-frequency ambient noise. Using a fixed window width resulted in a different number of data points for different segment durations (e.g. longer fricatives yield more windows). To get an equal number of data points for all tokens, we normalized the data by calculating nine normalized time points of the CoG trajectory over the fricative for each token separately. In line with [5,7,10], we assume that CoG is a suitable estimate of perceived fricative pitch. For intensity, we extracted ten normalized time points of the intensity trajectory over the fricative for each token separately (due to strong perturbations of the intensity measurements at the vowel-consonant transition, the first time point was excluded from the subsequent analyses, resulting in nine time points, analogously to the CoG measurements). Measuring the CoG and intensity at different points in time throughout the segment enabled us to analyze the time course of the spectral and intensity changes.

All data were analyzed with generalized linear mixed models using *R* [11] and the package *lme4* [12]. For CoG and intensity mean (mean of the intervals), we used a Gaussian error distribution (assuming normality). We adhered to the random effect specification principles outlined in [13] including a term for random intercepts for speakers and words, which quantifies by-speaker and by-words variability. The critical fixed effects in question were BOUNDARY TONE (i.e. H vs. L) and FRICATIVE (i.e. /ʃ/ vs. /x/), and for these fixed effects, we included random slopes for speakers and words (this quantifies by-speaker and by-word variability in the effects of BOUNDARY TONE and FRICATIVE). We tested whether the inclusion of the fixed effects BOUNDARY TONE and FRICATIVE did improve the model's prediction significantly for CoG and intensity mean via likelihood ratio tests (LRT).

To test whether the actual trajectories of CoG and intensity development throughout the fricative differed as a function of time, we performed a *Growth Curve Analysis* [GCA, 14]. GCA is a multilevel regression technique designed for analysis of time series data. It fits trajectories to multilevel polynomial curves and allows for comparison of such curves. We decided

to model CoG and intensity trajectories as second order polynomials (parabola shaped curves). Thus, for both CoG and intensity, the nine time steps entered the analysis as a second order orthogonal polynomial fixed effect (including first order polynomial). The crucial effect of interest was the interaction of BOUNDARY TONE with the FIRST and SECOND ORDER POLYNOMIAL. We included a term for random intercepts for speakers and words as well as random slopes for speakers and words for the FIRST and SECOND ORDER POLYNOMIAL interaction with BOUNDARY TONE. For all models, p-values were generated using likelihood ratio tests.

3. Results and Discussion

Figure 1 shows representative contours for both conditions, as produced by one male speaker. In the upper panel, the contours over the utterance "Wir hatten Brombeere" ('We had blackberry') are displayed. Here the difference between the conditions is clearly visible on the target word "Brombeere": A high accent on the initial syllable (marked in grey) is followed by a *low tone* in the case of the contrastive statement (left), or by a *high tone* in the case of the enumeration (right). In the lower panel, where the same contours are produced over the sentence "Wir brauchen 'nen Tisch" ('We need a table'), it can be seen that the contours on the target word "Tisch" are severely truncated. This observation is in line with [2], i.e. the intended boundary tone (H-% vs. L-%) is at least highly impoverished. In this context, in which F0 is drastically reduced, we expect spectral cues to retain the contrast between the two intonation contours and their meanings.

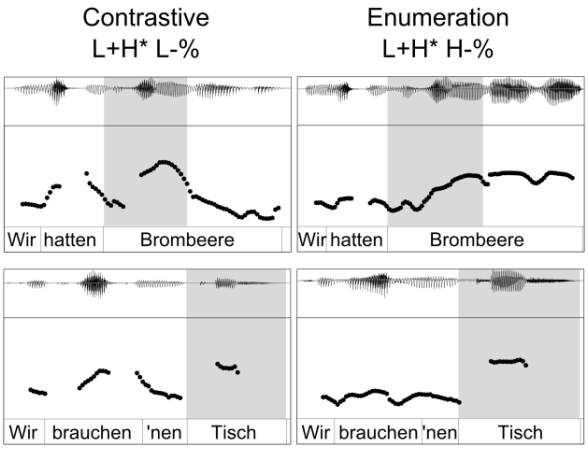

Figure 1: *F0 contours for the utterances containing the control word "Brombeere" (top) and the target word "Tisch" (bottom) in the two conditions Contrastive Focus (left) and Enumeration (right). The accented syllable is in grey.*

Mean CoG and intensity values are displayed in Figure 2. For both intensity and CoG mean, there was a significant effect of fricative, such that uvular fricatives /x/ had a 7.4 dB lower intensity (β=7.2 dB, SE=1.7, $\chi^2(1)$=11.5, p<0.0007) and a 1612 Hz lower CoG mean (β=1629.3 Hz, SE=241.3, $\chi^2(1)$=16.43, p<0.0001) than postalveolar fricatives /ʃ/. Crucially, there was a significant effect of BOUNDARY TONE on mean CoG and intensity, such that H tones elicited 4.0 dB higher mean intensities (β=4 dB, SE=1.2, $\chi^2(1)$= 8.2, p=0.00414) and 366.3 Hz higher CoG means (β=315.6 Hz, SE=120.2, $\chi^2(1)$= 5.66, p=0.0174) than L tones.

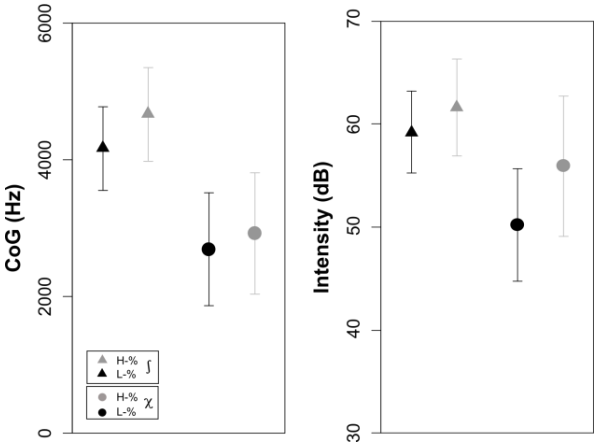

Figure 2: *CoG and intensity means and standard deviations for both fricatives and boundary tones (black = low boundary; grey = high boundary).*

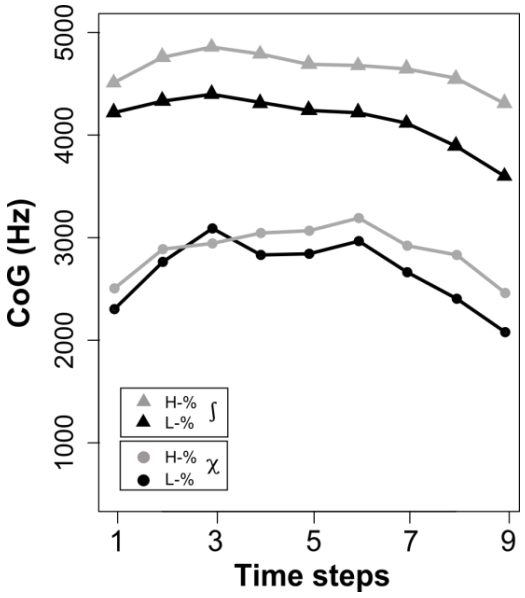

Figure 3: *CoG development as a function of time for both fricatives and boundary tones. (black = low boundary; grey = high boundary).*

To investigate the development of the measurements over time we performed growth curve analyses. As can be seen in Figure 3 and 4, for both CoG and intensity there are intercept differences, i.e. CoG and intensity start lower in the case of L-%. This difference appears to become stronger over time for intensity, that is, intensity trajectories have slightly steeper slopes for L-%. Looking at the CoG trajectories, there appear to be only small slope differences between L-% and H-%, mainly manifested in the last three time steps.

This is reflected in a significant interaction effect of BOUNDARY TONE with the FIRST ORDER POLYNOMIAL (the linear component of the models) for intensity ($\chi^2(1)=14.2$, $p=0.0002$) such that L tones corresponded to intensity trajectories with a steeper negative slope. This interaction is not significant for CoG ($\chi^2(1)=2.2$, $p=0.14$), although numerical trends point towards a comparable slope difference. Even though the SECOND ORDER POLYNOMIAL (the square components of the models) ($\chi^2(1)<0.35$, $p>0.55$) did not significantly interact with BOUNDARY TONE there were numeric tendencies suggesting that the trajectories elicited by H-% are slightly less curved than the trajectories elicited by L-%, or in other words: flatter. It is important to note that even though we found significant differences between the conditions, CoG and intensity decreases over time for both low and high boundary tones.

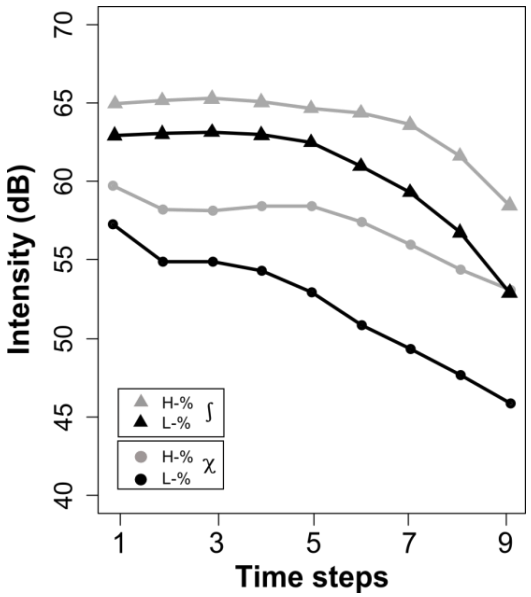

Figure 4: *Intensity development as a function of time for both fricatives and boundary tones. (black = low boundary; grey = high boundary).*

The present study has demonstrated that German speakers systematically modulate properties of voiceless segments to convey the meaning encoded in the intonation contours. Specifically, we have found that the spectral properties of voiceless fricatives, as reflected in the measure of CoG and intensity, are modulated in different intonational contexts: Higher CoG and intensity means are found for fricatives at the end of phrases ending with a high boundary tone. Thus, this study replicates earlier findings reported by [7], circumventing the confounding of boundary tone and pitch accents, and confirms that German speakers produce noise-induced correlates of intended boundary tones [4,5,6,7].

Crucially, the obtained mean differences can be ascribed to differences in development over time, at least for intensity: Intensity of high boundary tones starts higher (higher intercept) and remains flatter (flatter slope, less curved) than those of low boundary tones. CoG differences appear to be mainly due to intercept differences, i.e. CoG for high boundary tones starts higher than those of low boundary tones with a comparable development of the trajectory over time.

4. General Discussion

Grabe [2] noted that German native listeners hear truncated contours as falling even if an explicit fall in the F0 is missing. So listeners infer communicative intention even though relevant F0 movements may be entirely absent. This might be possible due to a highly over specified signal. The present study demonstrates that voiceless parts of the signal, which are not able to convey F0 information, bear their own acoustic dimensions which correspond to the missing F0 information. The question arises as to whether these acoustic differences have any communicative function – in other words, whether speakers are able to use these cues to distinguish e.g. sentence modalities. A semantic differential task performed by [4] has demonstrated that noise-induced cues of /t/ aspiration were able to shift the attitudinal meaning of the stimuli towards the meaning profile of the respective intonational context. This is a first indication that speakers, indeed, might be able to use such subtle cues communicatively. Future research is needed to further elaborate the impact of noise-induced pitch on communication.

Generally, research into this phenomenon would benefit from cross-linguistic investigations. It is important to note that the acoustic differences reported here are very subtle and prone to variation necessarily limiting its examination. Other languages could in fact be better suited for such investigations. For example, Tashlhiyt Berber, an Afroasiatic language spoken in Morocco, can have whole utterances with neither a vowel nor a voiced segment. As a result, the phonetic opportunity it affords for the execution of intonational pitch movements is exceptionally limited. In fact, it has been reported that entire complex tonal movements (Rise-Fall) can be missing in certain phonotactic environments [15,16]. Speakers of such languages might rely heavily on other cues than F0 to capture the meaning encoded in the intonation contour.

To conclude, the present findings suggest that the traditionally separated levels of analysis – segmental and suprasegmental – are strongly intertwined. Voiceless segments have been regarded as irrelevant for the interpretation of the F0 contour. They have been treated as elements to be ignored. The present findings, however, demonstrate that these parts of the signal contain acoustic dimensions that potentially contribute to the perception of the intonation contour. Thus, the results may provide an answer to the question why German listeners perceive a truncated contour as falling although there is no fall in the F0 contour [2].

Abstract

Expressive behavior linked to paralinguistic meanings finds grounds in codes proposed as universals, as well as in culture-specific conventions. This study observes performances in such kinds of attitudinal prosody for USA English, produced by L1 and L2 speakers. The results show that the observed variance is linked to individual competence, to the linguistic context, and to the cultural background of the speakers. They also show that the code used to express a given speech act, code learned in the L1 language by L2 speakers of English, may be used in their L2 language. For some of these expressions, L2 speakers received higher scores than L1 speakers, suggesting that expressions conventionalized in a foreign language, are adequately fulfilling not-conventionalized expressions in the L1 culture.

Index Terms: prosody, attitude, cross-cultural, first and second language

1. Introduction

Prosodic performances help a speaker to express a position about her/his speech and also about the addressee [1].They help to actualize speech acts (e.g. to convey doubt or authority) in a non-verbal way, thus allowing a smoother interaction – it is easier to retract from a position that has not been verbalized. Such attitudinal prosody has been theorized in pragmatic terms as intermediate between emotional expressions and illocutions [2,3]. Differing from emotions, they are intentionally produced and controlled by the speaker; unlike e.g. wh-questions, attitudinal prosody may not have a one-to-one relationship with the meaning of the intended speech act. Attitudinal prosody is rather part of a contextualized communication process, and speakers may use many tools, including prosody, to reach their goals.,

Most studies of attitudinal prosody focus on performance in a given language, either proposing inventories of the existing clichés observed in a language [4,5,6,7], or studying the various means used to express a given speech act in a given language (e.g. politeness in [8,9]). Some studies are interested in the cross-cultural comparison of attitudinal prosody perception by listeners of various linguistic origins [10, 11]. To that aim, they take samples of social affects from a given language's inventory to present stimuli to listeners from various languages, studying the biases induced by cultural backgrounds in the reception of prosodic attitudes. In all these works, attitudes are obtained and labeled according to the cultural specificities of a given language; that is they are interested in e.g. the performance of Catalan politeness, of French irony, etc.

But, as advocated by Wierzbicka [12,13,14] for emotions, the label of an attitude in a given language (e.g. French *ironie*, USA English *irony* or Brazilian *ironia*) does not necessarily cover the exact same concept: these three ironies are not produced in similar social context, or with a similar communicative goal. It is interesting to study these conceptual differences, but we'll here concentrate on how prosodic performances may vary across languages in identical situations – trying to freeze such conceptual mismatches (i.e., what would have been the prosodic performances of Brazilian Portuguese speakers expressing the speech act corresponding to French "*ironie*"?) The aim of this ongoing research is precisely to record speakers from various linguistic and cultural origins, and to compare their prosodic performances in the same situations of communication. Speakers are not asked to produce a sentence with e.g. irony or authority, but rather to behave in situations conducive of these attitudes, as exemplified below:

- *Authority*: Speaker A is a custom agent; speaker B is a traveler. B is in front of A, requesting permission to enter the country; A needs to impose his authority; the scene is at a custom counter at the airport.
- *Irony*: A & B are friends, same age; A is going to Boston to see an important baseball game, and B, who is living in Boston calls A. Unfortunately, the weather in Boston is rainy and B says its wonderful; the scene is at an airport.

The interaction contexts as well as the communication goals of speakers are the same, whatever the language of the speakers. Speakers may be L1 or L2 speakers of the studied language. Several speakers from the same linguistic origin, and of both genders, are recorded to enable a comparison of the cross-speaker, cross-gender, and cross-cultural influence on the prosodic performances. Among the hypotheses of the work are the codes that have been proposed in the literature as universal of prosodic expressivity – namely the frequency code [15], and the effort and production codes [16]. These codes would predict for example the use of higher pitch for expressions where the speaker is in an inferior position, and of lower pitch in the case of dominant expressions. Another research aim is to observe the possible influence of the linguistic and cultural backgrounds on the performances of speakers, for expressions corresponding to complex social settings. All interaction contexts do not necessarily correspond to a prototypical prosodic attitude in each culture, but this is precisely part of what is under investigation here. Will speakers use their L1 prosodic typology speaking in L2? If a situation is (or nor) conventionalized in the speaker's L1, will it help (or restrain) the performances of her/his productions, in L1 and in L2?

This paper focuses on the results obtained for USA English for L1 speakers, compared to L2 speakers whose L1 language is either Japanese (L2JP) or French (L2FR). The aims of the study include observations of prosodic performances across languages and cultural backgrounds, in comparable communication situations, and examination of the perception of these prosodic changes by L1 listeners of these languages. We will here review the evaluation by L1 listeners of USA English of the performances of L1 and L2 speakers in expressing speech acts that correspond to sixteen interaction situations.

2. Corpus

Sixteen communication situations have been designed, where the recorded speakers interact with an experimenter (L1 speaker of the target language) in order to elicit the corresponding attitudes. These attitudes are performed on two target sentences ("A banana" and "Mary was dancing") that are produced in the end of a small dialogue picturing a situation where these sentences may be produced with the intended attitudes. A complete description of the recording setting may be found in [17]. The sixteen situations correspond roughly to expressions described by the following labels: admiration (ADMI), arrogance (ARRO), authority (AUTH), contempt (CONT), doubt (DOUB), irony (IRON), irritation (IRRI), neutral declarative sentence (DECL), neutral question (QUES), obviousness (OBVI), politeness (POLI), seduction (SEDU), sincerity (SINC), surprise (SURP), uncertainty (UNCE), "Walking On Eggs" (WOEG), often referred to as "walking on eggshells" or "walking on thin ice."

Labels "sincerity" and "walking on eggs" correspond to situations typical of the Japanese society, where the speaker is supposed to behave in a specific way because of the hierarchical relationship with the interlocutor and the intended speech act. For sincerity, the speaker asserts the sincerity of her/his utterance to a higher-level interlocutor. The WOEG situation is close to the Japanese concept of *kyoshuku*, defined by [18] as "*corresponding to a mixture of suffering ashamedness and embarrassment, which comes from the speaker's consciousness of the fact his/her utterance of request imposes a burden to the hearer*" (p. 34). Expressions labeled "irony" and "seduction" correspond to attitude types frequently used in the U.S.A., where two speakers have mutually positive, friendly attitudes. Irony may often be used to help lighten an otherwise negative situation. Other types of "negative" irony, intending to hurt the other person, are not addressed in this study. The attitude of "seduction" might best be defined here as where the speaker interacts with her/his interlocutor with the intention of being attractive, fascinating, inviting to the listener. This type of attitude may be akin to that frequently seen in Hollywood movies, but without necessarily being sexually provocative.

Among the speakers recorded for this study on USA English, eight (5 females and 3 males) are L1 speakers; six (3 females and 3 males) are L2 speakers with Japanese (Tokyo variety) as their L1; five (3 males and 2 females) are L2 speakers with French (standard French variety) as their L1. Most speakers are university students. To select L2 speakers – and to ensure a basic level in the target language-selected L2 speakers all spent one year studying in the USA. All speakers were audio-visually recorded performing the two sentences in the 16 situations. The video were hand segmented, resulting in 256+192+160=608 stimuli.

3. Performance evaluation

3.1. Experimental paradigm

These audio-visual performances were presented to listeners, whose L1 is USA English, who had to judge the performances on a raw 1 to 9 scale. Three different groups of listeners evaluated each of the three groups of speakers (L1, L2 Japanese, L2 French). Subjects were first presented with the 16 situations, explained showing the pictures used to elicit the 16 attitudes for "banana." The stimuli were then presented in isolation, by speaker (in order to give subjects a better idea of the expressive habit of this speaker) for both sentences and were randomized. Prior to the presentation of a stimulus, the name of the targeted attitude was displayed, then the stimuli was presented (only once), and listeners had 10 seconds to use the keyboard to give a performance score; then the next stimuli was presented. In cases of no answer, a 0 score is given to the stimulus (it represents less than 0.1% of the number of answers) – these 0 scores were latter removed from the data. A test session lasts typically 30 to 45 minutes. To move to the next speaker, subjects were instructed to press the "enter key."

3.2. Subjects

17 subjects (7 females, mean age 25) evaluated the L1 speakers' performance; 16 subjects (6 females, mean age 21) evaluated the L2 speakers with Japanese L1; 35 subjects (26 females, mean age 24) evaluated the L2 speakers with French L1. The evaluations for all three groups were conducted in Midwest U.S.A., (the prevailing dialect is Midwestern English). The first two evaluations were conducted in Ohio and South Dakota, the third group, in New Mexico.

3.3. Performance judgments analysis

The performance judgments received by each stimulus were analyzed using a mixed-effects model [19] based on the lme4 library [20] of the R software [21]. The performance scores were normalized using a z-score for each subject to avoid individual differences in the use of the answer scale. These performance measures were fitted as a function of the subjects and the speakers – as random effects; the latter being nested into the group of linguistic origin factor, and the linguistic group factor interacts with the targeted attitude and the sentence (the last three being fixed factors).

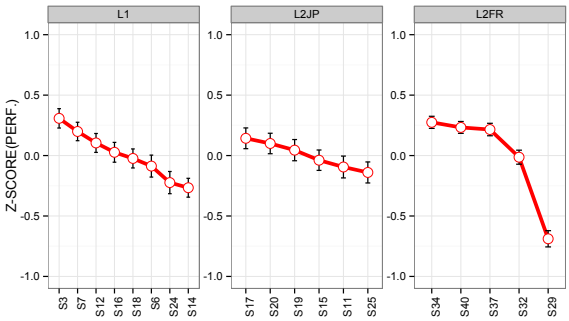

Figure 1: *Mean performances (expressed in z-scores) obtained by individual speakers, nested in the linguistic groups (L1 speakers, L2 Japanese, L2 French); the error bars represent the confidence intervals at 5%.*

Note that, because each of the three groups of listeners evaluate one of the three groups of speakers, the raw performances between speakers' group cannot be directly compared – thus the use of z-scores. But z-scores, since they are standardized, also prevent us from comparing the average performances of two groups of speaker. The present analysis focuses on the differences inside each group of speakers, and compares their relative performances in the 16 situations.

An ANOVA based on the mixed-effects model presented above shows that the linguistic group and the subject factors

did not have a significant main effect (this result is obvious, after the preceding comment on z-scores), but the linguistic group shows a significant interaction with the attitude ($\chi^2_{(30)}$=156.2, p<2.2e-16), with the sentence ($\chi^2_{(2)}$=22.1, p=1.6e-5), and the triple interaction was also significant ($\chi^2_{(30)}$=80.9, p=1.4e-6). The main effects of targeted attitudes and support sentences are also significant (respectively: $\chi^2_{(15)}$=1105.5, p<2.2e-16; $\chi^2_{(1)}$=7.3, p=0.007). The speaker factor also has a significant effect on the performances (effect tested using the method presented in [19:242]; comparing this model with another model, it is identical except it did not have the speaker factor – $\chi^2_{(1)}$=940.1, p<2.2e-16).

3.3.1. *Speakers performances*

The mean performances reached by each speaker, in each linguistic group, are displayed in figure 1. There are important variations across speakers. These variations are mostly linear in the L1 and L2 Japanese groups; one speaker (S29) departs from the others in the L2 French group. Performance variations are more restricted (the group of speakers is more homogeneous) in the L2 Japanese groups, compared to the two other groups. The following analyses consider performances averaged across all speakers of each of the three groups.

3.3.2. *Effect of sentences*

Targeted expressions were produced on two sentences ("A banana" and "Mary was dancing"), chosen for their syntactic simplicity and absence of affective meaning. These individual sentences did have a small – yet significant – effect (cf. Figure 2) on the performances. This effect is different in the case of the L1 group of speakers, as compared to the two L2 groups: L1 speakers received higher scores for their performances on the "Mary" sentence than on the "banana" one, while the reverse is observed for both groups of L2 speakers.

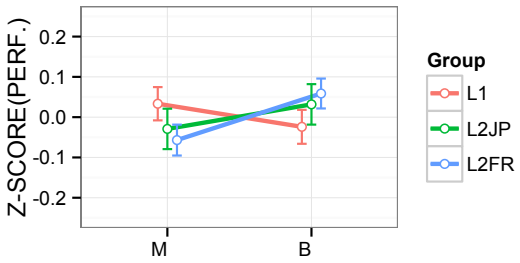

Figure 2: *Mean performances (in z-scores) for both sentences ("Banana" and "Mary was dancing"), for each linguistic group (L1, L2 Japanese, L2 French); error bars represent the confidence intervals at 5%.*

3.3.3. *Effect of attitudes*

Expressing each of the 16 individual attitudes is not achieved by speakers with the same accuracy. The significant main effect of attitude on the performance is depicted in figure 3, and shows important differences (of about one standard deviation) between the best-elicited expression (the situations of surprise) and the worst one (the situation of irony).

The tendency observed for the speakers of all linguistic groups for the two best (surprise and doubt) and the two worst (irony and seduction) expressions holds for the L1 speakers, while it seems culture-specific competences or constraints induce varying patterns of performances for the two L2 groups of speakers.

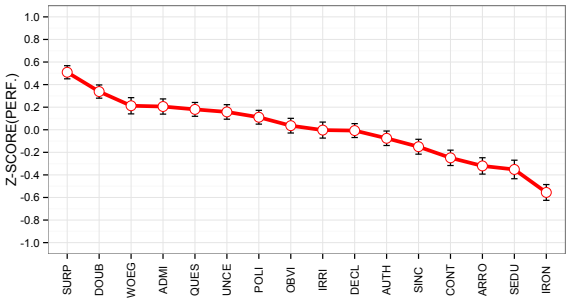

Figure 3: *Mean performances (in z-scores) for each attitude (see text for labels), all linguistic groups averaged; the error bars represent the confidence intervals at 5%. Attitudes are sorted in descending level of performances.*

These cultural-specific patterns, as well as some cross-cultural similarities, are displayed in figure 4, where attitudes are sorted in descending order of performances for the L1-speaker group. The expression of surprise received the highest performance scores whatever the linguistic origin of speakers; the expression of doubt is also ranked amongst the best performances for all speaker groups (if only the third best for the L2 Japanese speakers).

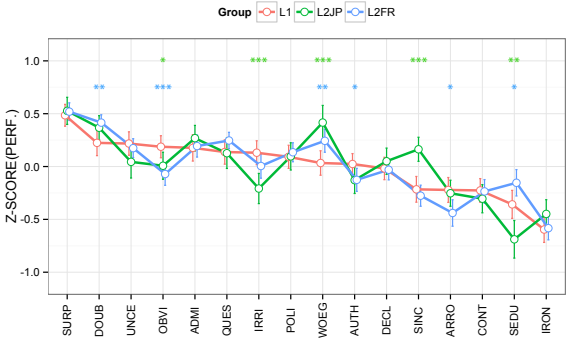

Figure 4: *Mean performances (in z-scores) for each attitude (see text for labels), and for each linguistic group (L1, L2 Japanese, L2 French); the error bars represent the confidence intervals at 5%. Attitudes are sorted in descending level of performances for the L1 speaker group. Stars above attitudes indicate significant differences between the L1-speaker group and L2 Japanese group (top line of stars) or L2 French group (bottom line of stars).*

More differences are observed amongst the performances of the lowest ranked attitudes. The expression of irony seems to be difficult to elicit for speakers of all linguistic origins, but it is not necessarily the most problematic one: L2 Japanese speakers received their lowest performances scores for their behavior in the situation of seduction. The expression of seduction received also the second lowest scores for L1 speakers, while it received only the fifth lowest score for L2 French speakers (close to the mean performance level of this group). Other important differences are observed between the L1 speaker group and the two L2 speaker groups.

In order to focus on the most important differences between language groups, T-tests were run to test significant

differences between performances for a given attitude of the L1-speaker group and each L2-speaker groups. Significant differences are indicated on figure 4 by stars above the significant differences observed for a given attitude (*: $p<0.05$; **: $p<0.01$; ***: $p<0.001$).

The L2 Japanese speakers received significantly different scores from the L1 group for five interaction situations. For irritation, obviousness, and seduction, Japanese speakers received significantly lower scores than L1 speakers; conversely, Japanese speakers outperformed L1 speakers in the cases of sincerity and WOEG expressions.

The L2 French speakers received significantly different scores from the L1 group for six interaction situations. For arrogance, authority, and obviousness, they received lower scores than the L1 speakers, while for the expressions of doubt, seduction, and WOEG, L2 French speakers outperformed the L1 speakers.

4. Discussion & conclusions

Speakers, depending on their personalities among other things, performed differently. The interaction situations were prepared to ease the expression of the targeted attitude in a laboratory environment – but still, in the laboratory as in real life, individuals behave differently, and express themselves with more or less change in voice and face; thus the observed variation in the performances. The focus of this paper is not on individual differences. In order to have a better idea of performance differences at the linguistic and cultural levels, several speakers have been recorded in each language group. It would of course be of a great interest to enter the details of these differences and study the influence of individual characters on expressivity (cf. [22, 23, 24] on this topic). Along this line, it is interesting to note that some speakers received low mean scores for their performances, but may have received the best score for their elicitation of a given situation. It is typically the case for L1 speaker S24, whose mean performance scores are rather low, but who was rated amongst the best for expressing surprise.

Also, the variations induced in performances by the sentences may be related to the type of elicitation contexts used for each of the sentences. L1 speakers tended to perform better for the "Mary was dancing" sentence, which is introduced by a written dialogue, while the L2 speakers received higher scores in the "banana" situations, which are presented using iconic presentations based on images. The language level, and the linguistic complexity may be an explanation for the observed differences. Another explanation of this observation (not necessarily exclusive of the first one) could be linked with the greater linguistic complexity of the "Mary was dancing" sentence, compared to "Banana".

Most of the explained variance is linked with the varying performances of the 16 attitudes, and with the differences between linguistic groups in the performance of individual attitudes. A first remark about these differences is that they concern only a minority of the communication contexts: in most cases, L1 and L2 speakers do perform comparably and this result is in itself interesting. This supports literature reporting few differences found cross-culturally e.g. in [25]. The differences observed between L1 and L2 speakers can be explained by different factors.

- A first kind of differences is the one where L1 speakers outperform one (and only one) group of L2 speakers in performing a social attitude. It is the case for irritation with L2 Japanese speakers, and for arrogance and authority with L2 French speakers. These situations are conventionalized in the considered cultures. Whether they are based on different codes may be answered by comparing the productions of both L1 and L2 groups of speaker.
- In the situation leading to expressions of obviousness (a propositional attitude, see e.g., [26]), both groups of L2 speakers are outperformed by L1 speakers. Although the expression of obviousness may be conventionalized in each of these cultures, propositional attitudes address the linguistic content of the utterances and thus are subjected to more variations in their pitch contours [26]. One can suppose that the L2 speakers did not catch the typical prosodic patterns used by L1 speakers.
- The situation demanding speaker to have a seductive behavior shows an interesting partition, with L2 Japanese speakers receiving lower score than the L1 speakers, while L2 French speakers received higher scores. In this case, the social interaction is not conventionalized in the Japanese society, while it is – if under different conventions in the French culture. The lack of – or presence of – a conventionalization seems to be a critical point in the measured performance of speakers.
- In the case of the situation leading to the expression of sincerity and WOEG, the L2 Japanese speakers outperformed the L1 speakers. These expressions correspond to common situations in the Japanese culture, while they are not conventionalized in the culture of the USA, where the society is less based on hierarchical relations. This lack of conventionalization in the L1 culture may also, as in the previous case, be a key point in the observed differences in performance.
- The L2 French outperformed L1 speakers in the WOEG situation to a lesser degree, although it is not a conventional situation in the French culture. A possible explanation may lie in the more hierarchical nature of social relationships in France, as compared to the USA, that may play role for an unconventional expression, but not for conventional ones such as arrogance or authority.

A question remains. In the cases where L2 speakers outperformed L1 speakers, (perhaps because the L2 culture conventionalization "trained" the L2 speaker how to behave in these situations), why were these performances evaluated so highly by L1 speakers of USA English who did not know the conventions. Why did they give high ratings to L2 French speakers' seduction and L2 Japanese speakers' WOEG and sincerity? Could it be possible that the judges do have stereotypic representations of peoples from these cultures, and thus relate Japanese behaviors more easily to politeness expressions, and French to seductive behavior? It could be possible to test for such stereotypes by running performance judgments of the same expressions with native listeners of the two L2 cultures less biased by such stereotypes.

Abstract

The present paper investigates automatic prosodic phrasing of spontaneous speech: a two-step segmentation technique is presented, based on unsupervised learning. In the first step, the Intonational Phrases (IP) are detected automatically based on speech energy, spectral centroid and a double-thresholding technique. In the second step, Phonological Phrases (PP) are identified within the IPs. As acoustic features, F0, overall energy and vowel duration are investigated. An adaptive thresholding method is used based on Kullback-Leibler divergence computed in an autocorrelative manner for the feature streams. For Hungarian spontaneous speech, a phrasing accuracy of over 80% can be reached when comparing to a hand-labelled reference phrasing. It is found that in Hungarian sponatenous speech, F0 and energy play an essential role in IP level phrasing, whereas PP level phrasing is most effective using F0 related features alone. Vowel durations are shown not to contribute to prosodic phrasing in Hungarian. Although the evaluation targets the Hungarian language, the applied method is universal and can be easily adapted for other languages.

Index Terms: phrasing, spontaneous speech, hierarchical

1. Introduction

Prosodic phrasing and/or prosodic boundary detection is an important research topic and several phrasing or boundary detection approaches have been developed and analysed for read and slightly spontaneous speech (such as semi-formal speech used in information retrieval systems) [1], [2]. When using a supervised approach, machine learning can be applied on labelled data, which will end in producing a classifier or detector capable of predicting prosodic boundaries based on the associated acoustic-prosodic features. This approach also implies that the entities to be classified or detected (boundary or break and their types) are a priori known and annotated in the training corpus. More recently, unsupervised modelling of prosody [3] or adaptation of seed prosody models in an unsupervised manner has also received attention [4]. Such approaches are of primary interest when dealing with spontaneous speech, as due to its extreme variabilty (disfluencies, atypical or non-canonical realizations in terms of acoustic correlates), prosodic entities worth modelling can be problematic to be identified or clustered even by human experts.

This paper focuses on exploring the prosodic structure of spontaneous speech, work is done on a Hungarian spontaneous speech database. Earlier efforts for prosodic event detection and automatic phrasing in Hungarian read speech showed that based partly on the fixed stress of Hungarian, robust stress detection was possible [5] and a phonological phrase alignment approach was proposed [6], where modelling of F0 and energy contours of phonological phrases was used in a supervised machine learning approach to perform automatic phonological phrase alignment and based on this, a partial, but powerful recovery of the prosodic and, to a lesser extent, of the syntactic structure in read speech. However, not surprisingly, when trying to adapt this automatic approach for spontaneous speech, recall rates fall by approx. 20-30% from around 80%. An effort to try to identify and cluster characteristic prosodic entities or phrase types in Hungarian spontaneous speech by using an unsupervised approach lead only to partial success [7].

However, supposing a hierarchical structure of prosody as described by Selkirk [8], the automatic phrasing implemented for read speech in [6] was able to yield a reliable (accuracies close to 80%) phrasing down to the phonological phrase level, and also to separate intonational phrase level from the underlying phonological phrase level. This approach required clustering of a number of phonological phrase prototypes, which were then modelled by HMM/GMM based on acoustic-prosodic features. As already mentioned, clustering of such characteristic prototypes in sponatenous speech failed. However, our hypothesis is that upon the intonational phrase level, also the phonological phrase level should be identifiable based on prosody in spontaneous speech as well. Moreover, cues for the perception of phonological phrasing are supposed to be simple enough, in order to allow the listener to concentrate also on other modalities (attitudes, emotions, also dialogue management functions) of the complex and rich information transmitted during a spontaneous conversation. Therefore, in this paper an attempt is made to detect intonational and phonological phrases in spontaneous speech with a two-step method, able to separate these two levels according to the prosodic hierarchy.

This paper is organized as follows: First, the spontaneous database is presented, than the intonational and phonological phrase segmentation approaches are described. Phonological phrase detection is implemented and evaluated in the subsequent section, and finally conclusions are drawn.

2. Data and methods

The BEA (BEszélt nyelvi Adatbázis: spoken language database [9]) spontaneous speech database was used in this research. BEA is a multi-purpose database of Hungarian spontaneous speech. 8 spontaneous narratives were selected (4 male and 4 female) from the database. The subcorpus was manually annotated by two different phoneticians, although the annotation will be exclusively used as reference for evaluation. The

annotation contained three levels: Intonational Phrases (IP), Phonological Phrases (PP) and also involved a word level transcription. The intonational phrase can be thought of being a part of speech forming a unity in terms of stress and intonation contour, and is found often between two pauses. The IPs can be further divided into phonological phrases based on intonation and stress pattern. A PP is a unity characterized by its own stress and intonation contour, but this latter can be unterminated (continued in next PP). The corpus contained 398 IPs and 751 PPs in total from the 8 speakers.

2.1. Intonational Phrase segmentation

In the spontaneous speech of the BEA database, turns can usually be further segmented into separate utterance units. However, there is no consensus on how to define an utterance unit [10]. The manner in which speakers segment their speech into intonational phrases undoubtedly plays a major role in its definition. Intonational phrase endings can be signalled through variations in the pitch contour, segmental lengthening and pauses. Cruttenden [11] in his theory uses external criteria for identifying intonation groups defined by *potential* boundaries. One of them is a potential pause following an intonation group, however, pauses are not obligatory boundary markers and may occur within a group. According to Shriberg and his colleagues [12] important cues to boundaries between semantic units, such as sentences or topics, are breaks in prosodic continuity, including pauses. In their system for sentence segmentation, the pause model used by the recognizer was trained as an individual phone. The result showed that this pause model was among the ones with the highest influence in sentence segmentation task. Pauses are without a doubt the most expressive instruments for marking of strong boundaries [13]. For Hungarian language, Gósy's research results showed [14] that pauses were among the most important features for utterance segmentation in human perception. In our database, in most cases the IP boundaries are bounded to pauses. A number of filled pauses and unfinished words were perceived as separate IPs as well by the annotators. These findings suggest using two features: a feature which plays an important role in speech detection such as speech energy or speech centroid; and a second feature which is sensitive to speech intonation such as fundamental frequency. In IP segmentation, the task is not only to find silent regions in continuous speech, but to detect the strong intonation changes in the acoustic signal. There are many solutions to detect silence and speech in the audio signal. In this research we choose a very simple and fast algorithm to segment pauses, created by Giannakopoulos [15] and implemented in MATLAB. In this system, a fundamental frequency estimation algorithm is also implemented.

This algorithm first extracts three features: signal energy, spectral centroid and fundamental frequency. These features are extracted for every frame using a 50 ms long window. The signal energy is higher in case of a speech segment than a silent segment. The spectral centroid is a spectral position and this expresses which frequency region contains the most part of intensity in the spectrum. A higher value of the spectral centroid usually corresponds to a speech segment in the audio signal. F0 can refer to the speech signal, and provides a good representation of intonation movements. On both features, 5 point median filtering is applied to smooth the signal. After the feature extraction, a threshold is calculated to each feature stream. In order to determine the threshold, first the smoothed histogram of the feature is used. The following step is to find local maxima of the histogram. In this step we deviate from the original method. To find the two most frequent values in the histogram we use k-means unsupervised learning algorithm. K-means clustering [16] is one of the simplest and oldest unsupervised learning algorithms. Given a set of data (consisting of n different, d-dimensional observations) and the desired number of clusters (k), this algorithm clusters iteratively the data around the so called centroids. For bootstrapping, k data can be randomly chosen as centroids, then each observation is clustered to the nearest centroid. The nearest centroid is computed using some distance measure, such as the Euclidean distance or sum of squares, for example. Centroids are iteratively updated to the mean of the belonging observations, until a specified level of convergence is reached. The main drawback of the algorithm is that the number of clusters (k) has to be determined prior to the clustering itself. In this process we used two clusters: pause and speech.

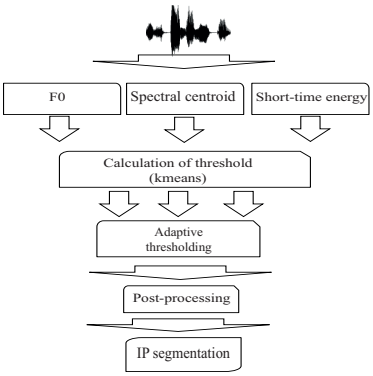

Figure 1: Block diagram of IPs detection

The clustering problem can be formulated as minimizing:

$$\arg\min_{C} \sum_{i=1}^{k} \sum_{x_j \in C_i} D(x_j, \mu_i) \tag{1}$$

for clusters $C_1, C_2, ...C_k$, given n observations ($k < n$), using a $D(.)$ distance function to evaluate the distance between centroid means (μ_i) and observations (x_j). Since this problem is NP hard, usually heuristic approximation is used to solve the problem. If the two cluster centers are available, we calculate the threshold using the following equation:

$$T = \frac{W * M_1 + M_2}{W + 1} \tag{2}$$

where W is a user-defined parameter (set to $W = 0.5$ in our case). Once the threshold is calculated, we apply it to the feature streams. The last step is the post-processing step. In this step the overlapping segments are merged using a large window (usually of a length of about $250ms$, see Figure 1).

2.2. Phonological phrase segmentation

Segmentation for PPs is a harder task than detecting IPs in the continuous audio signal. As PPs are embedded into IPs, the output of the segmentation for IPs constitutes the input of the segmentation for PPs (Figure 2), leading to a two-level, hierarchical approach.

As PPs can be described as phrases with own (proper) intonational and stress patterns, we used fundamental frequency

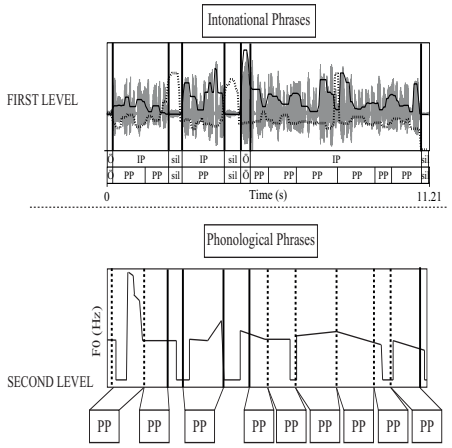

Figure 2: Hierarchical PPs detection

(F0), mid-term speech energy and vowel's duration for their detection. PP boundary detection is carried out as described in the next subsection.

2.2.1. Feature extraction

We use the three basic acoustic correlates of prosody as features: fundamental frequency, energy and duration (tempo).

Fundamental frequency (F_0) is extracted by ESPS method using a 25 ms long window, by a frame rate of 10 ms. The obtained F_0 contour is first filtered with an anti-octave jump tool. This is followed by a smoothing with a 5 point mean filter. F_0 is linearly interpolated in log domain. The interpolation is omitted for voiceless sections longer than 150 ms and also for F_0-rises higher than 110% after an unvoiced part.

Energy is extracted with a 150 ms window by 10 ms frame rate and then a further 5 point mean filtering is applied. As duration features, vowel lengths are used. In order to make the feature extraction automatic, an HMM-GMM based broad phoneme classifier is used. Broad phoneme classes cover vowels, nasal and approximant consonants, plosives, affricates and fricatives. The phoneme classifier uses standard MFCC features as input (with first and second order deltas) and produces a phoneme class level alignment at its output. Resulting vowel length is normalized per speaker, made continuous by a 10 ms frame rate and smoothed in order to obtain a vowel duration contour, called tempo feature. The reason for using a broad phoneme classifier instead of an ASR is twofold: we would like to keep the system generalizable to untranscribed, highly spontaneous speech with no proper language model coverage and hence use a phoneme-class loop grammar, and the phoneme classifier is more accurate in the required pure phoneme-class loop recognition task.

Although the phoneme classifier itself works by some incertaincy, confusions between classes are not crucial if they are systematic, whereby they can even reflect important prosodic information (such as in case of utterance final positions, where vowels are often confused due to low energy and irregularity). For each feature we calculate the first and second order deltas as differential and acceleration coefficients. The dimensionality of the feature vector is hence 9. After the feature extraction we normalise features to 1.

2.2.2. Segmentation using symmetrical Kullback-Leibler distance

The Kullback-Leibler (KL) distance is one of the most commonly used algorithms to measure the dissimilarity between two distributions [17]. The KL distance has been used for various tasks like speaker diarisation, speaker recognition, speech recognition, voice activity detection, etc. The KL distance can be used in speech segmentation and music segmentation as well. In this study, we apply the KL distance to detect phonological phrase boundaries in spontaneous speech. Matthew et al. [18] showed that the symmetric Kullback–Leibler distance is an effective distance metric to facilitate the detection of long-term statistical differences in speech signals. The mathematical background is as follows: let us assume X and Y are two random distributions, and KL is the dissimilarity between these two distributions. The distance $KL(X;Y)$ between X and Y can be calculated as:

$$KL(X;Y) = E_X(log(\frac{P_X}{P_Y}), \tag{3}$$

where E_X stands for the expected value of the probability density function of X. If distributions are modelled by Gaussians, the above equation becomes:

$$\begin{aligned} KL(X;Y) = \frac{1}{2}tr[(\Sigma_X - \Sigma_Y)(\Sigma_Y^- 1 - \Sigma_X - 1)] + \\ + \frac{1}{2}tr[(\Sigma_Y^- 1 - \Sigma_X^- 1)(\mu_X - \mu_Y)(\mu_X - \mu_Y)^T], \end{aligned} \tag{4}$$

where Σ refers to covariance matrices and μ to mean vectors of the respective distributions.

As this function is asymmetric we can symmetrise it with the following method:

$$KL2(X;Y) = KL(X;Y) + KL(Y;X) \tag{5}$$

As said before, if both distributions are considered to be Gaussian, a closed form solution exists for the $KL2$ symmetric KL distance.

In this work, the $KL2$ distance was calculated between two consecutive parts of the signal, corresponding to 4 frames (40 ms) length each. The window step was 1 frame (10 ms). The following task is to find the peaks in $KL2$ value curve. In $KL2$ value a high distance value indicates a possible acoustic change, whereas a low value indicates that the two compared regions of the signal are acoustically similar. From the point of view of the peak detection, it is very important to choose the right window length. For this reason, we used various window sizes from 25 frame (250 ms) up to 70 frame (700 ms) on the $KL2$ curve.

The second problem is the threshold estimation. To detect the changing point, we use two adapted thresholds (thr_A and thr_B). The first is computed as the mean of a window around the given point, multiplied by a constant:

$$thr_A = \alpha \frac{1}{2N_1} \sum(F). \tag{6}$$

where F is the feature vector, N_1 is the length of windows, and α is a constant.

However, in order to be detected as PP boundary, the given value must also be greater than thr_B, which is calculated by:

$$thr_B = \sigma_F + \beta \frac{1}{2N_1} \sum(F) \tag{7}$$

where σ_F is the standard deviation over the windowed area, β is the size of the window. The first threshold ensures that the

given value is greater than the surrounding area, calculated over a small window. The second threshold is calculated over a larger window, and ensures that the change takes into account the general trend of the data changes. The window sizes are currently set to 3 and 4 seconds respectively. Use of these thresholds enables us to reduce false positive rate, and to return only the highest value at any possible PP boundary.

3. Evaluation

The techniques described in this section allow us to measure the performance of any segmentation algorithm. For evaluation method we use Brandts GLR method [19]. This method proposes three common measures which show the performance of the automatic segmentation. The first is the insertion (Ins), which means that there an extra boundary (event) in automatic segmentation to the reference segmentation. Omission (Oms) value means that there are left boundaries (missed events) in the automatic segmentation compared to the reference segmentation. The accuracy (Acc) is calculated using the number of correctly matched boundaries ($Corr$) – if the distance between the automatic label and manual label is within a pre-set tolerance –, the insertion value and the omission value:

$$Acc = \frac{Corr - (Ins + Oms)}{All} \quad (8)$$

The accuracy can measure the performance of the segmentation algorithm. As reference, the PP hand labelling is used. The result depends on the tolerance value, therefore we tried various tolerance values between 25 ms and 100 ms.

4. Results

First, the automatic IP boundary segmentation algorithm is evaluated. Based on speech energy, speech centroid and F0, accuracy of IP boundary detection was 83.1% in spontaneous speech. Leaving one of the features out considerably lowered performance. Most of the errors are caused by the IPs starting or ending by filled pauses. The second aim was to test the automatic PP boundary segmentation algorithm. In our research we tried several features an their combination to detect the PP boundary as well. We compared results obtained from five combinations of the three features. In our first experiment, we focused on the impact of the window size (used for similarity measure calculation in KL2) on PP boundary detection. Window length for the KL2 similarity measure ranges between 100 ms and 400 ms. The result shows the accuracy of the segmentation depending on window length for KL2 and the type of features as well. The best result is obtained by using F0 alone and a 400 ms long window for KL2 (Table 1).

Table 1: *Accuracy of PP segmentation depending on window length.*

Windows length (ms)	100	200	300	400
F0	68.71	75.83	76.33	**80.18**
Tempo	55.33	56.67	56.91	57.38
F0+energy	68.45	74.75	74.25	79.04
F0+tempo	68.79	73.15	72.33	78.22
F0+energy+tempo	68.86	72.60	71.84	77.05

We especially focused on speech tempo in PP boundary detection, as it was found unhelpful for read Hungarian [5]. When we use only the speech tempo for IP boundary detection the accuracy is very poor. However, the accuracy improves when the speech tempo is combined with F0, but it is still lower than using only F0. The accuracy also decreases if speech tempo is combined with F0 and energy. The result shows that the accuracy increases if speech tempo is discarded. Speech tempo does not correlate well with F0 (R=-0.06) or energy (R=-0.04). Based on these results, its contribution to the perception of PPs is likely to be negligible in Hungarian.

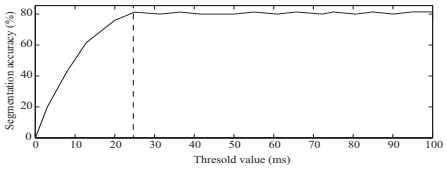

Figure 3: Accuracy of segmentation depending on threshold value

Next, the performance of the segmentation (accuracy) is shown, depending on the tolerance value. We tested our segmentation algorithm using various tolerance values (Figure 3). The result showed that if the tolerance is 25 ms the segmentation accuracy is 80.2%. By further augmenting the tolerance, there is no additional gain, accuracy saturates. This means that the segmentation algorithm is quite precise in time.

These results also suggest that F0 is the basic acoustic cue in PP boundary perception, whereas energy is also important in the perception of upper level unit boundaries is spontaneous Hungarian. The relatively powerful detectability of such boundaries in spontaneous speech strengthens the hypothesis that this kind of segmentation plays a key role in human perception as well.

5. Conclusions

The aim of this research was to segment spontaneous speech based on an unsupervised learning technique and a sophisticated peak detection approach. Phonological phrase segmentation was implemented in two hierarchical steps: first intonational phrase segmentation was performed using k-means clustering. Thereafter, intonational phrases were further segmented for phonological phrases, based on prosodic event detection exploiting symmetric Kullback–Leibler distance in an autocorrelation like approach. KL-distance features were themselves used as derived features, and peak detection was carried out on these. In our research we tried several features an their combination to detect the PP boundary as well. The results showed that fundamental frequency can be clearly associated with the phonological phrase level, as the best PP segmentation result is yielded by using F0 features alone by allowing only 25 ms time deviation between the detected PP boundary and the reference one. In this case, the accuracy was 80.2%. Results showed that speech tempo had no identifiable role in PP boundary detection. Regarding energy-based features, they seem to be associated to the IP level and did not improve PP detection based on F0 alone. However, some lack of robustness is supposed for the energy cues despite using normalization, due to the high degree of channel variability in the corpora (for example the speech recorded with a single microphone in a two-party conversation). These results are comparable to results seen for read speech [5], especially by the low uncertainty of the PP boundary detection regarding accurate placement in time.

Abstract

Research has shown that audio-visual speech information facilitates second language (L2) speech learning, yet multiple input modalities including co-speech gestures show mixed results. While L2 learners may benefit from additional channels of input for processing challenging L2 sounds, multiple resources may also be inhibitory if learners experience excessive cognitive load. The present study examines the use of metaphoric hand gestures in training English perceivers to identify Mandarin tones. Native Mandarin speakers produced tonal stimuli with simultaneous hand gestures mimicking pitch contours in space. The English participants were trained to identify Mandarin tones in one of four modalities: audio-only (AO, speaker voice only), audio-visual (AV, speaker voice and face), audio-gesture (AG, speaker voice and hand gestures) and audio-visual-gesture (AVG). Results show significant improvements in tone identification from pre- to post-training tests across all four training groups, demonstrating that gestural as well as visual articulatory information may facilitate tone perception. However, further analyses with individual tones reveal some group differences. Most noticeably, the AVG group had a slower learning curve during training compared to the other trainee groups for Tone 4, the least accurately identified tone, indicating a negative effect of multiple input modalities on the perception of difficult L2 sounds. In contrast, for Tones 2 and 3, the AG group revealed slower learning effects compared to the AV group, presumably because of the similar gestural trajectories for these two tones, which made the gestural input less distinct. Overall, the results suggest a positive role of gestures in tone identification, one that may also be constrained by phonetic and cognitive demands.

Index Terms: auditory, visual and gestural speech perception, Mandarin tone, L2 speech learning

1. Introduction

Research on multimodal speech processing has indicated that integration of auditory and visual articulatory information can enhance native and non-native speech perception [1], [2]. Additionally, co-speech hand gestures have been shown to facilitate native speech perception [3]. However, research has been inconclusive to the amount of gain from gestures in L2 speech learning [4], [5], [6]. For example, while beat gestures can aid L2 learners in parsing words into syllables [7], they are not as effective in discriminating durational differences [6]. Indeed, when integrated effectively, simultaneous auditory, visual and gestural information may have a combinatory effect in aiding speech learning [7], [8]. Conversely, the addition of gestural input may also be inhibitory as learners may experience excessive cognitive load, especially when phonetic demands are high [5], [6]. This discrepancy in the role of gestures motivates the present research.

In this study, native speakers of Canadian English were trained to perceive Mandarin Chinese lexical tones with one of four input modalities: audio-only (AO), audio-visual (AV), audio-gestural (AG), and audio-visual-gestural (AVG). The gesture used here is the metaphorical gesture, which traces an imaginary tone as it changes in pitch along the dimension of time (duration) and height (pitch), as is commonly used in Chinese tone teaching environments. This type of gestures has been shown to help pitch learning in contexts such musical training [9]. Training follows previously established high variability perceptual training procedures which involve various phonetic and speaker voice contexts to expose trainees to a variety of exemplars of the non-native speech categories [10], [11]. Trainees' performance was assessed by a pre- and a post-training tone identification test along with three intersession tests during training. Comparisons of the training effects with AG vs. AO or AV groups would determine whether and to what extent gestural information is beneficial in tone perception. On the other hand, if the addition of gestural input caused information overload, we would expect AVG training to be less effective than AG or AV training.

2. Methods

2.1. Participants

Four native Mandarin-speaking instructors (2 male, 2 female) were recorded to provide the training stimuli. They were chosen because of their familiarity with training students and knowledge of the Mandarin tones. Two additional native Mandarin speakers (1 male, 1 female) produced the pre- and post-test stimuli.

The trainees were 57 native Canadian English young adults. They had no prior experience with any tonal languages and no extensive experience with music either (with fewer than five years of musical training [12]). They were randomly assigned to one of the training groups (AO, AV, AG, or AVG), with 16 in each group (8 male, 8 female), except for the AO group, which had 9 participants (2 male, 7 female).

2.2. Stimuli

The training word list contained 80 Mandarin monosyllabic real words (20 syllables x 4 tones, Tone 1: high-level pitch, Tone 2: mid-high-rising pitch, Tone 3: low-falling-rising pitch, Tone 4: high-falling pitch), which was derived from those used in [11] and [13]. Audio-visual recordings of these words were made twice for all speakers, with and then without hand gestures. The stimuli used for the pre- and post-tests were the 60 additional Mandarin monosyllabic real words (15 tone quadruplets) used in [11].

Training stimuli speakers were instructed to simultaneously speak a word and trace an acetate graph

representation [14] of the corresponding tone on the feedback screen of the digital camera with their right index finger so that the gestures would be standard across speakers. The video was then mirrored so that the tone contour was presented in the correct direction for the trainees. For the AG condition, the speaker face was blacked out so that the only area visible was the arm including the hand and finger during tone tracing. Six additional native Mandarin speakers then participated in a stimuli goodness evaluation task. All the stimuli used in training were correctly identified and rated as good tokens of the Mandarin syllables by the native Mandarin speakers. Figure 1 displays sample images of (a) tone contour tracing used as gestural input in training, and (b-e) the four training conditions (AO, AV, AG, and AVG).

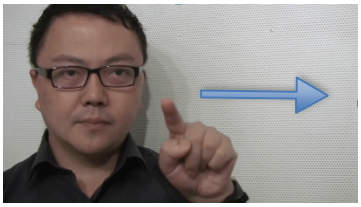

Figure 1-e: *Audio-visual-gestural (AVG) training presentation. The arrow indicates where the speaker will trace the contour of Tone 1.*

2.3. Procedures

Trainees were set up in a sound-treated booth in the Language and Brain Lab (Simon Fraser University, SFU) wearing AKG-brand circumaural headphones to hear the stimuli. They were first familiarized with the Mandarin tones by listening to a tone quadruplet and learned to associate each tone with its tonal label. They repeated this familiarization at the beginning of subsequent training sessions to review the task and hear an example before starting.

Prior to and after training, participants were tested with auditorily presented tone words described above. The identical pre- and post-tests employed a four-alternative forced choice task with no feedback provided. Identification was made using corresponding keys on the keyboard, with the labels "LEVEL" (for Tone 1), "RISING" (for Tone 2), "DIPPING" (for Tone 3) and "FALLING" (for Tone 4). Trainees were familiarized with these terms before the pre-test. After the pre-test, participant scores were calculated to determine if their percent-correct score was suitable for our inclusion criteria: If the participant scored between 25-80% correct, they were permitted to continue with the training. If the participants' scores fell outside that range, they were excluded and did not continue training. This was done to exclude those who had extreme scores due to hitting floor or ceiling.

Training took place during a two-week period with six sessions of 40 minutes each. Each session contained 40 words balanced across tones and syllables and produced by four speakers. Training stimuli were presented in AO, AV, AG or AVG, depending on the condition (as shown in Figure 1, b-e). The video was presented on a 12" (H) x 15" (W) display computer monitor, with the trainee's face roughly 18" away from the monitor screen.

Each trial started with presentation of a stimulus, followed by the trainee's task to identify the tone, and end with the feedback along with stimulus replay. Three intersession tests were administered after every second training session. These tests were used to track learning trajectory during training. They were presented in audio-only format, similar to the pre/posttest. The 80 intersession test stimuli (5 syllables × 4 tones × 4 speakers) employed selected stimuli used in training.

3. Results

3.1. Overall performance

The participants' percent correct identification scores were first analyzed using a three-way repeated measures ANOVA with Training Group (AO, AV, AG, AVG) as the between-subject factor, and Test (pre-test, intersession test 1 [Int1], intersession test 2 [Int2], intersession test 3 [Int3], post-test) and Tone (Tone1, Tone2, Tone3, Tone4) as the within-subject factors.

Significant main effects of Test [$F(4,212)=198.3$, $p<.001$] and Tone [$F(3,159)=31.6$, $p<.001$] were found. Bonferroni adjusted post hoc pairwise comparisons among tests reveal that across groups and tones, the mean pre-test score (48%) was significantly lower than all the intersession and post-test scores (Int1: 79%, Int2: 85%, Int3: 87%, post-test: 83%, $ps \leq .001$), and additionally, Int1 score was lower than Int2 and 3 scores ($ps \leq .001$), indicating significant

improvements with training. Post hoc tone comparisons show that, across tests and groups, perception of Tone 4 was significantly less accurate (68%) than Tones 1 (76%) and 2 (75%), which were in turn less accurate than Tone 3 (87%) ($ps \leq .038$), revealing Tone 4 as the most challenging tone.

The ANOVA also yielded significant interactions of Test x Tone [$F(12,636)=17.6$, $p<.001$] and Test x Tone x Group [$F(36,636)=1.6$, $p=.017$].

3.2. Individual tones and groups

Further analyses were performed based on the above interactions to identify possible Group differences as a function of Test and Tone. These involve sets of two-way Test x Group ANOVAs for each Tone, followed by further one-way ANOVAs for each Tone and Group with Test as a factor. Group comparisons of the five Tests for each Tone are displayed in Figure 2 (a-d).

First, only for Tone 4 (Figure 2-d) did the two-way ANOVAs show a significant interaction of Test and Group [$F(3,53)=4.0$, $p=.012$], along with a significant main effect of Test [$F(1,53)=337.4$, $p<.001$]. Bonferroni adjusted pairwise comparisons among the five tests for Tone 4 are consistent with the overall patterns. Across groups, the pre-test score (25%) was lower than all other test scores (Int1: 72%, Int2: 81%, Int3: 82%, posttest: 80%, $ps<.001$ for all). Furthermore, performance at Int1 was significantly poorer than that at Int2 and Int3 ($ps \leq .001$). Subsequent one-way ANOVAs with individual groups revealed that the aforementioned differences among intersession tests only occurred with the AVG group, with Int1 (67%) scoring marginally less well than in Int2 (81%, $p=.050$) and significantly lower than Int3 (86%, $p=.005$) and post-test (83%, $p=.007$), indicating a slower learning curve (during training) and a lack of generalization (to new stimuli at posttest) when training involved all three input modalities.

Consistently, for Tones 1-3, the two-way Test x Group ANOVAs also revealed significant main effects of Test. Though the ANOVAs yielded no significant interactions of Test and Group for these tones, the multiple levels of variables may obscure any possible difference in Test scores for each Tone and Group. Therefore, one-way ANOVAs were still run for each Group and Tone.

For Tone 1 (Figure 2-a), the two-way ANOVA yielded a significant effect of Test [$F(1,53)=125.5$, $p<.001$], with the scores being significantly lower at pre-test (45%) than at all the other tests which scored equally high (Int1: 81%, Int2: 85%, Int3: 85%; post-test: 82%, $ps<.001$ for all). Further one-way ANOVAs for each Group did not reveal any different patterns either. Thus all four training groups improved equally and retained the level of performance observed at Int1.

For Tone 2 (Figure 2-b), there was also a significant effect of Test [$F(1,53)=102.3$, $p<.001$], with pre-test (52%) being significantly lower than the other tests across groups (Int1: 75%, Int2: 83%, Int3: 86%, post-test: 76%, $ps<.001$ for all). Additionally, Int1 score was significantly lower than Int2 and Int3 scores ($p \leq .014$), both of which scored higher than post-test ($ps \leq .005$). Subsequent analyses with each trainee group revealed some group-specific patterns. First, the overall result of a higher-intersession-than-post-test performance was only exhibited in AO and AG groups, whose Int3 (AO=92%, AG=88%) score was higher than the post-test (AO=72%, AG=77%, $ps \leq .008$). Moreover, the overall gradual learning pattern was particularly true for AG, whose Int1 (75%) score did not differ significantly from the pre-test (51%, $p=.163$). Finally, only for AO, the pre- (50%) and post-test (72%) scores did not show significant improvement ($p=.074$). These results show different learning trajectories across groups for Tone 2.

For Tone 3 (Figure 2-c), a significant effect of Test was again found [$F(1,53)= 61.0$, $p<.001$], with the pre-test (69%) being lower than the subsequent tests across groups (Int1: 89%, Int2: 90%, Int3: 92%, posttest: 93%, $ps<.001$ for all). Subsequent individual group analyses revealed that only the AG group showed exceptions to this general pattern, in that their pre-test score (65%) was not significantly different from their Int1 (82%, $p=.068$) and Int2 (81%, $p=.138$) scores, showing a slower learning effect.

3.3. Summary

The results demonstrate that the performance for all four groups improved through training. The perception for each tone was slightly different, with Tone 4 being the most difficult tone to identify. Moreover, the results for individual tone and group showed robust differences in Tone 4 learning, where only the AVG group exhibited a delay in improvement during training and a failure in generalization at post-test. Similar gradual learning patterns were also observed for Tone 2 and Tone 3 with the AG group. Furthermore, for Tone 2, the AO group did not improve significantly from the pre-test to the post-test.

4. Discussion and concluding remarks

Overall, the results showed substantial improvement after training for all groups, which is in keeping with previous research indicating that speech perception from multimodal presentation benefits L2 speech learning [2], [7], [8], [15].

However, further analysis with individual tones did reveal differences in the extent of improvement among the four training groups. Most noticeably, compared to the other three trainee groups, the AVG group exhibited a slower learning curve during training and a lack of generalization after training for Tone 4 (with high-falling pitch), also shown as the most difficult tone to identify. It is possible that the cognitive resources for the identification of Tone 4, the most challenging tone, were overtaxed by too many channels of input, which in turn resulted in lower performance of the AVG group compared to the other trainees. This supports the "information overload" hypothesis, being in line with previous claims that gestural input in addition to auditory and visual input may increase the cognitive load, resulting in an inhibitory effect in learning [6], particularly when phonetic demands are high [5].

Results for the learning trajectory of Tone 2 (with rising pitch) showed an increased identification from the pre- to post-training tests for AV and AG but not for AO, suggesting that the addition of either visual or gestural input could result in a significant improvement in tone identification. This is in line with the results for Tone 4, where similar levels of improvement were found in both AV and AG groups. The positive effects of visual input support the previous findings that visual articulatory movements involving the head, mouth, and eyebrows provide robust correlates to tone perception [16], [17], [18]. Unlike visual speech information present in a speaker's face, which has anticipated and fixed articulatory configurations for the resultant speech sounds, the gestures used in the current study involve spatial changes which are not directly bound to speech. However, the AG group's improvements demonstrate that the trainees were able to make the spatial-auditory association embodied by the hand gestures tracing pitch trajectories and utilize that to aid their learning, just as how similar gestures could guide musical pitch processing [9] and aid L2 prosodic perception [7].

Nonetheless, it is also worth noting that visual and gestural modalities are not always equal in terms of degree of improvement. For both Tone 2 and Tone 3, the increase in tone identification accuracy during training for the AG group was more gradual than that for AV. One possible reason for the slower improvement of the AG group may be due to the similar gestural trajectories of the two tones (both involving a long rising pitch contour), which may have made the two gestures less distinct. Thus it may have taken the AG group longer to effectively integrate the gestural information as compared to the AV group whose input involved more predictable articulatory-auditory correspondence.

Taken together, the differing patterns observed within these results demonstrate the complex role of multimodal input in L2 speech perception. The most promising finding is that co-speech gestural as well as visual articulatory information can aid L2 speech learning. However, facilitation from multiple input domains may not be additive and may be constrained by phonetic and cognitive demands. When perceiving phonetically challenging sounds, learners (particularly those at the elementary level) may find multiple input resources distracting, as they may not be able to simultaneously focus on all these input domains and effectively integrate them into a single percept. As such, training with fewer input domains may reduce the cognitive load required to attend to multiple channels [6], [19]. Moreover, the different patterns for individual tones and training groups suggest that multimodal facilitative effects may take place in a complimentary manner. Learners could be trained to selectively focus on those domains that can most readily and reliably aid their learning. Further research may delve into these avenues to better understand the complex relationship between L2 prosody learning and gestures.

Abstract

Fundamental frequency, the primary acoustic correlate of speech melody, is generally analysed and displayed using a linear scale (Hertz) or a logarithmic one, generally in semitones and usually offset to an arbitrary reference level such as 100 Hz. In this paper we argue that a more natural scale for analysing speech is the OME (Octave-MEdian) scale, using the octave (o) as the basic unit, offset to the median value of the speaker's range. We present results showing that a reasonable estimate of a speaker's neutral pitch range can be obtained directly from the median.

Index Terms: Tone, intonation, melody, pitch, octave.

1. Introduction

Although one can observe some non-linearity in the perception of the pitch of speech sounds, fundamental frequency is unquestionably the main acoustic correlate of perceived pitch height. Psycho-acoustic scales for the study of speech have also been proposed, particularly the *Mel*, *Bark* and *ERB* scales. The relevance of these scales, however, remains unproven. A recent study [25], for example, using a task of replicating pitch contours between male and female voices, showed that a logarithmic scale better reflects the performance of speakers than either a linear or a psycho-acoustic scale. The physical scale in *Hertz* (cycles per second) is very often transformed, in studies of prosody, to a logarithmic scale, most often expressed in semitones with a reference value (called C0), arbitrarily set at 16.3516 Hz [28]. This reference was chosen as being close to the lowest pitch perceptible to the average human ear and as well as corresponding to the tuning of A_4 (= 'A above middle C') to 440 Hz, in conformity with the ISO Standard ISO16 [19].

Fant [12] proposed the St (= semitone) unit defined as:

$$St = 12 \cdot \frac{ln(\frac{Hz}{100})}{ln(2)} \quad (1)$$

The semitone is, however, in no sense a natural unit of measurement. It is, in fact, the product of a complex history of Western classical music culture, corresponding to the division of the octave into 12 equal intervals, an idea that had first been described in a treatise published in China in 1584 [20]. In Europe, the scale of 12 equal semitones equal (= *equal temperament*), has been used increasingly since the 18th century to tune keyboards, replacing the *natural scale* ('just intonation') previously used, or Bach's *well-tempered scale*. All these scales were the result of a search for a compromise which would allow musicians to modulate from one scale to another without introducing major discord and without having to switch keyboards.

In different civilizations at different times, the use of different sets of notes can be observed. Practically all of these scales, however, have in common the fact that the names of the notes are generally the same, regardless of the octave. Thus, in the Western classical scale, for example, the sequence *Do Re Mi Fa Sol La Ti Do Re Mi ...* etc. can be repeated indefinitely within the physical limits of sound production.

This circularity (also known as *chromatic repetition*) seems to stem from a physiological basis of human perception [6, 5] including that of neonates [22] and also that of rhesus monkeys [27]. It was observed as early as the 60s, in an anatomical study of a cat, that the auditory thalamus is organised in stacked layers or laminae. It was suggested that this organisation may have a specific function in the processing of acoustic frequencies [24]. [23] and [18] later demonstrated that the auditory thalamus of the cat actually contains a neural chroma map, underlying an octave architecture. While the functional role of the mammalian auditory thalamus octave topography still needs to be determined, recent research has suggested that it may cause, as a side effect, the octave circularity of pitch that has been observed in the rhesus monkey as well as in humans [6]. This study investigated the effect on a musician with absolute pitch, of the neurotropic medical drug carbamazepine (CBZ), known to have a down-shift pitch side effect,in order to better understand the mechanism of octave circularity of pitch. They observed in their subject, during a pitch identification task, an internal tone-scale or chroma representation. When CBZ was taken, pitch shift was indeed observed but the pattern of tone representation remained unchanged. This suggests that the human brain may be hard-wired for octave-circular pitch perception.

In any case, it is the octave, not the semi-tone, which appears clearly as the basic unit for the natural perception of the pitch of speech sounds and music.

The use of the *semi-tone* (or in more precise studies, its subdivision the *cent* [where $1st = 100cents$) has paradoxically had the negative effect of masking the importance of the octave as a basic unit in pitch production and perception. Rereading a number of studies on pitch range with this in mind reveals a very large number of cases where authors report an interval close to an octave (= 12sts) or half-octave (= 6sts) without drawing attention to this fact, or perhaps, even, sometimes without having noticed it. In [26], for instance, the authors reported a f0 mean at the beginning of sentences produced in neutral, happy, angry and scared voices of 6.72, 12.64, 12.52 and 12.38 sts respectively. If we calculate the difference between the neutral voice mean f0 and the other voices mean f0, it reveals for each 'arousal' voice a shift of half-an-octave.

The intervals octave and half-octave may play a specific role in speech production. [4] investigated the pitch contours of utterances produced under two conditions (in a normal voice in a quiet room vs. in a louder voice when exposed to noise over headphones), and observed for instance a raising of half-an-octave for the increased loudness condition. A raise of a half-an-octave or an octave may be used to convey specific linguistic and paralinguistic functions in speech, e.g. signaling focus, topic change, turn-taking as well as expressing arousal.

2. The octave as the basic unit for the perception of pitch.

We recommend the systematic use of the octave (o) and its subdivision the millioctave (mo) for the study of pitch. For precise measurements, the (mo) gives, in fact, approximately the same degree of precision as the cent [$1mo = 1.2cents$] and has the advantage of being in conformity with the general practice of the *International System of Units: SI,* in which prefixes corresponding to an exponent divisible by 3 are generally preferred.

As a derived *SI* unit, the octave can be defined as:

$$o = log_2(s^{-1}) \quad (2)$$

where s is the duration in seconds of a period.

The second author has suggested elsewhere [13, 14] that there may also be a physiological explanation for the octave and half octave as a basis for the production of melodic intervals. [14] reported an experiment where these two intervals were observed as modal values in a task of producing varied contours on isolated syllables in French, *oui* and *non*.

In so far as the vocal folds behave like vibrating strings, the relationship between tension and frequency is governed by Mersenne's law which states that

> *The frequency of a vibrating string is proportional to the square root of its tension.*

A doubling of the tension would consequently correspond to a rise of half an octave. This might explain why the intervals - octave and half octave - seem to be frequent in the production of speech melody, even though a rise or fall of an octave on a single syllable is certainly not perceived in its entirety.

3. Corpora

Four corpora, a total of about 2 hours of speech, were selected for this study: these consisted of extracts of the *PFC* and the *CID* corpora for French and the *PCA* and *Aix-MARSEC* corpora for English. These are briefly described below.

The PFC corpus (Phonology of Contemporary French) [9].

We selected 10 French speakers, from the region of Marseille, 6 female and 4 male. We chose the recordings of their production reading aloud a passage of text, such as an extract from a regional newspaper. This corresponded to approximately 30 minutes of recording.

The CID corpus (Corpus of Interactional Data) [2].

We selected six French speakers, from the region of Marseille, 3 male and 3 female. The recordings corresponded to conversations, where speakers discuss either professional conflicts or unusual situations in which they had found themselves, a total of 30 minutes of recording.

The PCE corpus (Phonology of Contemporary English) [7].

We selected eight English speakers, four male and four female, from the North of England. We chose the the recordings of their production reading aloud a passage, such as an extract from a regional newspaper. This corresponded to approximately 25 minutes of recording.

The Aix-MARSEC corpus [1]. The recordings correspond essentially to extracts from the BBC made in the 1980's.

We selected 51 speakers, 13 women and 38 men. 11 types of production are represented: comments, newsletters, public speech, religious programs, documentaries, fiction, poetry, dialogues, propaganda, etc. This represented a total of approximately 50 minutes of recording.

4. Estimation of pitch range

In [11] we reported results based on the 4 corpora, in English and French, described in the previous section, which showed that, in the production of natural speech, the lower range of fundamental frequency systematically corresponds to half an octave below the median pitch of a speaker's voice, and the upper range generally extends between half an octave and one octave above the median.

The pitch range of a speaker (ie the tonal space actually used in an utterance) is generally measured by two parameters: its *height* (or key) and its *extent* (or span) [21]. Pitch height is generally measured by taking the mean or the median of the distribution of f_0, or by taking the mean value of points considered as representative targets. The span of the pitch range can be calculated by comparing the minimum and the maximum value produced in an utterance or the average values for high and low targets.

A measurement of pitch based on the analysis of tonal targets can be both costly and error prone, especially if the targets are annotated manually.

In this study, we calculated the value of pitch range with respect to the median of the distribution of f0 since this is more stable than the mean which is influenced by extreme values some of which may be erroneous. In addition, the median is a non-parametric measure, independent of the unit or scale of measurement. The median value, in other words, is always the same value whether it is measured on a linear scale or on a logarithmic scale or on one of the psyco-acoustic scales mentioned above.

To avoid the problems inherent in manual measurements, our calculations were carried out using the *Momel* and *INTSINT* algorithms [15].

The Momel algorithm takes as input the raw fundamental frequency curve and models it as the sum of two components, a 'macroprosodic' component on the one hand, consisting of a smooth continuous underlying function corresponding to the intonation pattern of the utterance, and a 'microprosodic' component consisting of a sequence of functions, some of which are discontinuous and which correspond to the local effect of the different individual speech sounds. For more details on these two components cf [16], for a recent attempt to model the 'microprosodic' component for speech synthesis in Arabic, cf [8].

The INTSINT algorithm takes as input the target points detected by the automatic pitch modeling algorithm (Momel) and codes these targets using an alphabet of 8 discrete symbols. The symbols **T**(op) and **B**(ottom) delineate *high* and *low* values of the speaker's pitch range, respectively, while **M**(id) codes its central tendency. Targets coded **H**(igher), **L**(ower), **S**(ame),

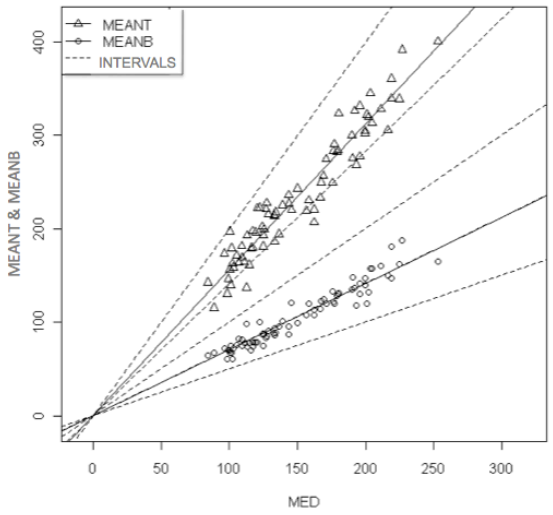

Figure 1: Linear regressions corresponding to Mean-**B** and Mean-**T** are traced in continuous lines and the dotted lines represent, from top to bottom, the intervals +octave, +half-octave, unison, -half-octave and octave compared to the median.

U(pstepped) or **D**(ownstepped) are defined not globally but locally, with respect to the value of the immediately preceding pitch target and are defined as being, respectively, *higher*, *lower*, *equal to*, *slightly higher* or *slightly lower* than the preceding target. For the precise definitions of the coding cf. [15].

In this study, we focus on the values obtained for the absolute **T** and **B** tones since all the other values are dependent on the value of the preceding target.

As we mentioned, one of the most common ways to measure a speaker's pitch range is by comparing the mean values of pitch which have been identified as corresponding to high tones and low tones. It is instructive to look at the correlations between the mean values of the low tones (**B**) and high tones (**T**), as determined by the INTSINT algorithm, and that of the *median* of the pitch distribution.

We find, in fact, two strong correlations. Affine relations are as follows:

$$B = 0.741 * median - 5.52$$

$$T = 1.537 * median + 3.75 \quad (3)$$

Significance tests of regression coefficients are highly significant $p < 2^e - 16$. The critical probabilities of the offsets are, however, not significant (p = 0.161 and 0.659). An adjustment of the model without the offset gives:

$$B = 0.706 * median$$

$$T = 1.561 * median \quad (4)$$

For **B**, we find a coefficient of determination (R^2) of 0.92 and for **T** 0.91. This means that it is possible, at least as a reasonable approximation, to predict the limits of the register of a speaker and hence its span, from the median of the distribution of f_0.

ANOVAs on the prediction of average low (**B**) and high (**T**) tones from the median showed no effect of either sex (p = 0.0917 (**B**) and 0.381 (**T**)) or language (p = 0.170 (**B**) and 0.274 (**T**)), or type of production (p = 0.134 (**B**) and 0.368 (**T**) on the slopes of linear regression. It is therefore possible, from the value of the *median*, regardless of the sex of the speaker, both in English and French and whatever the style of speech, to make a reasonably good prediction of the limits (span) of the pitch range. In fact, [10] showed that the relationship between the height and span of the pitch range is actually more complex. In the model given in 4, the range in Hz is strictly proportional to the height because the relationship between T and B is fixed. An even better correlation is obtained with the values on a logarithmic scale, corresponding to a model where the span in octaves is proportional to the height, going from one octave for a low-pitched voice to a little less than an octave and a half for a high-pitched voice.

This co-variation was pointed out by [21] in his discussion of pitch range. The author explains that the difficulty of admitting two dimensions for the register is that these two dimensions co-vary.

5. The OMe scale. A natural scale for the melody of speech

It is interesting to note in the relationships defined in (2) that the coefficient 0.706 corresponds almost exactly to half an octave($log2(0.706) = -0.502$) and the coefficient 1.561 is just slightly over half an octave ($log2(1.561) = 0,642$). We can therefore conclude that the average of the high tones and the average low tones, i.e. the limits of the range of a speaker, for unemphatic speech, usually correspond to about an octave centered on the speaker's median.

This led us to propose [11] a new scale of measurement: the *OMe* (Octave-MEdian) scale defined by the formula:

$$ome = log_2(\frac{Hz}{median}) \quad (5)$$

where *median* corresponds to the median value of f_0 for the recording.

Figure (1) gives a graphical representation of the average low tones (**B**) and the average high tones (**T**) compared to the speaker's *median* pitch. The corresponding linear regressions are plotted in solid lines and dotted lines represent the intervals + *octave*, + *half-octave*, *unison*, - *half-octave* and - *octave* with respect to the *median*. The linear regression on the mean of the low tones (**B**) coincides with the half-octave below the median so that the two lines are not distilnguishable in the figure. That of the average of the high tones (**T**) falls between half an octave and one octave above the median. These musical intervals, defined relative to the median, can therefore be used to estimate the range of a speaker with a reasonable reliability.

They also allow us to propose, as suggested above, a natural scale for the analysis and visualisation of the melody of speech defined in octaves, centered on the median, which we call the *OMe* (Octave-Median) scale.

Figure 2 shows an example of expressive speech by a radio broadcaster pronouncing the sentence 'He dra**MA**tically flourished a **CO**py of Time from nineteen fifty-**THREE**.". As can be seen, the places where the pitch goes above half an octave above the median, correspond precisely to the parts of the words which are perceived as being emphasised expressively.

Figure (3) illustrates the sentence "What can I have for dinner tonight? " read by one male and one female speaker.

The visualisation of these recordings was obtained automatically from the signal and TextGrid using the Praat plugin

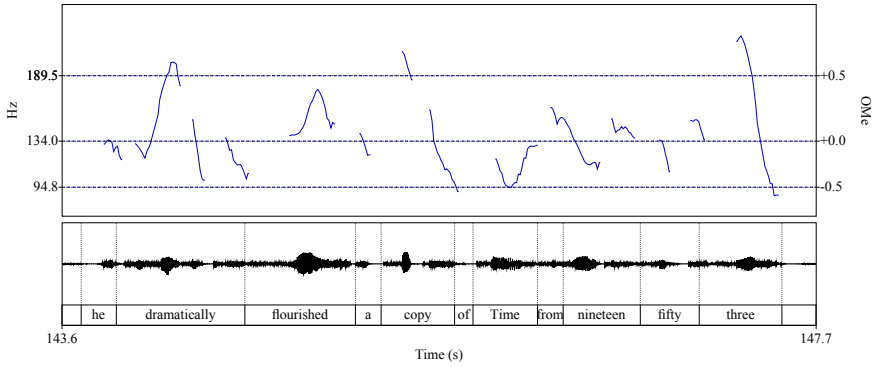

Figure 2: An extract of journalistic speech "He dra**MA**tically flourished a **CO**py of Time from nineteen fifty-**THREE**."

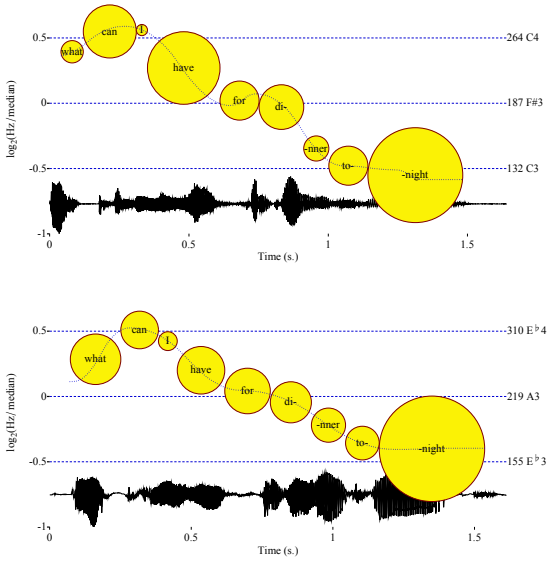

Figure 3: Graphical representation of readings of the sentence "What can I have for dinner tonight." by one male (top) and one female (bottom)speaker, displayed using the *OMe scale* (Octave-Median). The diameter of the circles corresponds to the duration of the syllables. The horizontal blue lines delimit the central octave surrounding the speaker's median pitch.

ProZed [17], which is freely downloadable from the *Speech and Language Data Repository* at: http://sldr.org/sldr000778/en.

The diameters of the yellow circles correspond to the syllable durations and the dashed blue line corresponds to the Momel curve. The horizontal dotted lines correspond to the speaker's median (middle line) and a half octave above and below the median, delimiting the speakers unemphatic pitch range corresponding to the median-centred octave. The values of the *Median* and the *Top* and *Bottom* of the central octave are given both in Hz and as musical notes as defined with respect to concert pitch at 440 Hz.

With this technique, the optimal parameters for the analysis of the fundamental frequency of the speaker are automatically determined from the median pitch.

6. Conclusions.

We propose in this paper that it is the octave, rather than the semitone, which should be considered the basic unit of a scale for natural speech prosody. This follows evidence reported in several studies based in neuronatomy, neurophysiology, behavioral studies, speech production as well as speech perception. In particular, we propose the use of the OMe scale to define an automatic display of the fundamental frequency curve. The reference (key) for such a scale is given by the median of the speakers fundamental frequency. The *Bottom* of the central octave of the speakers voice is consequently half an octave below the median while the *Top* is half an octave above.

The Bottom and Top lines of the display should not be thought of as physical obstacles for speakers. Obviously, in more spontaneous corpora we are likely to find a larger pitch range - up to two octaves has been reported in the literature. Pitch often goes beyond these lines, particularly in the case of the Top , but when it does so, it may be taken as a good sign that the speech is expressive or signalling important information.

Since the expressive use of pitch particularly concerns the top of the range, it is natural that the distribution of pitch in these cases will be skewed. It should be noted, however, that taking the median pitch rather than the mean pitch as reference value largely reduces the impact of the skewness, but this naturally remains to be tested on much more data.

Further research is also necessary on the variability of the median pitch for given speakers. As mentioned previously, the octave and half-octave intervals may be used in structuring the discourse (e.g. indicating focus, topic change, turn-taking) as well as in expressing arousal or attitudes. The relation between speakers' span and median voice may have facilitated the perception of linguistic and paralinguistic functions of pitch range in speech production across genders, languages and speaking styles and may be interesting to examine in terms of prosodic universals. It opens up the debate on the formal and functional aspects of speech prosody as a result of learning and experience or of having some basis in the operation of the auditory system.

Automatic Discovery of Simply-Composable Prosodic Elements

Nigel G. Ward

Department of Computer Science, University of Texas at El Paso
nigelward@acm.org

Abstract

As a way to discover the elements of prosody, Principal Component Analysis was applied to several dozen contextual prosodic features, sampled at 600,000 timepoints in dialog data. The resulting components are interpretable as prosodic patterns, including some which involve behaviors of both interlocutors. Examining contexts and co-occurring words, many of these have clear interpretations. This suggests that English has at least several dozen prosodic patterns, each with its own communicative function.

Index Terms: principal components analysis, prosodic elements, prosodic patterns, factors, dimensions, contours, superposition, intonation, modeling, dialog, interaction, pragmatics

1. Introduction

To understand a complex machine, one needs to identify the pieces and how they work together. Classical approaches to prosody have found many likely pieces, including targets, contours, impulses, and events, and much has been written about each. However the question of how these elements are combined has received less attention; many models of prosody are vague here. This is a problem because theories that rely on unexplained mechanisms have little predictive power: they are impossible to test rigorously and potentially falsify [1, 2].

Well-specified descriptions of how prosodic elements combine do exist, for example [3, 4, 5, 6]. However so far these have been worked out only for carefully circumscribed sets of phenomena, in datasets where every other prosody-related factor is controlled. The more general trend is, it seems, to give up on modeling prosody in terms of composable elements, instead using machine learning techniques that operate directly over raw features [7, 8]. While this can be of great practical value, the resulting models are tailored to single applications, are difficult to interpret, and do not much advance our understanding of prosody.

This paper presents a way to outflank the problem of combination mechanisms. The novel idea is to start with a composition rule, and to then use it to infer the elements; the reverse of the classical strategy. This guarantees that these elements will compose simply, with no slack in the model. Originally developed for purely practical reasons [9, 10], this method is here presented as it relates to other approaches, with new visualizations, and with more dicussion of the broader implications and prospects.

2. Principal Component Analysis for Prosody

The fundamental assumption of the method is that superposition is the main combining principle for prosodic elements. Thus the elements, whatever they are, are required to be summable, and, when summed in various combinations and weightings, to fully explain the observed reality. The discovery task is accordingly to infer the underlying elements from data. This is an underconstrained problem; however, the desire for models that minimize the number of elements and maximize their explanatory power leads us to Principal Components Analysis (PCA).

PCA can be described in several ways, but it is helpful to view it as an iterative analysis process. In each stage, PCA finds the factor that explains as much as possible of the observed variation, across many datapoints and many variables. It then subtracts out what that factor explains, finds another factor to explain much of the remaining variation, and iterates. For example, if we are interested in statistics on people, including income, wealth, family size, number of cars, age, education level, food budget, and so on, the first underlying factor may be something like socioeconomic status, the second may be related to age, the third may be gender, and so on. The observed variable values for any datapoint (person) are modeled as linear combinations of the factors, and conversely, one can go from the observed values for any datapoint to the values of the underlying factors trivially, with a simple matrix multiplication.

PCA is good for dealing with variables which are highly correlated and thus mutually partially redundant. This is commonly the situation in prosody, and PCA has indeed been used here, for identifying the prosodic and other vocal parameters relevant to emotional dimensions [11] and to levels of vocal effort [12], for categorizing glottal-flow waveforms [13], for finding the factors involved in boundaries and accents [14], for characterizing ambiance [15], and for purely practical purposes [16, 17, 18, 19]. A related method, Functional Data Analysis (FDA), has also been applied to prosody, including for identification of the key dimensions of variation in pitch contours [20, 21, 22, 23]. Despite all these precursors, our strategy, of using PCA as a way to discover prosodic elements, is something new.

3. Base Features

In our approach, the datapoints input to the PCA are points in time, and the variables are various prosodic features. PCA is then applied to discover the underlying factors, and these are the elements of prosody.

Because a prosodic value at a point in time is meaningless without context, for each datapoint we use several dozen base features to broadly represent the local prosodic context. For example, in addition to the average pitch over the past 50 milliseconds, we also use the average pitch over a 50 millisecond window centered 75 ms in the past, and over a 100 ms window centered 150 ms in the past, and so on, for both past and future windows, spanning about 6 seconds centered around the point of interest. Including such features enables the use of PCA for

time-series analysis [24, 20, 21]. Unusually, our features are not uniformly spaced, but are denser closer to the point whose context is being considered, as detailed elsewhere [9, 25].

Given that the features are from the local prosodic context, each PCA-derived factor will represent a patterning of prosodic features over that context: a 'phonological entity with a distinct time course' [1]. For example, one factor has a region of speech with a slowly dropping pitch, followed by a region that is quiet and slow in rate, followed by a second region of speech that has an early fast region, but then turns slower and lower. The bottom half of Figure 1 shows a visualization of this.

Mathematically a factor can be present either with a positive weight or a negative weight. However it can be difficult to intuitively understand the contributions of a factor when it has a negative weight for a given datapoint. Accordingly the discussion below will focus on one or the other of the two poles of each factor (dimension), discussing either the pattern characterizing points that are high on the dimension or the one for low points. For example the pattern in Figure 1 is the high side of dimension 6.

For PCA to work, the base features should be continuous-valued, on scales for which summation is meaningful. The features we have used approach this ideal but imperfectly. For loudness we use log energy normalized per track to correct for different recording conditions and different speakers. For pitch height we use percentile in the distribution of pitch seen for that track, thus again normalizing for speaker. For pitch range, we similarly use the number of percentiles between the highest pitch point in the window and the lowest. For windows without voiced frames, the mean pitch values and ranges are used instead. For rate, we use a simple frame-by-frame energy-shimmer measure. These features are from our standard inventory, chosen for utility for modeling turn-taking prosody and for language modeling. Better choices could certainly be made, but fortunately PCA is robust to imperfect and noisy features. Finally, following standard practice, we z-normalize all features before applying PCA.

In contrast to previous uses, here we apply PCA to dialog data, with featuresets accordingly including features of both speakers' prosodic behavior. As a result, the top factors discoved by PCA tend to be those which explain variance not only in the speaker's behavior but also in the interlocutor's behavior. That is, this predisposes the method to find patterns that have interactional significance, with ones that relate purely to one speaker's behavior destined to rank lower.

Further, again in contrast to previous work, we applied PCA to a heterogeneous and large data set. This is because our aim is to see what we can find, rather than to refine some model or answer some question. In particular, most of our work has been with the Switchboard corpus of American English telephone conversations. In each case we built the models using about 600,000 data points, the maximum our computer's memory could handle for PCA. These were obtained by sampling every 10 milliseconds during 16 dialogs, without regard to any notion of sentence, utterance, or turn. Thus each model is built from about 100 minutes of dialog, across multiple speakers, multiple dialog activities, and multiple topics.

Finally, PCA involves an (optional) interpretation step. While some researchers are happy with fully automatic methods, we think that human judgments are a necessary part of scientific inquiry, and in this respect our method is aligned with classical approaches. We differ in choosing to apply the human interpretation after the data-reduction step, rather than up front.

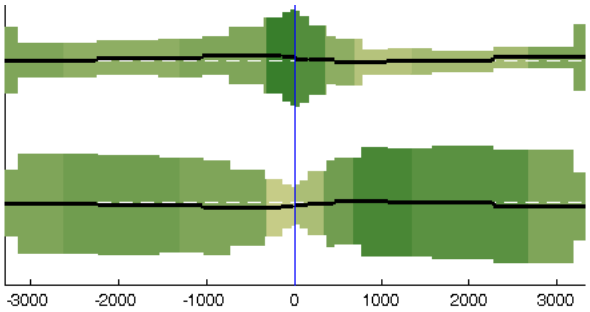

Figure 1: The pattern exemplifying the high side of factor 6 (dimension 6). Time is in milliseconds. First-speaker features are on top and second-speaker features below. Line width shows volume, with the median volume seen at the far left and right of the figure. Height shows pitch, with the median indicated by the dashed line. Darkness shows rate. While what is shown is the strengths of factor loadings — not directly the pitch height, volume or rate — it is not seriously misleading to interpret the figures as indicating typical values for the features across time.

4. Findings

4.1. Interpretable Elements

While PCA is guaranteed to find elements, there is no guarantee that they will be interpretable. While uninterpretable models of prosody can still be useful, interpretable ones are preferable. Luckily, most of the factors that PCA outputs have indeed been interpretable, with each pole corresponding to a simple pattern or 'construction' [26, 27] with an identfiable meaning or function. These generally relate to meanings and functions familiar from the prosody literature. (Although not so far to meanings at the degree of specificity claimed for some sentence-level contours [28, 29, 30].) Space allows just two examples:

4.1.1. The Upgraded-Assessment Pattern

Switchboard dimension 6 is positive to the extent that: the interlocutor was speaking loudly but trails off and this occurs with a low pitch, during which while the speaker was quiet; followed by a loud region by the speaker with a slightly expanded pitch range and increased speaking rate (the upgraded assessment); followed after a short pause by a long and loud continuation by the interlocutor. This is seen in Figure 1.

An example very high on this dimension occurred 309 seconds into dialog sw2402, where A has spoken favorably about warm places:

> A: a lot of people go to Arizona or Florida for the winter and they're able to play all year round but
>
> B: yeah, oh, Arizona's beautiful!

Words frequent in this context include *neat*, *ooh*, *absolutely*, and '*laughter-right*' (laughed tokens of the word *right*).

Thus three kinds of evidence — the feature loadings, impressions of the pragmatics, and statistics of the co-occurring words — provide convergent evidence for a coherent interpretation of the pattern: that it involves one person seeking and the other displaying empathy, in extreme cases in the form of an upgraded assessment. This matches well with a previously-described prosodic construction [31]: a pattern in which a listener expresses agreement with an assessment by producing an

upgraded version, for example when one speaker tentatively observes *it's pretty* and the other follows with *absolutely gorgeous* with increased volume, pitch height and pitch range, and 'tighter' articulation. This is exactly what happens when dimension 6 is high.

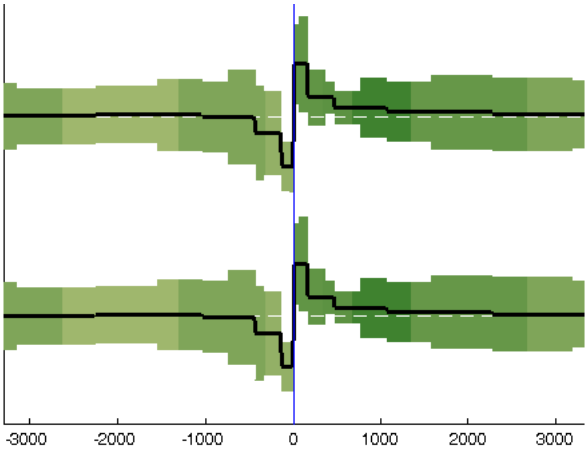

Figure 2: Dimension 26, high side, as above.

4.1.2. The Interestingness-Signalling Pattern

Figure 2 shows dimension 26 of the Switchboard corpus. The loadings on this factor do not distinguish between the tracks, but this is just an artifact of the prevalent cross-track bleeding in this corpus, which affects many of the lower dimensions. Examining places in the corpus where this factor was strongly present, we found that these frequently aligned with backchannels. Quantitatively, of all *uh-huh*s in the data, 79% occurred in contexts where factor 26 was present with a positive weight, significantly more than a 50% baseline. Looking at the behavior in the other track, places where factor 26 was high were often places where one speaker was finishing up the delivery of one piece of information and preparing to continue on with some elaboration or new aspect. In general, this pattern of joint behaviors [32] signals that the recent content was interesting and will be interesting again soon.

Looking at the feature loadings, there is a very salient region of low pitch just before the point of interest, for about 150 milliseconds. This is the pattern that previous work has identified as a cue for an interlocutor backchannel [33]. Despite various work aiming to refine and elaborate this cue [34, 35], not much more had been found. However from the figure we can easily read off more information: that this pattern involves a slightly increased pitch for about a second, followed by a short, somewhat louder region (often a content word), followed by a short low-pitch region with reduced volume, and then, about a second after the backchannel, a short region with faster rate (as the speaker resumes the turn with a fresh start). Here PCA serves to reveal the larger pattern encompassing the salient feature.

Just to complete the story, in the opposite pattern, characterizing points where this factor was strongly negative, the speaker was typically involved in a narrative and speaking with low volume, and appeared to be downplaying the importance of what he's saying, for example when it was just background to a main point to come later.

4.2. Numerous Elements

In the quest to reduce prosody to the minimum number of elements, it would be helpful to have estimates of how many elements are really needed. PCA is useful for questions like this: often it reveals that superficially complex phenomena can be explained by just a handful of underlying factors. However that was not the case here; on the contrary, the top 25 factors in Table 1 account for no more than 86% of the variance, despite this featureset being one with many strong correlations. Moreover, at least 30 of the factors (and thus 60 patterns) have clear and distinct functions, as summarized in Table 1. These observations suggest that the research program of reductively explaining prosody [36, 37] may not work for the prosody of dialog.

4.3. Continuous-Valued Elements

A recurring debate in prosody involves the extent to which prosodic elements are categorical or continuous. For these elements we can address this by examining the distributions of values on each dimension. All looked normally distributed, with only two exceptions (on the first dimension, which is bimodal, and on the second, which is skew), which suggests that they are not categorical. This interpretation is compatible with the functions they bear, all of which seem likely to be experienced in a graded rather than categorical manner.

4.4. General Elements

While the elements of prosody are likely to vary somewhat with domain and speaker and so on, it would be disappointing if those found by one application of PCA were entirely limited to one specific genre. To see whether this was the case, we tried it on a different corpus, Maptask, and using a different set of base features (computed using the same feature extractors, but with different densities at different temporal offsets). Again we found meaningful patterns, and of those analyzed so far, most are similar to those found in the Switchboard data, as seen in Table 2.

5. Prospects

Ultimately the aims of prosody research must surely include the identification of the inventory of prosodic elements, for any given language (despite the difficulties [29]). This paper has presented a way to use PCA to advance us towards that goal. Next steps include: 1. using better and finer-grained features, to infer the exact shapes and timings of the patterns. 2. using features that are phrase-, word-or syllable-aligned, rather than fixed in width and offset, 3. analyzing different types of data, to replicate findings obtained with other methods, and 4. examining individual differences, as it is unlikely that all speakers of a language have identical prosodic elements, even if the functions are shared.

In addition to superposition, a complete model will certainly require other combining mechanisms: most obviously concatenation, but also probably stretching, warping, alignment, synchronization, assimilation, undershoot, and others, especially for prosodic phenomena at finer time scales. It important to elucidate how superposition works together with these other mechanisms [1, 40].

Beyond acoustical compositionality, the compositionality of the meanings of these patterns is an open question [41]. The heterogeneity of the functions (Table 1) suggests that they could be composed without mutual interference, but this needs to be

1	this speaker talking *vs.* other speaker talking	32%
2	neither speaking *vs.* both speaking	9%
3	topic closing *vs.* topic continuation	8%
4	grounding *vs.* grounded	6%
5	turn grab *vs.* turn yield	3%
6	seeking empathy *vs.* upgraded assessment	3%
7	floor conflict *vs.* floor sharing	3%
8	dragging out a turn *vs.* ending confidently and crisply	3%
9	topic exhaustion *vs.* topic interest	2%
10	lexical access or memory retrieval *vs.* disengaging	2%
11	low content and low confidence *vs.* quickness	1%
12	claiming the floor *vs.* releasing the floor	1%
13	starting a contrasting statement *vs.* starting a restatement	1%
14	rambling *vs.* placing emphasis	1%
15	speaking before ready *vs.* presenting held-back information	1%
16	humorous *vs.* regrettable	1%
17	new perspective *vs.* elaborating current feeling	1%
18	seeking sympathy *vs.* expressing sympathy	1%
19	solicitous *vs.* controlling	1%
20	calm emphasis *vs.* provocativeness	1%
21	mitigating a potential face threat *vs.* agreeing, with humor	$< 1\%$
22	personal stories/opinions *vs.* impersonal explanatory talk	$< 1\%$
23	closing out a topic *vs.* starting or renewing a topic	$< 1\%$

25	personal experience *vs.* second-hand opinion	$< 1\%$
26	signaling interestingness *vs.* downplaying the current information	$< 1\%$
29	no emphasis *vs.* lexical stress	$< 1\%$
30	saying something predictable *vs.* pre-starting a new tack	$< 1\%$
37	mid-utterance words *vs.* sing-song adjacency-pair start [38, 39]	$< 1\%$
62	explaining/excusing oneself *vs.* blaming someone/something	$< 1\%$
72	speaking awkwardly *vs.* speaking with a nicely cadenced delivery	$< 1\%$

Table 1: Brief descriptions of the interpretations of some of the top dimensions found in the Switchboard corpus, with the variance explained by each. Visualizations of all dimensions are at http://www.cs.utep.edu/nigel/dimensions/ .

investigated.

As noted in the introduction, some recent applications of prosody use raw features directly, without models, or at least without interpretable models. It would be nice to reverse this, to help reunify the scientific study of prosody and practical uses. PCA-derived elements, being computationally convenient yet also interpretable, may help. We already have found them useful for language modeling for speech recognition [10], for information retrieval [42, 25], for finding important information in dialog [43], and for characterizing the pragmatics of a non-lexical discourse particle [44]. Other potential applications include dialog-act inference, simultaneous interpretation, detecting emotion, detecting social roles, language identification, speaker recognition, realtime behavior prediction, dialog outcomes prediction, computer-assisted language learning, language proficiency evaluation, diagnosis of communication disorders, and speech synthesis.

1	this speaker talking *vs.* other speaker talking	$\sim$s1
2	low activity, low rapport *vs.* highly engaged	new

6. Conclusions

Xu and Prom-on envisage models where "a full repertoire of communicative functions can be simultaneously realized in prosody, with all the details of the surface prosody still linked to their proper sources" [6]. PCA-derived prosodic elements can be part of such models, as they meet several important desiderata: 1. a fully explicit composition mechanism for combining elements, here simple addition, 2. groundedness of elements, whose presence at any point in any dataset can unambiguously determined, here by a simple linear combination of easily computable acoustic features, and 3. meaningfulness of elements, here with each bearing a specific communicative meaning or function.

This technique also has other advantages. It works not just for careful, professional speech and the phenomena therein, but for 'messy' unconstrained dialog. It covers elements at multiple 'levels' with a single mechanism. It's single mechanism covers not only pitch but also duration and volume (and potentially also voicing modes, gaze, gestures, etc.). Finally, it has been truly useful for discovery, and in this respect the results it gives, and the visualizations they support, are far clearer than those obtained by previous approaches [45, 46, 47, 35]; in essence this is because PCA is good at stripping out the variation involved in dimensions other than the single one being focused on.

Given the simplicity of the method, these results are surprisingly promising and the potential value seems great.

7. Acknowledgments

I thank Olac Fuentes for suggesting PCA, Alejandro Vega for the initial implementation and much more, Luis F. Ramirez for the initial Maptask analysis, Steven D. Werner for analyzing the distributions of values on each dimension, and the NSF for support, as project IIS-0914868.

P-centre Position in Natural Two-Syllable Czech Words

Jan Volín, Eliška Churaňová, Pavel Šturm

Institute of Phonetics, Faculty of Arts, Charles University in Prague

jan.volin@ff.cuni.cz

Abstract

The ability to lock motor activity oscillator with external acoustic events is typical of various forms of human behaviour. Previous research showed that the beginning of an action is not necessarily the beginning of the rhythmic phase and led to the concept of p-centres. We present an experiment with 18 natural two-syllable Czech words spoken in synchrony with metronome beats by 18 subjects. Complexity of the consonantal onset and the type of coda together with distinctive phonological vowel length were carefully controlled to reveal a complex but comprehensible relationship between the word structure and phase locking.

Index Terms: Czech, p-centres, speech rhythm, syllable, synchronization

1. Introduction

Speech rhythm is a fascinating phenomenon attracting humans from their pre-linguistic babbling age through teenage years until their old age. Natural rhythmic flow apparently makes cerebral speech processing easier than uncommon or unpredictable patterns of prominence contrasts. Reaction times in monitoring experiments were by more than 150 milliseconds shorter in sentences with modal rhythm than in the same sentences with altered temporal structure [1], but cf. [2]. Certain types of rhythm in speech may contribute to speaker attractiveness or credibility of the speaker's propositions [3].

There is still considerable uncertainty, however, as to the descriptive principles that should be applied to speech rhythm [4]. One of the key missing pieces of the puzzle is the position of the "beat" – the moment of the perceptual emergence of an acoustic event in the mind of the listener. For syllables this moment was named a *p-centre* [5]. Several experiments of the early 1980s confirmed the intuitions of previous researchers about the importance of the vowel onset. It is not the beginning of the acoustic features pertinent to a syllable but the vicinity of its vocalic nucleus that starts the rhythmic phase.

The attempts to predict the position of the p-centre more accurately exploit mainly timing parameters [6,7], sometimes in combination with the information about energy of the signal [8,9,10]. Moreover, [11] suggested a link between the p-centre position and articulatory movements. Both acoustic descriptors and microbeam data explained substantial amount of variance also in [12], while [13] showed relevance of their kinematic data obtained with an articulometer.

However, Barbosa et al. [14] pointed out that mainly the Germanic languages had been investigated from this perspective. Cross-language comparison is therefore highly desirable. On the one hand, the fundamental principles of rhythmic structuring of speech are universal, since all languages are spoken in syllables, and, for instance, all healthy human ears detect the energy difference between /p/ and /a/ in the syllable /pa/. On the other hand, the rhythm type of an individual language predestines its users to specific strategies in speech perception, speech acquisition, and, naturally, speech production (e.g. a review in [15]). Not only the rhythm type (stress-based, syllable-based, mora-based), but also the phonotactic properties of individual phonemes in the language inventory might influence the exploitation of prominence alternations in speech. Our study is, therefore, aimed at mapping the behaviour of speakers of Czech – a west Slavonic language of central Europe.

Another issue addressed in our approach is the number of subjects. As, e.g., [10] noted, the rhythmic behaviour of human subjects is extremely disparate, and [4] rightly complains that the rhythmic proficiency of individual speakers who serve as subjects or respondents in experiments is often ignored. The pioneering study of [6] was based on four subjects, [7,9,10] on three speakers, [13] on six speakers (only three of whom provided kinematic data), while [14] studied data from one speaker only, and [8] hypothesized without empirical testing. Thus, one of our aims was to increase the number of subjects considerably and provide an estimate of the distribution of the rhythm aptitude in the population.

The third goal of our study concerned the speech material. Many of the previous experiments were carried out with meaningless syllables. This is advantageous in making the experiment neat and highly controlled, and desirable at initial stages of research. However, as [4] stresses, speech is not an object – it is a communicative behaviour. Also, de Jong noticed deviant reactions in his experiments to stimuli that departed from naturally sounding speech tokens [12]. On that account, we abandoned some of the comfort provided by nonsense syllables and used naturally occurring words.

In summary, our search for the position of the p-centre in a speech synchronization task was carried out with the following questions in mind:

- Will the results from a typologically underrepresented language in rhythm research – Czech – be consistent with the previous research? Specifically, do the structural and/or durational features of the stimuli affect the position of the p-centre? If yes, how?
- Given that p-centre position is dependent mainly on syllable onsets and less on codas [e.g., 9], will the rest of a two-syllable word matter if it is used instead of a monosyllable typical of p-centre research? (The rest of a word is actually beyond the stressed syllable coda.)
- Three pairs of our words do not differ structurally but in terms of phonetic identity of the onset consonants. A similar problem was studied by [9]. Do their results hold for a different language and testing conditions?
- Since [14] found dissimilar responses for different tempos, while other researchers seem to implicitly presume proportional changes in p-centre position, will two temporal modes natural to Czech speakers (4 and 6 syll/sec.) produce mutually coherent results?

We intend to answer these questions whilst expanding the number of participants beyond the numbers usual in the field.

2. Method

2.1. Target words

The design of the experiment required a reasonably restricted segmental structure of the targets, yet existing Czech words were favoured over nonsense words because of the reasons outlined above. The disyllabic targets contained the vowel pairs /e aː/ and /eː aː/. Other Czech vowels were not included due to their relative infrequency, occurrence only in foreign words or a salient qualitative difference. Moreover, the demand on using real words necessitated the selection of certain verb forms differing in their suffix, and many vowel combinations were therefore precluded. Each stem was used with the third-person singular zero suffix (open syllables), the first-person singular suffix *-m* (/m/), and the second-person singular suffix *-š* (/ʃ/). The intervocalic consonant was always a voiceless plosive (/t/ or /k/). The onset of the word contained either a single consonant (/l/ and /c/), a CC cluster (/sl/, /st/ and /ʃc/), or a CCC cluster (/spl/). Such a design yielded 18 combinations of word-initial syllable onsets and word-final syllable codas (6 different onsets × 3 different codas). The target words are recapitulated in Table 1.

onset	0-suffix	*m*-suffix	*š*-suffix
C	leːtaː	leːtaːm	leːtaːʃ
CC	sleːtaː	sleːtaːm	sleːtaːʃ
CCC	spleːtaː	spleːtaːm	spleːtaːʃ
CC	steːkaː	steːkaːm	steːkaːʃ
C	cekaː	cekaːm	cekaːʃ
CC	ʃcekaː	ʃcekaːm	ʃcekaːʃ

Table 1. *Summary of the 18 target words. Six lexical items (lines) and three grammatical forms (columns).*

2.2. Speakers and task procedure

18 native speakers of Czech participated in the experiment (14 female and 4 male, aged from 20 to 32). They were mostly students at Charles University in Prague, and reported no speech or hearing impediments. They received financial compensation for their involvement.

The speakers listened to a series of metronome beats (over headphones) and pronounced the target word presented on the computer screen several times. They were instructed to synchronize their repeated articulations with the isochronous sequence of beats so that each beat was aligned with the first syllable of the word spoken in isolation. A clear and "natural" pronunciation was demanded, as natural as it was possible in the experimental conditions (they were explicitly asked not to chant or recite the words). Each item contained 12 pulses followed by soft music and speakers began to articulate on the fifth – the initial four pulses served as a lead-in for steadying listeners' attention. The first and last realizations were omitted from analyses since they were considered prone to effects of uncertainty/accommodation at the beginning of the sequence or anticipation of the stimulus end.

As it is hypothesized that listeners use different processing modes depending on the pace [16], two tempos were tested: in the "normal" tempo the metronome pulse appeared at the rate of 70 bpm (i.e. every 857 ms), while in the "fast" tempo the pulse appeared at the rate of 90 bpm (i.e. every 667 ms). The two tempos were chosen to induce production rates of about 4 to 6 syllables per second (the pulse was associated with the disyllabic word, not with individual syllables).

The items were presented in two blocks separated with a one-minute break; the subjects chatted with the experimenter, could stretch their bodies and refresh themselves with a drink. The first block proceeded in the normal tempo and the second in the fast tempo, which resulted in two occurrences of the target items. In addition, filler items (mono- or trisyllabic words with no restriction on the segmental content) were used to provide variation to the task and prevent subjects from lapsing into monotonous behaviour. Each block was also preceded by several training items in which the subjects accustomed themselves to the tempo and task. Items within each block were pseudo-randomized for individual speakers. The duration of the session, comprising 55 items in total, was approximately 15 minutes.

2.3. Extraction of data

Given the purpose of this study two channels were used simultaneously to record the session, one for the metronome beat and one for the spoken production. The stereo recordings were subsequently processed in the programme *Praat* [17], and TextGrid objects were created for annotation. Individual items were segmented into words and phones using the *Prague Labeller* algorithm [18]. Segment boundaries were marked automatically and then manually checked and corrected where necessary. A script based on the detection of an intensity threshold in the metronome channel was used to determine the position of the recorded beats, which allowed us to identify the location of the metrical pulse for each produced word. The duration of each segment was measured, along with the distance of its boundaries from the metrical beat (*zero* = a segment boundary coincides with the beat; *positive numbers* = boundary located after the metronome beat; *negative numbers* = boundary located before the beat). In the subsequent analyses the term synchronization interval (SI) is used for the distance of the first (i.e., stressed) vowel onset and the beat.

3. Results

3.1. Phonological weight of the word

Since all the research in p-centres we have come across relates the position of the 'mental beat' to the onset of the first vowel, we will do the same for the sake of comparison. It should be also pointed out that Czech word stress is fixed to the first syllable – there are no words stressed on the second syllable.

Assuming that each consonant and short vowel weighs 1 phonological unit and long vowels weigh 2 units we could order the target words from the lightest (5 units) to the heaviest (8 units). However, knowing that individual syllable constituents affect the p-centre position with different power and having tied the weight of the intervocalic consonant and the second vowel, we ordered the overall results by the phonological weight of the first syllable and the type of coda of the second syllable. That seems to arrange the results in an internally congruent manner (see Table 2).

Apparently, the synchronization of the first vowel onset with the metronome beat changes with both the complexity of the first syllable and the absence or nature of the word coda. More complex word onsets pull the synchronization point more ahead of the vowel onset (into themselves, so to say.)

first syllable	word coda	word	mean SI (ms)	SI %
CV	∅	ceka:	-3.7	0.7
CV	Son		5.7	-12.7
CV	Obs		18.1	-34.2
CVV	∅	le:ta:	23.2	-14.0
CVV	Son		25.9	-18.4
CVV	Obs		44.4	-29.4
CCV	∅	ʃceka:	36.4	-57.9
CCV	Son		38.5	-60.0
CCV	Obs		72.8	-120.3
CCVV	∅	sle:ta:	65.3	-41.7
CCVV	Son	ste:ka:	64.7	-43.0
CCVV	Obs		57.5	-39.2
CCCVV	∅	sple:ta:	82.1	-57.1
CCCVV	Son		100.2	-71.7
CCCVV	Obs		94.9	-72.5

Table 2. *Mean synchronization intervals (SI) in milliseconds and percentages of vowel durations for individual phonotactic types (n = 36 apart from CCVV, where n = 2 × 36, i.e.,* sle:ta:/ste:ka: *).*

Long vowels seem to have an effect similar to heavier onsets: they prolong the distance between the first (i.e., stressed) vowel onset and the metronome beat.

Although there can be just one or no consonant word finally, this one coda consonant can still be either an obstruent or a sonorant. This distinction apparently matters – adding a sonorant coda (bilabial /m/ throughout our set) influences the synchronization less than adding an obstruent coda (postalevolar /ʃ/ throughout the set), at least in the case of simpler (phonologically lighter) words. Zero codas leave the vowel onset nearer the beat. Figure 1 displays the mean synchronization intervals (SI) as a function of the first syllable structure, Figure 2 as a function of the word coda.

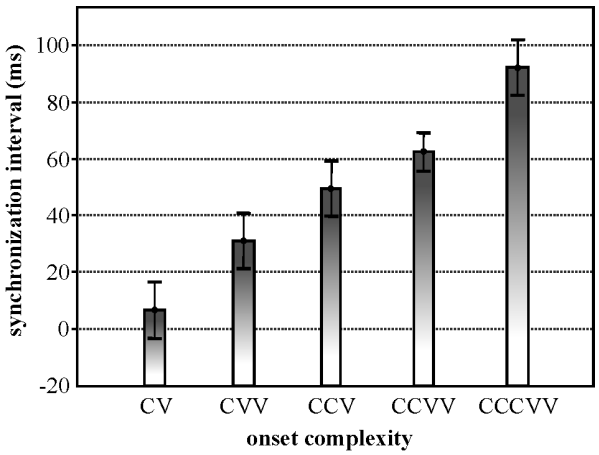

Figure 1. *Mean synchronization intervals for words with various phonological structure of their first syllable. The whiskers delimit the 95% conf. interval.*

Statistical significance of the differences was tested through two-way ANOVA for independent measures with synchronization interval as the dependent variable and ONSET and CODA as independent variables or factors. The main effects of both factors were found significant. For ONSET $F_{(4, 632)} = 43.6$, $p < 0.001$ and for CODA $F_{(2, 632)} = 5.4$, $p < 0.01$. Post-hoc Tukey HSD tests revealed significant differences among all onset complexities with the exception of the CCV which did not differ from CVV and CCVV. Zero codas differed from obstruent codas. No significant interaction was found between the two factors.

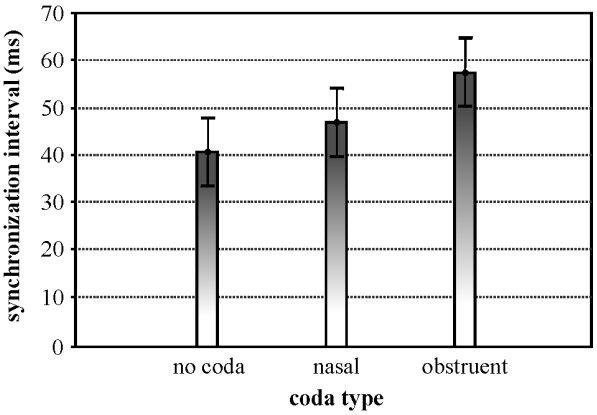

Figure 2. *Mean synchronization intervals for words with various final consonants (zero, nasal, obstruent). The whiskers delimit the 95% conf. interval.*

The situation described above disregards the tempo so it has to be ascertained if both slow and fast modes of synchronization display analogical trends. Inspection of the data showed that in the faster mode the speakers tended to prolong the synchronization interval, while in the slower one the metronome beat tended to be closer to the vowel onset. However, a closer look supported by a two-way ANOVA and post-hoc Tukey tests revealed that the speakers' behaviour was almost identical for simple words. For CV, CVV and CCV the difference between fast and slow tempos produced $p > 0.99$. For CCCVV it was still insignificant with $p \approx 0.52$, and only CCVV produced significant difference ($p < 0.05$). It has to be remembered, though, that the CCVV groups is twice as large as the other groups since it collapses words /ste:ka:/ and /sle:ta:/. (For comparison of these two words see below.) The variance is then lower and the effect is more visible. Clearly, if the effect is sensitive to number of cases in this way, it is not a strong effect. The influence of coda types seemed to be the same for both tempi.

3.2. Pairwise comparisons

Some of the items of our test were designed for direct comparison with others to answer less general questions. The first such comparison concerns the two CCVV words. It was actually carried out prior to the analyses above to make sure that the words /ste:ka:/ and /sle:ta:/ can be collapsed. Although the former has two obstruents in the onset, of which the second is a voiceless plosive, while the latter has got a sonorant sound in the same position, no difference was found in the synchronization interval: $F_{(5, 210)} = 0.44$, $p = 0.817$ (All six forms of these words were entered into the test.) Likewise, no difference was found in their overall duration or of the duration of their consonantal onsets. Internal durational ratios within the onset were different: /k/ was systematically longer than /l/ at the expense of /s/. In summary, although the energy distribution in the onset and the phonetic identities of its constituents differs, the synchronization interval does not.

The pair /ceka:/ × /ʃceka:/ can be observed in Table 2 and it is represented in Figure 1 by the first and the third column. The effect of the additional post-alveolar /ʃ/ is quite substantial. The synchronization moment moves by about 42.5 ms. The durational difference between the /c/ and /ʃc/ onset is about 80 ms, but this value is difficult to measure rigorously since /c/ is a voiceless plosive so the closure phase has to be estimated. Nevertheless, the mean overall duration of the word changes by 35 ms only.

Just as the two previous comparisons addressed the issue of consonantal onset, the following will focus on the vowel length in the first syllable. The relationship of the words /ʃceka:/ × /ste:ka:/ can be estimated from the third and fourth column in Figure 1. Their synchronization differs by about 10 ms which is not a statistically significant result. It is still informative to explore the durational differences in these two items. First of all, the mean duration of /e/ is by 93 ms shorter than that of /e:/, but the durations of the words only differ by 54 ms. It could be inferred that the missing 39 ms are due to the difference between the /st/ and /ʃc/ onsets. That, however is not the case: the difference between the alveolar and palato-alveolar cluster is only 12 ms. The missing time has to be accounted for by durational reorganization of the otherwise identical rest of the word: velar intervocalic consonant, long open vowel and codas. T-tests showed that it is the second vowel that is significantly different ($p < 0.01$). It seems to compensate for what is happening in the first syllable. Interestingly, this complex situation occurs in a pair of words that differ phonologically only in the length of the first vowel. The 10-ms difference in synchronization, which was not found significant actually means a 128-ms distance from the acoustic onset of the word /ʃceka:/ and a 106-ms distance from the acoustic onset of the word /ste:ka:/ suggesting that the first vowel onset is, indeed, a better synchronization point than the very beginning of the word.

Multiple regression analysis

In order to shed more light on the results reported in Table 2, a series of multiple regression analyses were performed with mean synchronization interval (first vowel boundary position) as the dependent variable and several temporal and phonotactic parameters as the predictors. When only TEMPO (slow × fast) and WORD DURATION were taken into account, the explanation power was negligible ($R^2_{adj} = 0.10$), partly because the two factors express similar facts. However, slightly better results were obtained for TEMPO and ONSET DURATION, assuming to reflect the phonotactic complexity of the onset, with $R^2_{adj} = 0.17$. Next, we extended the model with the variable of V1 DURATION, which further increased the amount of variance explained ($F_{(3,643} = 55.3$, $R^2_{adj} = 0.20$, $p < 0.001$). Interestingly, when a phonological category was used instead of a phonetic variable (vowel length instead of vowel duration), the power of the model did not decrease but, on the contrary, slightly increased: $F_{(3,643} = 60.2$, $R^2_{adj} = 0.22$, $p < 0.001$.

Adding information about the coda, whether in the form of CODA DURATION or CODA TYPE, did not make much difference. In both cases the model gained one more percent of explanatory power: $F_{(4,642} = 49.3$, $R^2_{adj} = 0.23$, $p < 0.001$.

If we wanted to use the regression analysis to create an analogy to Marcus' classic formula: $P = 0.65x + 0.25y + k$ (in [6]), where P is the synchronization interval, x is the onset duration and y is the rhyme duration (in the case of our first syllable only vowel), we would get $P = 0.37x + 0.20y - 27.2$. This analogy is not out of proportion, but it has to be remembered that it only explains 16 % of variance and that the methodology leading to it is not comparable with the Marcus' procedure. Be that as it may, the model with the information about coda (z in the following formula) and the whole word duration (w in the following formula) would have:

$$P = 0.61x + 0.50y + 0.27z - 0.29w + 73.6$$

4. Discussion

In a task of synchronizing words with an isochronous auditory sequence, the moment of the acoustic event can be considered the surface manifestation of the p-centre [14]. Our respondents clearly modified their behaviour according to the structure of the word and aligned the words differently for different consonant-vowel (CV) strings and different arrays of features attached to these segments. To answer the first question from the introduction then, we can state that our results based on Czech, typically classified as syllable-timed (but cf. [19]), resonate with previous research on stress-timed English and provide descriptors that can be further tested.

The current analyses are based on durational or structural characteristics only. They explain some of the variance in the data and show the trend for longer and more complex structures to push the p-centre farther ahead of the onset of the first vowel. Word-final segments exert smaller influence on the outcome. They display greater variation and little effect in regression analyses. Little, however, does not mean zero. The triplets of words in our set that differed solely in the presence or absence of the word-final consonant or its manner of production did not behave uniformly. Therefore, the answer to the second question from the introduction is positive as well.

The title of [9] stated that p-centre positions were unaffected by phonetic categorization. We supported that claim using different methodology by showing that our speakers' behaviour was identical for two (triplets of) words that differed in their two-consonant onset. In one of them it consisted of a sibilant + lateral approximant, in the other it was the same sibilant + voiceless plosive. The energy distribution was not equal, but the duration of the onset was. This seems to be the essential property of the item to condition the outcome. Our corroboration concerns the syllable onset only, though. It cannot be generalized for codas where we saw the difference between sonorant /m/ and post-alveolar /ʃ/. The issue will be further investigated in the nearest future as we have already prepared more stimuli for forthcoming testing.

The final question in the introduction reacted to findings in [14], where the respondent produced different patterns of behaviour for different tempi. Our results revealed no interactions between slow and fast mode of testing. That does not provide any evidence against [14] since our methods were incomparable, but rather suggests that for the pace of approximately 4 syllables per second and 6 syllables per second we can expect rather proportionate trends. Our linear regression found word duration as an expression of rate useful.

Correlations between prosody and epistemic bias in negative polar interrogatives in Japanese

Abstract

This study investigates correlations between prosodic patterns and speaker's bias observed in Japanese negative polar interrogatives, with special attention given to the perceptual and functional aspects of the correlation. The result of a naturalness rating test and a comprehension test demonstrate that listeners perceive the matching context-prosody pairs to be more natural, compared to the conflicting pairs. The results indicate that the prosodic patterns successfully guide listeners to identify the speaker's bias in negative polar interrogatives.

Index Terms: epistemic bias, negative polar interrogatives, comprehension test, naturalness rating test

1. Introduction

1.1. Speaker's bias in negative polar interrogatives

It has been widely recognized that English negative polar interrogatives often, though not always, convey the speaker's bias toward either a positive or negative answer [1, 2, 3, 4, 5].

(1) (negative interrogative with a positive epistemic bias)
A: John is such a linguist.
B: Yeah, doesn't he even speak Japanese?

(2) (negative interrogative with a negative epistemic bias)
A: There is nothing John can help with here.
B: Doesn't he even know how to keep accounts?

The speaker B in (1) expects confirmation for the proposition "John speaks Japanese", whereas the speaker B in (2) requests confirmation for "John does NOT know how to keep accounts". Compare these with (3), which is neutral in terms of epistemic bias.

(3) (negative interrogative without an epistemic bias)
Context: A and B are making a list of teetotalers for a party.
A: Jane and Mary do not drink.
B: OK. What about John? Does he not drink (either)?
(Examples from [4])

A similar distinction in speaker's bias has also been reported in Japanese [6, 7]. In particular, Ito and Oshima [6] points out that Japanese negative polar interrogatives differentiate their intonation patterns depending on the speaker's bias.

1.2. Prosodic patterns of negative polar interrogatives in Japanese

Negative polar interrogatives in Japanese contain the form of ... *X-nái?*, where *–nái* is the negative morpheme. Two prosodic patterns are pervasively used in this construction; (i) both X and the negative morpheme retain their lexical accents (AA), (ii) only X retains its accent, and the negative morpheme is deaccented (AD). While both the adjective (*nagái* 'long') and the negative morpheme exhibit an F0 fall in the top contour of Figure 1, the negation in the bottom contour lacks an F0 fall.

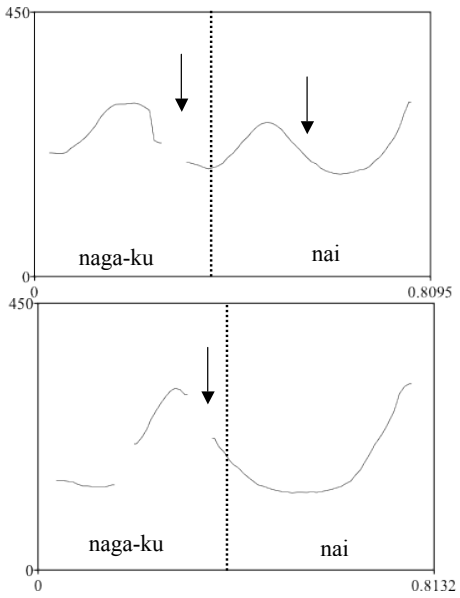

Figure 1: *AA (top) and AD (bottom) pattern of negative polar interrogatives in Japanese; arrows indicate the F0 fall.*

It has been claimed that the AA pattern is associated with a neutral/negative epistemic bias, and the AD pattern with a positive bias [6]. However as yet no experimental/quantitative data was provided to support their claim.

Beside the two patterns above, one more prosodic pattern with adjectival predicates is observed among younger speakers: (iii) both X and the negative morpheme are deaccented (DD). The pitch contour of the DD pattern is demonstrated in Figure 2. It should be noted that no F0 fall is observed either on the adjective or the negative morpheme, and the entire phrase displays a single gradually rising pitch contour.

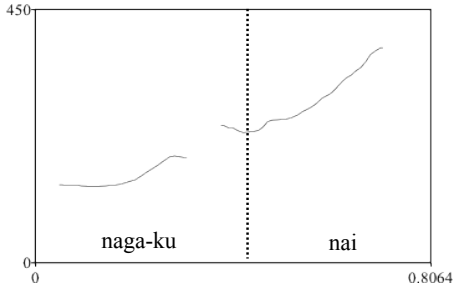

Figure 2: *DD pattern of negative polar interrogatives in Japanese.*

Hara and Kawahara [8] compare the AD and DD patterns in terms of evidentiality. Based on the result of a naturalness rating test, they argue that the DD pattern is felicitous only when the participants of conversation have public evidence which is stronger than hearsay or circumstantial evidence, for the positive answer. However the AA pattern is not discussed in their study.

Thus, experimental investigation is needed to uncover the correlation between the epistemic bias and all three prosodic patterns. In the current experimental study, we aim to test the perceptual and functional aspects of the correlation, involving all three prosodic patterns. Also, we reconsider the difference between the AD and the DD patterns argued in [8]. The results of a naturalness rating test and a comprehension test confirm the correlation between the prosody and the speaker's bias. The experiment also highlights the fact that prosodic patterns play a crucial role in identifying the epistemic bias of negative polar interrogatives in Japanese.

2. Methods

2.1. Material

The tested phrase was *nagáku-nái*? ('isn't it long?'). Only an adjective as a predicate was chosen, as adjectives allow us to test all the prosodic patterns. A major reason for this is that the DD pattern is regularly realized with adjectival predicates, but unavailable or highly marked with non-adjectival predicates. In order to provide a contextual prompt for the speaker's bias, the target phrase is embedded in three different bias conditions: neutral, negative and positive bias. The positive bias condition is further divided into two subgroups depending on the presence or absence of public evidence.

Concerning the prosodic pattern, both neutral and negative biases are expected to exhibit the AA pattern. On the other hand, the positive bias condition can be realized in either the AD or the DD pattern. The bias conditions together with the expected prosodic pattern are summarized in Table 1.

Table 1. *Tested bias conditions and expected prosodic patterns.*

Bias	**Neutral**	**Negative**	**Positive**	
Public Evidence			No	Yes
Prosodic pattern	AA		AD	DD

The contexts provided to the subjects for each bias condition are given below.

(4) Neutral
(Situation) One morning, Taro, a high school student, was talking with another high school student named Hanako (H), who had just transferred from another school that day. Taro (T) and Hanako were speaking just before morning assembly. Hanako needed to go to the bathroom but since it was her first day, she did not know how long morning assembly would last. Therefore, she asked Taro:

H: **Morning assembly isn't that long**, is it?
T: No, it's not that long. Why do you ask?
H: If it's very long, I think I may need to go to the restroom first.

(5) Negative
(Situation) Taro wanted to use his PC but his power cord was too short, so he asked Hanako if she had an extension cord. Hanako handed Taro her extension cord (but the cord was not long enough).

T: Hmmm... Actually, I think this might not be long enough…
H: Oh really? **It isn't long** (enough)?
T: Yeah, it seems like it's not quite long enough…

(6) Positive bias without public evidence
(Situation) Taro and Hanako were in the school yard listening to the principal's speech. Hanako felt like the speech was a little long that day, but she didn't have a watch, so she asked Taro (who was standing in front of her).

H: **Isn't today's morning assembly (a little) long**?
T: Yeah, it's a bit longer (than usual) today.

(7) Positive bias with public evidence
(Situation) When Taro and Hanako were in the school yard listening to the principal's speech, they heard the bell for first period ring. When she heard the bell ring, Hanako asked to Taro (who was standing in front of her):

H: **Isn't today's morning assembly (a little) long**?
T: Yeah. That was the bell for first period, right? But that means first period will be shorter, so that's nice.

Note that the situation in (7) explicitly describes that the bell for the first period ring, indicating the assembly has run overtime.

2.2. Recording

One female and one male speakers of Standard Japanese were recorded. Both speakers were in their late twenties at the time of the recording. The recording was made in a sound attenuated booth at National Institute for Japanese Language and Linguistics. They were instructed to read the situations written in Japanese orthography carefully. In addition, pictures which visualized the situations were provided to ascertain their understanding of the situations. After self-reporting that they fully understood the contexts, speakers were asked to exchange the conversations as naturally as possible. The recording was repeated five times. The female speaker uttered the target phrase, and it is worth noting that this particular speaker exhibited alternation between the AD and the DD pattern regardless of public evidence in the positive condition.

2.3. Stimuli

Stimuli for a comprehension test and a naturalness rating test were created using the utterances obtained in the recording session. For the comprehension test, one rendition was chosen from the five repetitions, which was judged the most appropriate in terms of pronunciation, speed, and intensity. As the speaker showed alternation between the two prosodic patterns for the positive bias condition, we included both cases, which resulted in a total of six stimuli: Neutral-AA, Negative-AA, Positive with/without public evidence-AD/DD. For all the stimuli, the male speaker's answer for the target phrase was deleted, as it was to be identified by participants in the experimental task.

For a naturalness rating test, the target phrase *i.e.* negative polar interrogative was cross-spliced into the conversations of the four different bias conditions: Neutral, Negative, Positive with Public Evidence, and Positive without Public Evidence. As three possible prosodic patterns were observed, a total of twelve combinations (4 bias condition X 3 prosodic patterns) were created.

2.4. Participants and procedure

A total of thirty native speakers of Japanese ranged 18-35 years old took part in the tests. They were all born and grew up in or around Tokyo area. Both tests were conducted in a quiet office, and the stimuli were presented over a headphone with each situation and response choices on a computer screen. All conditions were randomly interspersed.

Specifically, for the comprehension test, participants were asked to read the situations given on a computer screen carefully. Then, they were informed that they would hear a short conversation between a male and a female speakers. The task was to choose the most appropriate answer for the female speaker's question in the situation given. They were asked to click on one of four boxes containing the four choices below.

(6) Yes, it is long. Yes, it isn't long.
No, it is long. No, it isn't long.

For a naturalness rating test, participants were instructed to read the situations carefully, and to rate the naturalness of the prosodic pattern of the female speaker's question on a 1-5 scale, taking into account the situation. For the naturalness judgments, the numbers were labeled as following: 1 "highly unnatural", 2 " somewhat unnatural", 3 "neither unnatural nor natural", 4 "somewhat natural", 5 "highly natural".

3. Results and discussion

3.1. Comprehension of speaker's epistemic bias

The results of the comprehension test reveal that the speaker's epistemic bias and prosodic patterns are highly correlated. (In Table 2, P.E. stands for Public Evidence.)

Table 2. *Percentages of correct responses depending on the epistemic bias and prosodic patterns.*

Bias	Neutral	Negative	Positive			
P.E.			No		Yes	
Prosody	AA		AD	DD	AD	DD
%Correct	94	100	97	100	97	97

Participants yielded extremely high accuracy in interpreting the speaker's bias, confirming the intuitive claim in [6]. The relatively low percentages-97% or 94% indicates only one or two unexpected responses, which could be attributed to a mistake at the performance level.

Surprisingly, there was no substantial difference between the two Positive conditions with/without Public Evidence. It should be reiterated that, according to [8], the Public Evidence condition with the DD pattern or No Public Evidence condition with the AD pattern is expected to exhibit greater accuracy compared the other two conditions. Besides the prosodic alternation observed in the female speaker's production, this result also suggests that evidentiality is not a determining factor for the correlation between speaker's bias and prosody in negative polar interrogatives.

3.2. Naturalness judgments

There are appreciable differences in perceived naturalness between the prosodic patterns, as illustrated in Figure 3.

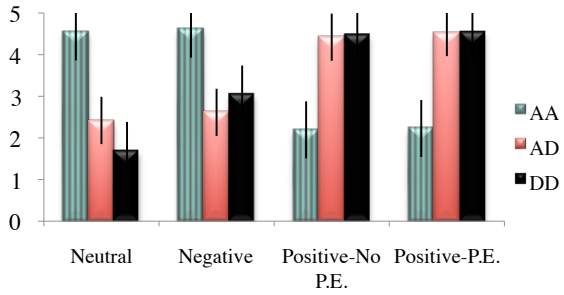

Figure 3: *Mean naturalness ratings depending on the bias and Public Evidence (P.E.) conditions.*

Overall, the AA pattern realized in the Neutral/Negative conditions (striped bars) were judged as highly natural. Likewise, similarly high naturalness ratings were assigned to the AD (bright colored bars) and DD patterns (dark colored bars) in the Positive condition. This result again supports the correlation claimed in [6], and corroborates the finding of the comprehension test.

Considering evidentiality in the Positive condition, both the AD and the DD patterns received equally high ratings. On the other hand, the AA pattern is judged as considerably less natural, regardless of the presence or absence of Public Evidence.

In order to test the statistical significance of the differences, one-way ANOVAs using a generalized linear model were performed using JMP 9. All reported effects were significant at the $p<0.05$ level. The dependent variable considered was the naturalness ratings. The independent factor was prosodic patterns in each bias condition. One-way ANOVAs show that there is a significant effect of the prosodic pattern on the rating across the bias conditions, as summarized in Table 3. For the Neutral condition, post-hoc comparisons using Tukey-Kramer HSD reveal that the AA pattern is perceived as significantly more natural than the other patterns. Interestingly, marginally significant differences are yielded between AD and DD (AD > DD, $p=0.03$). In relation to this, [6] points out that the AD pattern can be used in some other ways besides its "positive epistemic bias" use. The differences between AD and DD might stem from one of these usages,

which is called the "information gap" situation in [6], where the AD pattern has a distinct use where it does not convey an epistemic bias but indicates that the speaker considers the core proposition **P** possible based on some information that may not be available to the hearer. Thus, for example, for the negative polar interrogative with positive epistemic bias such as (1B), **P** will be roughly: λw.[speak⟨John, Japanese, w⟩]. The effect of using AD pattern in such a situation is similar to adding a phrase like: "You may be surprised by my asking this, but (is P the case?)". In this context it is predictable that the AA pattern is acceptable for most participants, as [6] anticipates. In addition, some participants noticed the "information gap" usage of the AD pattern in the neutral context in (4) and judged the pattern is also natural in context (4). That is, they felt that it is also natural to ask "You may be surprised by my asking, but is that morning assembly is long here the case?" by using the AD pattern in context (4). Interpreted this way, Table 3 suggests an interesting consequence: the DD pattern cannot be used for "information gap" situation while the AD pattern can.

Table 3. *Results of statistical analyses.*

df (2, 92)	Ratings	Tukey-Kramer HSD
Neutral	F=27.76 P<.0001*	**AA** > AD > DD
Negative	F=57.65 P<.0001*	**AA** > DD, AD
Positive-No P.E.	F=44.71 P<.0001*	**DD, AD** > AA
Positive-P.E.	F=47.88 P<.0001*	**DD, AD** > AA

Turning to the Negative bias condition, the AA pattern is rated significantly more natural than the AD or the DD pattern, confirming the correlation.

Finally, in the Positive bias condition, the subgroups depending on Public Evidence pattern together with respect to the naturalness rating; significantly higher ratings are assigned to the AD and DD patterns, compared to the AA pattern.

This result is in accordance with the finding in the comprehension test, but contrary to the results obtained in [8]. It is not clear how to account for the discrepancies between the result in [8] and the current finding. It is conceivable that differences in the stimuli played a role. Unlike the current study, only a positive condition was tested in [8], which could influence their participants to focus on the existence of public evidence, and to try to differentiate the two cases.

4. Conclusions

This paper discussed the correlation between prosodic patterns with adjectival predicates and the speaker's bias observed in Japanese negative polar interrogatives through two types of experiment. The result obtained from the comprehension test demonstrates that the distinct prosodic patterns are exploited to comprehend the epistemic bias and to appropriately respond to negative polar interrogatives. The result of the naturalness test reveals that Japanese speakers are sensitive to the prosodic patterns observed in negative polar interrogatives, and the prosodic differences play an important role in naturalness judgments. Taken together, the results reported in the current study confirm that prosodic patterns are highly correlated with speaker's bias in negative polar interrogatives in Japanese. Further, it was shown that the presence or absence of public evidence does not differentiate the AD and the DD patterns.

Future research concerning other parts of speech, in addition to adjectives, needs to be explored. With respect to the difference between the AD and the DD patterns, the current research suggests the possibility that the AD pattern might be able to be used for "information gap" situation while the DD pattern might not. More tests will be necessary to clarify this point. Also, further investigation of the fine-grained prosodic correlates of speaker's bias, and consideration of relevant constructions with greater complexity are necessary to better understand the nature of the interface between prosody and speaker's bias.

5. Acknowledgements

We are grateful to John Whitman for helpful comments and discussions. We would also like to thank all the participants of our experiments.

L2 production of Estonian quantity degrees

Einar Meister and Lya Meister

Abstract

The Estonian quantity system involves three contrastive patterns referred to as short (Q1), long (Q2) and overlong (Q3) quantity degrees. Our previous studies have shown that for L2 learners the distinction between Q2 and Q3 is a difficult task in both production and perception. While Q1 and Q2 structures are always distinguished in the orthography, this is not the case in most Q2 and Q3 words excluding the words with plosives between first and second syllable vowels (see examples later in the text). Thus, the orthography might be the reason for the use of the same L2 production pattern for both Q2 and Q3.

The current paper studies the role of L2 orthographic input on the L2 production of Estonian quantity degrees by two groups of subjects with different language backgrounds: Finnish and Russian. The material used in the study involves word structures with and without orthographic manifestation of quantity contrasts.

The results confirm the role of Estonian orthography on the L2 pronunciation, however, the two L2 subject groups show different prosodic patterns.

Index Terms: L2 speech, Estonian, Finnish, Russian, quantity opposition

1. Introduction

The domain of the Estonian quantity degrees is a disyllabic foot – a sequence consisting of the stressed syllable and the following unstressed syllable, e.g. [1], [2], [3], [4]. In the vowel-peaked structures (Q1: CV.CV; Q2: CVV.CV; Q3: CVV:.CV) the quantity contrast manifests mainly in vowels and diphthongs of the stressed syllable, e.g.: Q1: *sada* /sa.ta/ 'hundered', nom.sg.; Q2: *saada* /saa.ta/ 'to send', sg.imperat.; Q3: *saada* /saaː.ta/ 'to get'; Q2: *koera* /koe.ra/ 'dog', gen.sg.; Q3: *koera* /koeː.ra/ 'dog', part.sg.. In the consonant-peaked structures (Q1: CV.CV, Q2: CVC.CV, Q3: CVC:.CV) quantity oppositions occur in consonants and consonant clusters between the first and second syllable vowels, e.g.: Q1: *kala* /ka.la/ 'fish', nom.sg.; Q2: *kalla* /kal.la/ 'arum', nom.sg.; Q3: *kalla* /kalː.la/ 'pour', 2.sg. imperat.; Q2: *lehma* /leh.ma/ 'cow', gen.sg.; Q3: *lehma* /lehː.ma/ 'cow', part.sg..

Phonetically, the duration of a stressed syllable vowel (V1) in the vowel-peaked structures is shortest in Q1 and longest in Q3 – V1 duration in Q2 is ca 1.9 and in Q3 ca 2.5 times longer than in Q1 (as pooled from several studies [5]); the duration of intervocalic consonant (C2) in the consonant-peaked structures increases in a similar amount – ca 1.8 and ca 2.5 times in Q2 and Q3, receptively [6]. The duration of an unstressed syllable vowel (V2) varies inversely to the duration of V1 (or C2) being in Q2 ca 0.8 and in Q3 ca 0.6 times shorter than V2 in Q1 [5], [6]. Despite large variations of V2 duration, no quantity contrast exists in unstressed syllable and V2 is defined phonologically "short". Also, a consonant quantity contrast in word-initial position is not possible.

In addition to the inversely proportional durational relations within a foot, F0 contour is a complementary cue distinguishing the quantity oppositions – in Q1 and Q2 the F0-peak is located close to the end of V1, in Q3 it is located within the first half of V1 eg. [7], [8].

Lehiste [7] has introduced the syllable duration ratio as a characteristic feature distinguishing the three quantity degrees. The typical duration ratio for Q1 is 2:3, for Q2 3:2, and for Q3 2:1; similar ratios have been reported in numerous subsequent studies for both read [2], [8], [9], [10], [11] and spontaneous speech [12], [13].

As our previous studies [6], [14], [15], [16], [17] have shown, for L2 learners with Finnish- and Russian-language backgrounds the distinction between vowel-peaked Q2 and Q3 contrasts is a difficult task in both production and perception. It can be partly explained by the fact that in the orthography, vowel-peaked Q2 and Q3 structures, representing different grammatical words, are not distinguished (see examples above).

In our recent paper [5], we have addressed the role of L2 orthography on the production of Estonian quantities by focusing on consonant-peaked target words manifesting the Q1 – Q2 – Q3 contrast orthographically, i.e. the words with plosives between first and second syllable vowels, e.g.: Q1: *kade* /ka.te/ 'envious', nom.sg.; Q2: *kate* /kat.te/ 'cover', nom.sg.; Q3: *katte* /katː.te/ 'cover', gen.sg.; Q1: *lugu* /lu.ku/ 'story', nom.sg.; Q2: *luku* /luk.ku/ 'lock', gen.sg.; Q3: *lukku* /lukː.ku/ 'lock', part.sg.; Q1: *leba* /le.pa/ 'lay', 2.pers.sg.imperat.; Q2: *lepa* /lep.pa/ 'alder', gen.sg.; Q3: *leppa* /lepː.pa/ 'alder', part.sg.

Notice that, in Estonian orthography, the letters <bdg> and <ptk> denote short and long voiceless plosives, respectively.

The findings confirmed the effect of L2 orthography – L2 subjects with Finnish-language background produced different patterns for Q2 and Q3 structures in the case of target words with plosives, but not in the case of words with non-plosives.

In the current paper we study the role of L2 orthographic input on the L2 production of Estonian quantity oppositions by two groups of subjects with different language backgrounds: Finnish and Russian. The speech material analyzed in the study involves vowel-peaked and consonant-peaked words with and without orthographic manifestation of quantity contrasts.

2. Method

2.1. Subjects

The L2-FI group involves subjects (age 21-49, median 36) from the Helsinki, Turku and Oulu areas born in monolingual Finnish speaking families. They started to study Estonian at the age 18-35 at university and have studied it for 1-5 years; six subjects

use Estonian frequently (daily or weekly), other six rarely.

The L2-RU subjects (age 21-33, median 24.5) were born in monolingual Russian speaking families living in the north-east of Estonia or in the capital area. Most of the L2 subjects started to learn Estonian in school at the age of 6-13, one subject at the age of 16 and one at the age of 20. All (except one) L2-RU subjects communicate at home in Russian, but outside they use Estonian almost every day.

The L1-EE group of native speakers (age 21-54, median 26.5) came from monolingual Estonian-speaking families and represent the pronunciation of standard Estonian.

All subject groups have equal number of subjects balanced by sex (6 male, 6 female); none of the subjects reported any language impairment.

2.2. Speech material

A subset of the Estonian Foreign Accent Corpus [18], [19] involving disyllabic target words representing quantity oppositions in sentence context was used in the study. L2-FI subjects from Helsinki and Oulu were recorded in the recording studios of Helsinki and Oulu universities, the subjects from Turku in a quiet lecture room at Turku University. L2-RU and L1-EE subjects were recorded in the recording studio of the Laboratory of Phonetics and Speech Technology, Tallinn University of Technology. For all recordings the same microphones and high quality recording equipment (sampling frequency 44.1 kHz, resolution 16 bit) were used.

From each subject 48 words were analyzed, including nine triplets of vowel-peaked structures (CV.CV; CVV.CV; CVV:.CV) (referred later as Vowel set) and seven triplets of consonant-peaked structures (CV.CV, CVC.CV, CVC:.CV). Among the latter, three triplets (referred to as Plosive set) involved plosives /k/, /p/ and /t/ between first and second syllable vowels, in four triplets (referred to as Non-plosive set) the consonants /m/, /n/, /s/, and /l/ were present. All target words have been manually segmented and labeled on word and phone levels using Praat [20].

2.3. Measurements

The durations of all constituent segments (C1, V1, C2, V2) in each target word were measured using a Praat-script and the syllable duration ratio was calculated as the duration of the first (stressed) syllable rhyme divided by the duration of the second (unstressed) syllable nucleus [21].

In the case of vowel-peaked quantity contrast (i.e. target words CV.CV, CVV.CV and CVV:.CV) the characteristic duration ratio is calculated as the duration of the stressed syllable vowel (V1) divided by the duration of the unstressed syllable vowel (V2). In the case of consonant-peaked target words (CVC.CV and CVC:.CV) the calculation of duration ratio is more complicated since it involves splitting of the word-medial geminate consonant into two segments: the coda of the first syllable and the onset of the second syllable. For splitting a simple approach from [21] has been adopted. In Q2 (CVC.CV) the intervocalic geminate is divided into two parts of equal duration, in Q3 (CVC:.CV) the second syllable onset is taken equal to one-third of the duration of the intervocalic geminate, and two-thirds of geminate's duration is attributed to the first syllable coda.

Notice that syllable-initial consonants do not participate in forming quantity contrasts, thus they are left out of further analysis. However, durations of C1 and C2 are given in Table 1 and 2 for the reader's interest.

3. Results

3.1. Vowel-peaked structures

Table 1 provides mean segment durations and syllable duration ratios of the Vowel set (36 subjects x 27 words = 972 words) representing the vowel-peaked word structures in Q1, Q2, and Q3 produced by subjects in three groups. ANOVA with factors Subject group and Quantity, and TukeyHSD post-hoc test were applied for statistical analysis. Box plots (Figure 1) and scatter plots (Figure 2) demonstrate variations in V1/V2 ratio, and V1 and V2 duration produced by the three subject groups.

As expected, the segment durations and syllable duration ratios of the L1-EE subject group are in line with those reported in many earlier studies (e.g. [2], [4], [5], [13], and others). Quantity effects durations of V1 [$F(2, 321) = 350.5$; $p < 0.001$] and V2 [$F(2, 321) = 131.6$; $p < 0.001$], and consequently also V1/V2 ratios [$F(2, 321) = 503$; $p < 0.001$], among different quantity degrees.

In the L2-FI group, Quantity has a strong effect on V1 [$F(2, 321) = 210$; $p < 0.001$] and V2 [$F(2, 321) = 92$; $p < 0.001$] duration, and V1/V2 ratio [$F(2, 321) = 248.5$; $p < 0.001$]. However, the post-hoc test confirmed differences in these parameters among Q1 and Q2 ($p < 0.001$), but not between Q2 and Q3. Comparing L2-FI vocalic segments to those of the L1-EE group, there are no significant differences in the case of Q1 and Q3, but large differences exist between the two groups in the case of Q2 in V1, V2, and in V1/V2 ratio ($p < 0.001$). L2-FI subjects do not distinguish the Q2 and Q3 temporal patterns and produce them both similarly to the Q3 pattern of the native group. Notice the almost perfect match of Q2 and Q3 in L2-FI group in Figure 1 and 2 (mid).

Table 1: *Mean duration (in ms) and standard deviation (in parenthesis) of C1, V1, C2, V2, and V1/V2 duration ratio in the three word structures representing the quantity contrasts Q1, Q2 and Q3 read by L1-EE, L2-FI and L2-RU subjects.*

Group	Qs	C1	V1	C2	V2	V1/V2
L1-EE	Q1	**81**	**81**	**61**	**111**	**0.8**
		(20.1)	(15)	(15.7)	(26.9)	(0.2)
	Q2	**85**	**143**	**58**	**85**	**1.8**
		(19.4)	(28.2)	(10.8)	(23.8)	(0.4)
	Q3	**78**	**171**	**59**	**63**	**2.8**
		(21.5)	(30.4)	(11.9)	(12.9)	(0.7)
L2-FI	Q1	**94**	**74**	**71**	**114**	**0.7**
		(25.2)	(22)	(24.9)	(35.9)	(0.2)
	Q2	**106**	**170**	**60**	**66**	**2.8**
		(25.9)	(48.2)	(17.5)	(25.7)	(1)
	Q3	**96**	**173**	**60**	**66**	**2.8**
		(27.4)	(44.8)	(15.7)	(27.7)	(0.9)
L2-RU	Q1	**99**	**98**	**63**	**100**	**1.1**
		(32.4)	(30)	(19.2)	(38.7)	(0.5)
	Q2	**108**	**153**	**61**	**90**	**1.8**
		(28.8)	(35.7)	(16.1)	(33.3)	(0.6)
	Q3	**106**	**155**	**62**	**91**	**1.8**
		(40.2)	(40.6)	(16.6)	(30.8)	(0.6)

In the L2-RU group, in vocalic segments, Quantity has a strong effect on V1 [$F(2, 321) = 88.8$; $p < 0.001$], and on V1/V2 ratio [$F(2, 321) = 61.8$; $p < 0.001$], but a rather weak effect on V2 [$F(2, 321) = 2.8$; $p = 0.06$]. The post-hoc test revealed differences in V1 and in V1/V2 ratio ($p < 0.001$) in Q1 and Q2, but not in Q2 and Q3; Quantity had no effect on V2 duration.

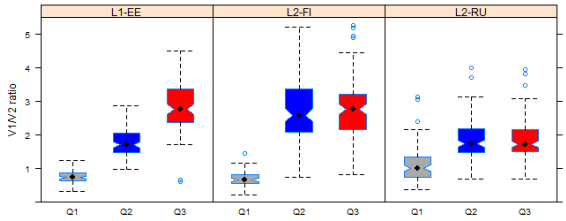

Figure 1: *Box plots of V1/V2 duration ratio in Q1 (gray), Q2 (blue) and Q3 (red) produced by L1-EE (left), L2-FI (mid) and L2-RU (right) subject groups.*

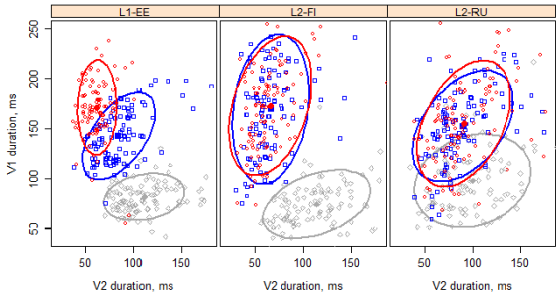

Figure 2: *Scatter plots of V1 and V2 durations in Q1 (gray), Q2 (blue) and Q3 (red) produced by L1-EE (left), L2-FI (mid) and L2-RU (right) subject groups.*

Compared with the L1-EE group, L2-RU vocalic segments deviate in Q1 ($p < 0.001$ in the case of V1 and V1/V2 ratio, $p < 0.05$ in the case of V2) and in Q3 ($p < 0.001$ in the case of V2 and V1/V2 ratio, $p < 0.01$ in the case of V1); no difference between the two groups was found in Q2. Similarly with the L2-FI group, the L2-RU group produces a single temporal pattern for both Q2 and Q3, but it coincides with Q2-pattern of the L1-EE group (see Figure 1 and 2, right).

3.2. Consonant-peaked structures

Table 2 provides mean segment durations of the consonant-peaked word structures in Q1, Q2, and Q3 produced by subjects in the three groups. Part A includes duration data of the Non-plosive set (36 subjects x 12 words = 432 words), and part B of the Plosive set (36 subjects x 9 words = 324 words). Variations in Syll rhyme/V2 ratio and Syll rhyme and V2 durations are shown in box plots (Figure 3) and scatter-plots (Figure 4).

In the L1-EE group, Quantity strongly effects the duration of Syll rhyme in both the Non-plosive [$F(2, 141) = 212$; $p < 0.001$] and in the Plosive [$F(2, 105) = 382.7$; $p < 0.001$] sets. Also V2 duration differs significantly among quantities in the Non-plosive [$F(2, 141) = 26.6$; $p < 0.001$] and the Plosive [$F(2, 105) = 43.2$; $p < 0.001$] sets. As a result, the characteristic duration ratio Syll rhyme/V2 reliably separates the three quantity degrees in both sets (Non-plosive set: [$F(2, 141) = 160.5$; $p < 0.001$], Plosive set [$F(2, 105) = 326.2$; $p < 0.001$]). Comparing L1-EE segment durations in the Non-plosive set to those of the Plosive set, differences in most segments emerge. However, these differences are natural due to the variable phonemic identity of the segments. It is important to notice that in both sets segment durations manifest quantity related patterns similar to the vowel-peaked structures: Syll rhyme duration is proportional to the quantity degree (shortest in Q1 and longest in Q3) and V2 duration is inversely proportional (longest in Q1 and shortest in Q3).

Table 2: *Mean duration (in ms) and standard deviation (in parenthesis) of C1, Syll rhyme (S1-rh), C2-s2, V2, and Syll rhyme/V2 duration ratio (S1-rh/V2) in the three word structures representing the quantity contrasts Q1, Q2 and Q3 in words in the Non-plosive (A) and the Plosive (B) sets read by L1-EE, L2-FI and L2-RU subjects.*

A: Non-plosive set						
Group	Qs	C1	S1-rh	C2-s2	V2	S1-rh/V2
L1-EE	Q1	**87** (17.7)	**85** (13.4)	**63** (20.4)	**93** (29.8)	**1.0** (0.28)

Quantity effects Syll rhyme and V2 durations, and also their ratios in both L2 groups, however, differences from the native group exist. In the L2-FI group, in the Non-plosive set, Quantity has strong effect on Syll rhyme [$F(2, 141) = 111.8$; $p < 0.001$]); however, Syll rhyme differs only among Q1 and Q2 (Q1: 73 ms, Q2: 154 ms; $p < 0.001$), but not in Q2 and Q3 (Q2: 154 ms, Q3: 159 ms; $p = 0.7$). In the Plosive set, L2-FI subjects produce different Syll rhyme durations in the three quantity degrees [$F(2, 105) = 121.8$; $p < 0.001$]), the mean durations for Q1 are: 65 ms, for Q2: 134 ms, and for Q3: 187 ms. V2 duration

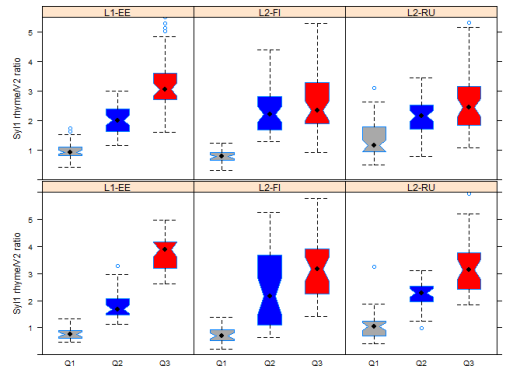

Figure 3: *Box plots of Syl1 rhyme/V2 duration ratio in Q1 (gray), Q2 (blue) and Q3 (red) of Non-plosive (top) and Plosive (bottom)sets produced by L1-EE (left), L2-FI (mid) and L2-RU (right) subject groups.*

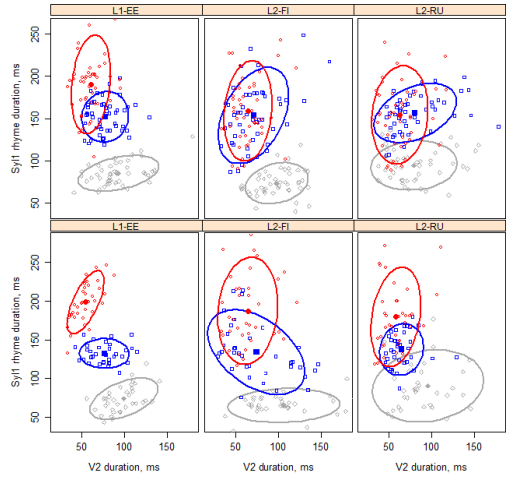

Figure 4: *Scatter-plots of Syl1 rhyme and V2 durations in Q1 (gray), Q2 (blue) and Q3 (red) of Non-plosive (top) and Plosive (bottom) sets produced by L1-EE (left), L2-FI (mid) and L2-RU (right) subject groups.*

has similar patterns in both word sets: V2 duration differs only between Q1 and Q2 ($p < 0.001$), but not between Q2 and Q3. As a result, the Syl1 rhyme/V2 ratio in the Non-plosive set is 0.8 for Q1, 2.4 for Q2, and 2.6 for Q3; these ratios differ between Q1 and Q2 ($p < 0.001$), but not between Q2 and Q3 ($p = 0.2$). In the Plosive set, the duration ratios are 0.7, 2.4, and 3.2, respectively, and provide a reliable difference between all quantity degrees ($p < 0.001$).

For the L2-RU group, Quantity has a similar effect as in the case of L2-FI group for Syl1 rhyme which differs in the Non-plosive set between Q1 and Q2 only (Q1: 95 ms, Q2: 157 ms; $p < 0.001$), and not between Q2 and Q3 (Q2: 157 ms, Q3: 155 ms; $p = 0.9$), and in the Plosive set, it differs among all quantities [$F(2, 105) = 72.2$; $p < 0.001$]), the mean durations are 91 ms, 138 ms, and 180 ms for Q1, Q2 and Q3, respectively. V2 duration shows different patterns: in the Non-plosive set it is almost the same in Q1 and Q2 (Q1: 79 ms, Q2: 81 ms; $p = 0.96$), but it differs between Q2 and Q3 (Q2: 81 ms, Q3: 63 ms; $p < 0.01$); in the Plosive set V2 duration differs between Q1 (95 ms) and Q2 (65 ms) ($p < 0.01$), but not between Q2 and Q3 (58 ms) ($p = 0.6$). Consequently, Syl1 rhyme/V2 duration ratio is distinctive among all quantity degrees in both word sets: in the Non-plosive set Q1: 1.4 vs. Q2: 2.1 ($p < 0.001$) and Q2: 2.1 vs. Q3: 2.7 ($p < 0.01$); in the Plosive set Q1: 1.1 vs. Q2: 2.2 vs. Q3: 3.3 ($p < 0.001$).

4. Discussion

The languages involved in the study differ in the way the duration cue is exploited in phonological contrasts. Estonian and Finnish are quantity languages, both exploiting the duration cue contrastively, while Russian is a non-quantity language lacking duration-based phonological oppositions. There are two theoretical models addressing the role of duration in L2 speech: (1) the *Feature Hypothesis* states that "L2 features not used to signal phonological contrasts in L1 will be difficult to perceive for the L2 learner and this difficulty will be reflected in the learner's production" [22], (2) the *Desensitization Hypothesis* states that duration cues are easy to access whether or not listeners have had specific linguistic experience with them [23].

The first model predicted an advantage for the L2-FI group over the L2-RU group since L2-FI subjects can exploit the binary contrasts available in Finnish. The second model suggested that also L2-RU subjects should be able to distinguish Estonian quantity contrasts even though there is no corresponding prosodic pattern in Russian to rely on. The Q1 vs. Q2 results support the second hypothesis since both L2 groups were successful in producing the Q1 vs. Q2 opposition. With respect to the Q2 vs. Q3 results, neither hypothesis can be favored (more space would be needed to elaborate on theoretical implications).

The most surprising result was that the L2-RU group outperformed the L2-FI group in producing distinct Q2 and Q3 patterns in the Non-plosive set. This may have to do with the fact that our Finnish speakers had learned Estonian as adults while the Russian speakers mostly in childhood, in addition, the exposure to and use of Estonian is much more frequent in the case of the L2-RU group. Also, the methods how the Estonian quantity contrasts have been taught might effect the results.

5. Conclusions

In the paper we studied the effect of L2 orthographic input on L2 pronunciation of vowel-peaked and consonant-peaked quantity contrasts. Only in the Plosive set the quantity contrasts are explicitly expressed in the orthography, unlike the Vowel set and the Non-plosive set. The results confirmed the role of L2 orthographic input in the case of the L2-FI group – in the Plosive set the L2-FI subjects produced different patterns for Q2 and Q3 structures, but not in the other sets. However, the role of orthography can not be conclusive in the case of the L2-RU subjects since they produced different patterns for Q2 and Q3 structures also in the Non-plosive set.

6. Acknowledgements

We thank our volunteer speakers in Finland and Estonia, and Martti Vainio, Kari Suomi and Stina Ojala for their help in arranging the recordings at Helsinki, Oulu and Turku University.

This work has been partially supported by the Estonian Ministry of Education and Research target-financed research theme No. 0140007s12 and by the National Program for Estonian Language Technology.

Variation in list intonation in American Jewish English

Rachel Steindel Burdin[1]

[1]Department of Linguistics, The Ohio State University, USA

burdin@ling.osu.edu

Abstract

Yiddish-influenced intonation has been previously noted as a potential defining characteristic of American Jewish English and, specifically, list intonation identified as a possible area of differentiation. However, apart from remarks in general descriptions of Standard American English (SAE) prosody, a systematic study of list intonation has not been conducted in SAE. In this study, lists were defined, and extracted from sociolinguistic interviews with Jewish women with varying degrees of exposure to Yiddish. Speakers from different language backgrounds differed significantly in their use of contours, boundary tones and pitch accents on list items, with speakers with less exposure to Yiddish using more of the standard English contour (H* H-L%) than speakers with more exposure to Yiddish. Yiddish bilinguals were more likely to use a rise fall contour (L+H* L-L%), fewer H-L% boundary tones and H* pitch accents, and more rising pitch accents (L+H* and L*+H) than non-bilinguals. In addition, speakers of all language backgrounds used a variety of list intonations, showing the need for more systematic study into the uses and meanings, social and otherwise, of list intonations in English.

Index Terms: list intonation, variation, Jewish English

1. Introduction

"List intonation" is, in some sense, a misnomer, as there are in fact several list intonations that have been described for American English. The distinction between the types has been said to be one of pragmatics: Ladd [1] notes two list intonations, one involving a rise, and the other, a high plateau, with the rising one being used for exhaustive lists (those which have listed all possible items) and the plateau being used for non-exhaustive lists (in which the items are taken to be merely representative of a larger set). The high plateau, H* H-L%, can be seen in figure 1: the pitch, starting at the stressed syllable and through the end of the intonational phrase, is generally high, and flat. However, more than two intonations can be used in lists in English, although their use has not been studied systematically: Schubiger [2], for example, describes five different patterns that can occur on "enumerations".

Intonation has been noted as a potential characteristic feature of American Jewish English speech: in studies of Orthodox Jewish communities, both Fader's [3] and Benor's [4] subjects claimed that they could tell if someone was Jewish by their intonation. It is unclear what, exactly, this distinctive intonation is: A "rise-fall" contour has been proposed as a feature of Jewish English as far back as 1956 [5]. However, this contour does not seem to be phonologically distinct, being ToBI transcribed as L+H* !H-L% [6], a contour which does exist and is used in Standard American English, usually as a vocative or some other stylized utterance [1]. It is more likely, then, that the differences in Jewish English intonation lie in either differences in phonetic implementation of contours, in differences in the use and meaning of contours, or both.

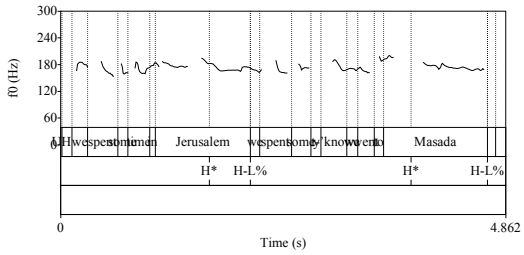

Figure 1: A standard H* H-L% on list items-"We spent some time in Jerusalem, we went to Masada"

One potential area of difference is in lists: some Jewish speakers produced non-exhaustive lists that contained falls on non-final items (described as being rarer by Schudiger [2]), as in figure 2.The speaker is describing how Brooklyn has changed since she lived there: it has become cool, and that there's always something going on, "with artists, with music, with food, with breweries". Each phrase has a H* L-L% contour, with high pitch on the stressed syllable, which then falls to the bottom of the speaker's pitch range. These types of lists, with falling (or rise-falling), rather than flat, contours, sounded distinctly "Jewish" to some listeners.[1]

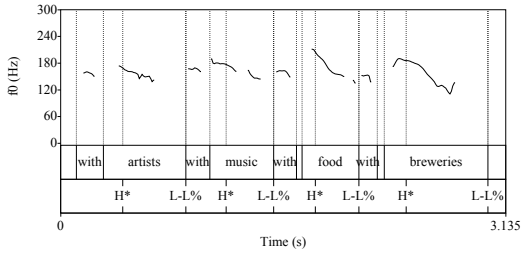

Figure 2: H* L-L% on list items

Data were analyzed from a series of sociolinguistic interviews to see if there was variation in list intonation between 10 Jewish women from the metropolitan NYC area. In addition, this study provides, as far as this author knows, the first systematic study of list intonation in any variety of American English.

[1]I am grateful for participants at the Linguistic Society of America 2013 meeting for this observation.

2. Methodology

2.1. The interviews

Ethnographic-type interviews with 10 Jewish women were conducted in the metropolitan New York area. The sample is non-random, with most of the subjects recruited through personal contacts. The women varied in their degree of exposure to Yiddish and other varieties with significant Yiddish influence. Degree of exposure to Yiddish has been previously found to influence the use of Jewish English features. Jewish speakers with more exposure to Yiddish use forms that show more Yiddish-like traits (e.g., using a loanword like *schmooze* with its original Yiddish meaning of "chat"), and speakers with less use forms more like non-Jewish speakers (e.g., using *schmooze* to mean "network, chat up") [7]. As such, it was expected that the speakers with more exposure to Yiddish would show some influence of Yiddish in their intonation, while those with less exposure would behave more like Standard American English speakers.

Three of the women, the bilingual group, grew up bilingual in Yiddish and English, in neighborhoods in Newark and New York City that had large populations of Yiddish-speaking immigrants. However, it should be noted that these women were, at the time of the interview, English-dominant, with no noticeable Yiddish accent, beyond possibly their prosody. Three of the women, the mixed exposure group, grew up speaking only English, but had significant exposure to Yiddish-influenced varieties: one had Yiddish speaking parents and lived in a neighborhood in New York City with a large immigrant population; the other two spent significant amounts of time in Israel and reported high proficiency in Israeli Hebrew, whose prosody is almost certainly heavily influenced by Yiddish [8]. Finally, four of the women, the limited exposure[2] group, grew up monolingual in primarily English-speaking neighborhoods consisting mostly of second or third generation Americans.

As the target of investigation was potentially a socially meaningful one, it was thought that a more naturalistic setting, with a known interviewer, would prompt the subjects to produce more speech that was markedly Jewish, and indeed, most of the subjects, particularly when discussing Jewish topics, did, e.g., use Jewish English lexical items, mostly loan words from Hebrew and Yiddish. The interview as a whole centered around the interviewee's life, and contained several prompts that were amenable to list-type responses: e.g., What did you do for fun when you were younger? What sort of activities would you do in New York City? The interviews lasted around 45 minutes.

Subjects were recorded using a head mounted microphone with a digital recorder. Transcripts of the interviews were made using ELAN, and analyzed using PRAAT [9].

2.2. Extracting lists

Lists have been described in various ways, with some claiming that only two items are necessary to make a list [10]; and others, three, with three items tending to be preferred [11]. I follow Selting [12] in allowing several characteristics to define a list, with one exception: Selting cites prosody as factor in marking a sequence of items as a list; however, using prosody as a feature to define a list would be obviously problematic for this study. As such, lists were selected solely on the basis of the transcripts of the interviews.

[2] As opposed to no exposure group; these women would have had experience, for example, speaking to women in the first or second group, and had command over various Yiddish lexical items and other linguistic features that are a part of the American Jewish English repertoire

A list was defined as a group of utterances of at least two items that were (1) non-temporally ordered and (2) displayed syntactic parallelism. Parallel NPs ("I had to buy everything-pillows, blankets, pots, pans...") and PPs (as in figure 2) were automatically included; parallel VPs and sentences needed to match in some other way besides simply being VPs and sentences, either (for sentences) by having some repeated part (e.g., "You could walk to Chinatown, you could walk over the bridge.."), or by having a similar argument structure (e.g., "We watched movies, we ate junk food..." but not "We had a lot of fun, we lived on a cul de sac, we used to play softball right in the street with our neighbors"). In addition, sequences of items concluded with a specific marker of list-hood, e.g., including a phrase like "and things like that", or, in one case, explicitly stating "we have a list", were included, regardless of whether or not the list items met the previous criteria.

Although previous studies have described lists as full, definable units, with the same prosody on each item apart from possibly the last (for example, Selting's study [12]), for this study, this was often not the case. While there seemed to be a preference for consistent prosody across list items, speakers did switch in the middle of a list. It was also difficult to determine what should count as a "list", singular. Take the following example, where a speaker is describing a part of Brooklyn:

(1)
1. You could walk to Chinatown
2. You could walk over, over the bridge
3. You can walk to work if you work downtown
4. You could jog over the bridge coming home
5. You had great restaurants
6. You had, um, beautiful, beautiful brownstones
7. And apartment buildings
8. And as I said, tree-lined-
9. Beautiful tree-lined streets.

The first four items are a list due to the syntactic parallelism, all being sentences starting with *you* + a modal; one could also perhaps include lines 5 and 6 due their starting with "you had", but here, the speaker has switched from listing attributes that were good about living near the Brooklyn Bridge to attributes that were good about the neighborhood in general. However, line 6 also seems to go with lines 7, 8, and 9, which are slightly different again: here, she's listing things that were attractive in the neighborhood, and has switched to listing NPs, as opposed to full sentences. Deciding whether this is one, two or three lists is non-trivial.

Similar problems can be seen in example 2, from a speaker describing her trip to Israel:

(2)
1. We spent some time in Jerusalem
2. We spent some time in-
3. We went to Masada
4. We went to the Dead Sea...

The false start in line 2, with the same frame as line 1, indicates that item 1 is meant to be in a list; however, the speaker reconsiders, perhaps because it's not possible to "spend some time" in Masada[3], and sticks with this new frame for the rest of the list. It was decided, in this case, to include item 1, as some syntactic parallelism exists with lines 3 and 4 (simple past tense verbs, with a location), and it fit into the theme of the list – places this speaker had gone in Israel – quite clearly.

[3] As it is a archeological site on a mountain, rather than a city.

Due to the problems of demarcating the lists as a whole, as well as the fact that often times, the lists did not have consistent prosody across all items, the results reported here are based on the list items, rather than by looking at the lists as whole units. This means, for example, that the entirety of examples (1) and (2) were included in the analysis, apart from those lines containing disfluencies at the end of the IP (example (1), line 8, and example (2), line 2).

The list items were extracted, and ToBI transcribed by the author based on the ToBI guidelines [13]. Due to the unscripted nature of the data, phonetic differences were not looked at this time; however, it is likely that they exist as, e.g., wider pitch range has been cited as a feature of Jewish English [14]. Uncertain transcriptions were discarded. Only list items ending with a full IP break were analyzed. Most of the time, there was a clean mapping of list item to IP; however, there were, at times, multiple IPs within a list item. These "extra" IPs were tagged as comments, and were excluded from the analysis. 504 list items were initially extracted; 467 were included in the analysis.

Lists were annotated for being exhaustive or not, as, as mentioned above, it has been claimed that exhaustive and non-exhaustive lists might have different prosody. An exhaustive list is one that a speaker intends to be a full account of possible items; a non-exhaustive list has items that are meant to be representative. Again, the distinction between exhaustive and non-exhaustive was based on the text, not on the prosody of the utterance, and fairly strict definition was used for "non-exhaustive": either the speaker had to name all items that could be in the list, or the speaker had to have stated that a specific number of items were in the list (e.g. "My three sons...").

List items were also annotated based on their position in the lists, first, medial, or last. For most of the lists, this was fairly straightforward; however, for lists like examples (1) and (2), the entire sequence of utterances was taken as one "list", and first, last, and medial were assigned accordingly.

3. Results

Table 1 gives an overview of the nuclear pitch accents and boundary tones used on the list items, sorted by language status; in this and the following tables, only the most common contours are shown for reasons of space. The limited exposure group preferred the contour previously noted for standard English, H* H-L%, shown in figure 1 above, with the H* !H-L% contour, consisting of a high tone on the stressed syllable and either a drop to a mid-range plateau, or a slight fall, shown in figure 3, as a slightly distant second.

Table 1: Nuclear pitch accents and boundary tones on list items

Bilinguals (n= 121)	Mixed (n=93)	Limited (n=253)
H* !H-L% (20%)	H* H-L% (26%)	H* H-L% (45%)
L+H* L-L% (15%)	H* L-L%(18%)	H* !H-L% (16%)
H* H-L% (15%)	H* !H-L% (12%)	H* L-L% (10%)
H* L-L% (14%)	L+H* !H-L% (11%)	L* H-L% (7 %)
L* L-H% (9 %)	H* L-H% (9%)	!H* H-L% (7 %)

The mixed and bilingual groups had more variety in their choice of pitch accents and boundary tones: For the mixed group, the H* H-L% contour, although a plurality of the contour types, was not close to being the majority, and, for the bilingual

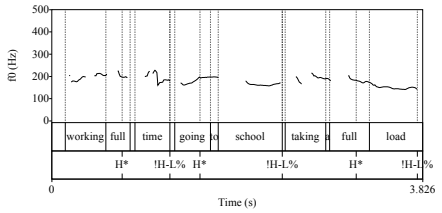

Figure 3: List items with H* !H-L%

group, the standard English contour tied with a rise-fall contour, L+H* L-L% (consisting of a sharp rise to the stressed syllable, then fall to the bottom of the speaker's pitch range, shown in figure 4) in second, with H* !H-L% ahead of it; preference was fairly evenly divided among the top 4 contours; again, cf. the limited group, which showed a clear preference for H* H-L%.

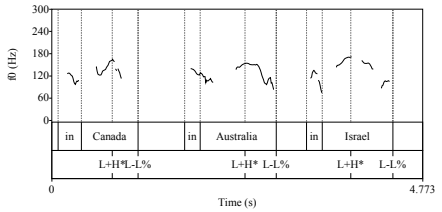

Figure 4: List items with L+H* L-L%

A logistic regression model was built using the contour type (H* H-L% or not[4]) as the dependent variable, as this is, as noted above, the contour previously noted for standard English, and also the contour that showed the most variance in use between the three groups. Language status, exhaustiveness of the list, and list position were included as fixed effects, and speaker as a random effect. Sum contrasts were used for all fixed effects. Log likelihood testing comparison revealed no significant differences between models including exhaustiveness and position and those without, so reports from the simplest model, with language status as a fixed effect, and speaker as a random effect, are included here. It was found that the limited exposure speakers and the mixed speakers were more likely to use the standard English H* H-L% contour ($p<0.001$, and $p<0.01$) than the average; the bilingual speakers were less likely to use the contour ($p<0.001$) than the average.

Another model was built using the L+H* L-L% contour or not as the comparison, as this was the second most used contour by the bilinguals, and showed, again, variance between the three groups. Position and exhaustiveness were found to be non-significant, and were removed from the model. The bilinguals used this contour significantly more ($p<0.05$), and the mixed group, less ($p<0.05$). The limited group also trended in this direction, but not significantly so ($p = 0.0508$). For the H* L-L% contour, no significant differences emerged for language status.

Table 2 shows the percentage of different boundary tones used by the speakers on list items. Again, a logistic regression model was built, using the same effects as above; however, neither position nor exhaustivetivity were significant. A log like-

[4]Converting the data to binary variables was necessary; multinomial logistic regression models were attempted, but failed to converge, probably due to the amount of data.

lihood comparison between models with and without these effects was non-significant, so the results from the model with only speaker and language status will be reported. The boundary tones were converted to binary factors: use of H-L% or not (the standard English contour), and use of L-L% (the contour preferred by the bilinguals) or not. The mixed and limited group were more likely to use H-L% boundary tones ($p<0.001$ and $p<0.05$) than the average; the bilingual group was less likely ($p<0.001$). No significant difference was found for the use of the L-L% boundary tones.

Table 2: Boundary tones

Tone	B (n= 121)	M (n=93)	L (n=253)
H-L%	20 %	36 %	48 %
L-L%	36 %	28 %	26 %
!H-L%	26%	22 %	17%
L-H%	16 %	11 %	7 %
H-H%	2 %	2 %	1%

Table 3 shows the pitch accents used on the nuclear accent of the IP. The pitch accents were converted to binary factors: H* pitch accent (the standard, preferred by all groups) or not, and rising pitch accents (L+H* and L*+H) or not (as these seemed to be preferred by the bilinguals), and logistic regression models were run with the same fixed and random effects as above; in this case, position was found to be significant, but exhaustiveness of the list was not, and so position, but not exhaustiveness, was included in the model. For the first model, the H* pitch accent was more likely to be used for first items. Bilinguals were less likely to use H* overall ($p< 0.01$); the limited exposure group and the mixed group were more likely to use H* pitch accents overall ($p<0.01$ for both). For the second model, looking at the rising pitch accents (L+H* and L*+H), again, position was significant, with first and last items being less likely ($p<0.01$ and $p<0.05$) to receive rising accents than middle items. The bilingual group was more likely to use the rising pitch accents ($p<0.01$); the mixed group trended in this direction, but not significantly so ($p = 0.059$). The limited group was less likely to use these accents ($p<0.01$).

Table 3: Pitch accents

Pitch accent	B (n= 121)	M (n=93)	L (n=253)
H*	55 %	68 %	74 %
L+H*	20 %	15 %	7%
L*+H	10 %	5 %	0 %
!H*	10 %	3 %	7 %
L*	15%	7 %	11%

4. Discussion

Table 4 provides a summary of the findings above. The differences between the groups showed up as significant in the use of the H* H-L% contour, L+H* L-L% contour, H-L% boundary tone, and H* and rising pitch accents.

The mixed group overall, looked more like the limited exposure group than the bilingual group, with the exception of use of the rising pitch accents, where they were not significantly different from the average, as well as in their use of the L+H* L-L% contour, where the limited group was not significantly different from the average. The mixed group, appropriate to their name, might occupy a space in between the bilingual group and the limited group in a very real sense, using mostly standard English prosody, but being able to adopt various features otherwise associated with the bilingual group when needed or wanted. The bilingual group, on the other hand, was markedly different from both groups. It is very likely that this difference comes from their Yiddish background. There has not yet been a systematic study of Yiddish prosody, so this remains speculative; however, the use of falling contours on lists has been noted in German [12], a language very closely related to Yiddish.

Table 4: Summary of findings: Use of contours, boundary tones, and pitch accents, compared to average. *($p<0.05$), **($p<0.01$), ***($p<0.001$)

	Bilingual	Mixed	Limited
H* H-L%	less***	more **	more ***
L+H* L-L%	more*	less*	n.s.
H* L-L%	n.s.	n.s.	n.s.
H*	less**	more**	more**
L+H*/L*+H	more *	n.s.	less**
H-L%	less***	more*	more**
L-L%	n.s.	n.s.	n.s.

In addition to this variability across groups, there was considerable variation within the groups, as even the speakers with limited access to Yiddish showed some variety in the type of contours used: although the H* H-L% was preferred by this group, other contours were used as well. It is likely that some of these contours have a difference in meaning or use from the H* H-L% contour above: although exhaustivity did not come out as significant in any of the models, this may be due to the fact that in some cases, the list's status as either exhaustive or not might be marked primarily by the prosody, rather than being able to be extracted from the text string, and that the prosody was the only clue to exhaustiveness vs. non-exhaustiveness. However, this still leaves the question of what, for example, separates the H* H-L% lists from the H* !H-L% lists.

These findings also open up the possibility that, in addition to more pragmatic differences between the use of the contours, like exhaustive and non-exhaustive, there might be social meaning differences as well, with the use or non-use of certain contours perhaps marking a speaker as older, or Jewish. The differences might also have to do with attitudes towards the items being listed: for lists with falling contours, the speakers occasionally sounded dismissive, or annoyed. However, perception studies will be needed to more accurately study what these contours mean, both in terms of social meaning and other meanings.

Abstract

We present a preliminary investigation on the usefulness of prosodic boundaries for unsupervised term discovery (UTD). Studies in language acquisition show that infants use prosodic boundaries to segment continuous speech into word-like units. We evaluate whether such a strategy could also help UTD algorithms. Running a previously published UTD algorithm (MODIS) on a corpus of prosodically annotated English broadcast news revealed that many discovered terms straddle prosodic boundaries. We then implemented two variants of this algorithm: one that discards straddling items and one that truncates them to the nearest boundary (either prosodic or pause marker). Both algorithms showed a better term matching F-score compared to the baseline and higher level prosodic boundaries were found to be better than lower level boundaries or pause markers. In addition, we observed that the truncation algorithm, but not the discard algorithm, increased word boundary F-score over the baseline.

Index Terms: term discovery, prosody, prosodic boundary

1. Introduction

During their first year of life, human infants extract word-like units from continuous speech without supervision [1]. In parallel, unsupervised term discovery (UTD) algorithms are increasingly used within speech technology [2, 3, 4, 5]. In both cases, the task consists in finding repetitive patterns, while using as input only the speech signal. An examination of how infants are solving this task may reveal useful strategies that could be implemented into UTD algorithms.

Many researchers have pointed out that prosody is an important cue that helps infants to segment continuous speech. Newborns are sensitive to the acoustic cues correlated with the presence or absence of phonological phrase boundaries in otherwise identical stretches of speech (e.g. /mati/ in "mathématicien" (mathematician) versus "panorama typique" (typical panorama) [6, 7]. Nine-month-olds use these cues to posit breaks within sentences [8, 9]. Ten- and thirteen-month old infants use these boundaries to constrain word recognition, i.e. they fail to recognize a string that straddles a phonological phrase boundary [10]. Similarly, adults use these boundaries to constrain online lexical cognition, i.e. they do not produce false alarms on word forms that straddle a phonological phrase boundary[11].

Unsupervised term discovery, so far, does not use prosodic information. The existing algorithms are based on computing a similarity score between stretches of speech signal, usually done by means of dynamic time warping (DTW). The proposed systems return a list of matched pairs [2, 3] and/or a library of clusters of discovered terms [2, 4, 5]. Some systems scan the entire corpus for repetitions [2, 3], while others only scan a small time buffer and match the signal against an incrementally built library of terms [4, 5]. The terms discovered with UTD systems have already been proven useful in a number applications like keyword spotting [12], topic segmentation [13], or document classification [14].

Based on the findings regarding the role of prosodic boundaries in speech processing for both children and adults, we investigated the use of such boundaries in unsupervised term discovery. The current study uses manually annotated prosodic boundaries in order to establish the upper boundary of their impact on the discovery task. The rest of the paper is organized as follows: the UTD system used in the experiments and the evaluation method are presented in section 2, while a short description of the corpus employed in this study is given in section 3. Two experiments are illustrated in section 4, in which we varied the strategy for using prosodic information. The paper concludes with a discussion of the results obtained and some possible paths to follow.

2. Methods

2.1. System Presentation

An open source system for spoken term discovery, MODIS [15], was employed for the experiments. It is based on a generic approach to mining repeating sequences, tolerant to term variability [5], and it uses a limited search buffer, making it more psychologically realistic than systems performing an exhaustive search.

MODIS takes a speech signal as input (represented as either MFCCs or posteriorgrams) and delivers a library of repeated terms as its output. Term discovery is based on the notion of seed fragments. A seed fragment is a stretch of signal segmented from the input stream and searched for in a fixed-length buffer ahead of the seed using a segmental variant of the DTW algorithm. If a match for the seed is found, the seed is extended to find the maximal length matching pattern and, if it exceeds a minimal term length, it is stored in the library of terms. This library is used as a long term memory to search for repeating terms: Each new seed considered is first matched against entries in the library before searching for self-repetitions in the buffer. Potential re-occurrences detected by DTW are validated using self-similarity matrix (SSM) comparison.

The key parameters of the seeded discovery algorithm are the seed and term lengths and a set of similarity thresholds used to validate template comparison (higher thresholds means potentially more variability at the expense of precision).

2.2. Evaluation Method

We evaluated two aspects of the discovered terms: the matching quality and the word boundary quality. For the matching

quality, we used a similar method to [16], which transforms the speech chunks corresponding to the found terms into a symbolic representation, based on the phonetic transcription of the speech signal. Then, the precision and the recall are determined based only on the strings of phonemes corresponding to the obtained terms. For a formal definition of the measures used for the evaluation, see Muscariello et al study [16]. The following steps are performed during the evaluation process:

- All phonemes falling inside the time interval corresponding to the found term are concatenated. A phoneme is considered to belong to the term if at least 50% of its duration falls within the term.
- For each class of terms, a centroid is computed, defined as being the string with the lowest normalized edit distance from all the other strings belonging to the class.
- The precision is calculated as the percentage of class members, out of the total number of tokens in the class, falling within a certain distance from the class centroid. The neighbourhood threshold was set to 0.2.
- Next, the recall is determined as being the percentage of how many strings belonging to the centroid neighbourhood were found, from the total number of occurrences of those strings in the whole corpus.

The second measure we evaluated, the word boundary quality, comes from the field of natural language processing (NLP) and it can be a useful measure when the terms discovered by the UTD systems are used in a downstream application. The boundary quality was computed by comparing the set of discovered term boundaries to the set of gold word boundary of the corpus, as done in [17]. We expect a very low recall on this metric, since UTD systems do not attempt to exhaustively segment a corpus, contrary to NLP systems, that perform term discovery based on text input.

3. Materials

The materials used in this paper are a subset of the Boston University Radio News Corpus (BU corpus) [18], which contains news stories recorded by 7 professional speakers. Out of the whole corpus, around 3.5 hours of data are annotated prosodically for phrase breaks and accent tones. The prosodic annotation is based on the ToBI system [19] for American English, which uses a 5-level scheme for prosodic boundaries of increasing strength, starting with cliticized word boundaries (level 0) and ending with intermediate phrase boundaries (level 3) and intonational phrase boundaries (level 4).

We used only levels 3 and 4 as we are interested in the effect of prosodic boundaries that can, in principle, be detected in an unsupervised fashion. We removed the recordings for which these two levels were missing and those with no phone-level segmentation, because this type of annotation was necessary for the evaluation procedure. Thus, for our experiments, we used about 3 hours of data, including 6 speakers (3 males, 3 females) distributed into 403 files. In these materials there were a total of 6059 intonational phrase boundaries and 2731 intermediate phrase boundaries annotations.

4. Experiments

We propose to investigate the usefulness of prosodic boundary information for term discovery, by integrating this type of information in MODIS in two experiments. In Experiment 1, we examined the idea of using boundary information to prune away

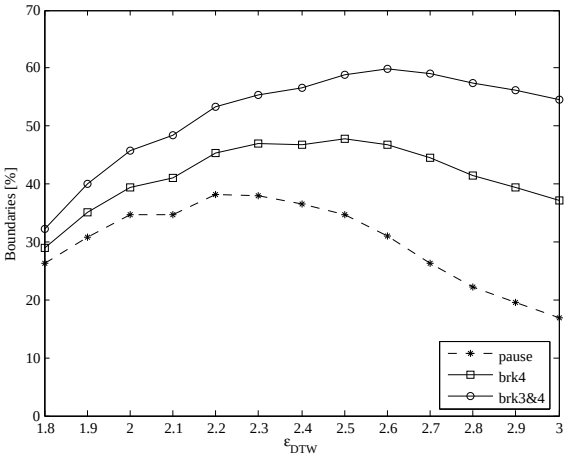

Figure 1: *Percentage of terms found by the baseline system overlapping pause markers, level 4 boundaries and level 3 and 4 boundaries.*

the terms found to be straddling a prosodic boundary ($discard$). In Experiment 2, we tested the option of truncating the terms instead of discarding them ($truncate$). In both experiments, besides intonational phrase boundaries ($brk4$) and intonational plus intermediate phrase boundaries ($brk3\&4$) we also tested another cue which denotes finality - the silent pause ($pause$). Pauses were chosen as they correlate well with prosodic boundaries, but are easier to extract automatically. In order to perform a fair comparison to the case when prosodic boundaries are used, the pauses were extracted from the manual transcription and were defined as a time instant (the beginning of the pause). We considered to be a pause all silent regions of speech having a length of at least 200 ms, resulting in 2723 pause boundaries. The pause markers correspond mostly to level 4 boundaries, but there are some which indicate level 3 boundaries.

The speech signal was represented by standard spectral features: 12 MFCCs plus energy and their first and second order temporal derivatives. The system used a seed length of 250 ms, a 90 second future buffer when searching for terms and it accepted a candidate as a term if it was at least 500 ms long. A found term was represented by its median occurrence, i.e. the token closest to all the other ones in terms of a dissimilarity score and SSM checking was also employed. In the two experiments done we varied the similarity threshold used by the DTW algorithm (ϵ_{DTW}) in the range [1.8, 3.0] and we reported the results for all the values.

4.1. Experiment 1

For the baseline system, spoken term discovery was only constrained by file boundaries (403 markers in total), which were processed by the algorithm in the same manner as the prosodic boundaries (here, discarded). Figure 1 shows the percentage of terms found with the baseline system which straddle a level 4 break, a level 3 or 4 break or a pause marker. One can observe that up to 60% of the terms straddle either a level 3 or a level 4 prosodic boundary. Given that prosodic boundaries match with constituent boundaries, it is likely that the straddling terms will be less meaningful to downstream applications. In addition, it is probable that such terms are purely coincidental, and therefore correspond to low quality clusters of word fragments. We will

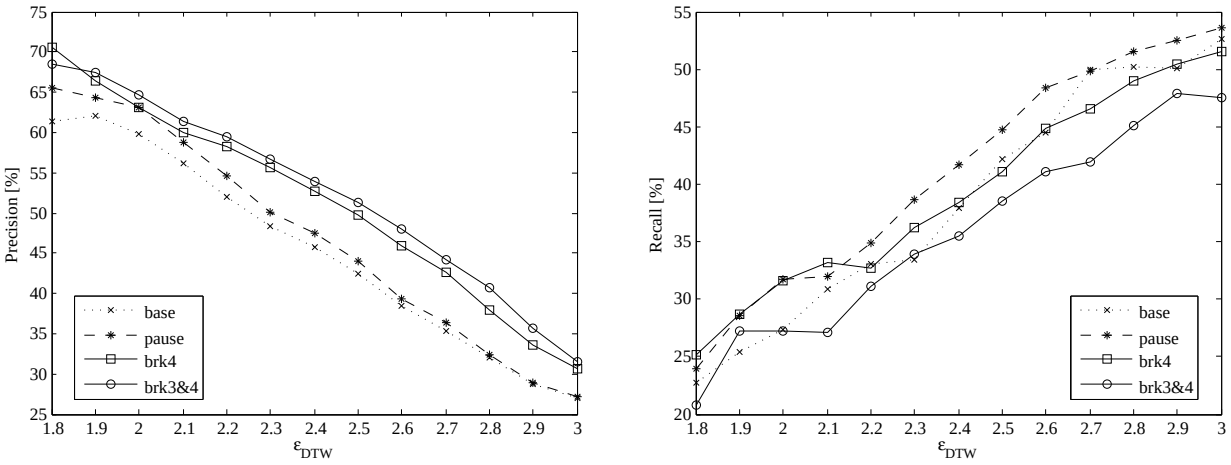

Figure 2: *Term matching precision (left panel) and recall (right panel) obtained for different ϵ_{DTW} values and various types of information used: baseline, pause information, level 4 boundaries, and level 3 and 4 prosodic boundaries.*

evaluate this premise next.

In order to measure the change in performance after the removal of straddling terms, compared to the baseline, we used the precision and recall, as computed with the method introduced in section 2.2. The results obtained with our baseline, and the same system employing prosodic or pause boundaries to discard straddling terms are illustrated in Figure 2. The left panel shows the precision obtained, while the right panel presents the recall rate. The baseline is represented with a dotted line, the system taking advantage of pause markers with a dashed line, and the results obtained with the prosodic boundary informations by a continuous line. The square represents the results for $brk4$, while the circle illustrates the $brk3\&4$ system.

It can be seen that, by adding extra boundary information into the system, besides file boundaries, the terms found are consistently more accurate. The average increase in precision is 6.0% for $brk4$, 7.3% for $brk3\&4$, and 1.8% for $pause$. In terms of recall, the system using intonational phrase boundaries gives similar performances to the baseline, which, in turn, performs better than the system having knowledge of both types of prosodic phrase boundaries, but worse than when pauses are known.

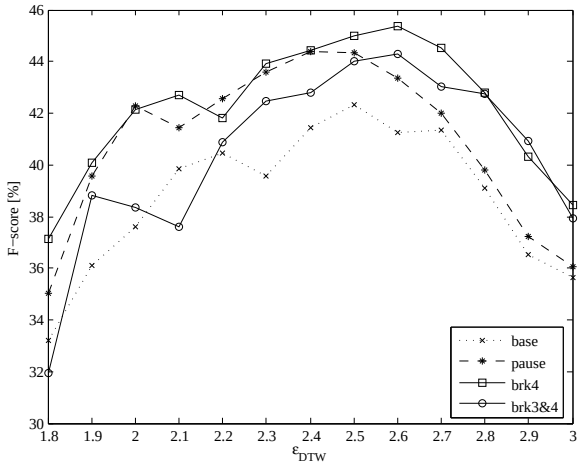

Figure 3: *Term matching F-score obtained for different values of ϵ_{DTW} and various type of information used: baseline, pause information, level 4 boundaries, and level 3 and 4 prosodic boundaries.*

We also looked at the F-score curve over the different ϵ_{DTW} values tested (Figure 3). When comparing the baseline with the other three systems, one sees a consistent improvement throughout the range of values investigated, resulting in an average F-score increase of 3.4% for $brk4$, 1.6% for $brk3\&4$ and 2.1% for the $pause$ system. We observed similar $brk4$ or worse $brk3\&4$ performance than for pauses at low values of the DTW threshold, but consistently better results for boundaries at high values of ϵ_{DTW}. This demonstrates that, when more heterogeneous terms are found, the boundaries tend to help discriminate better between occurrences of different terms, showing that prosodic boundaries encode more information than the pauses.

For an overall comparison of performance, we have summarized in Table 1 the two measures used for evaluation: the goodness of the obtained terms and the word boundaries discovered by the terms. The number in each cell represents the average precision, recall and F-score computed over all DTW threshold values (ϵ_{DTW}). The term matching measurements illustrated in the table mirror well the results displayed in Figures 2 and 3, showing a better performance than the baseline. Still, in terms of of word boundaries, the systems employing boundary information are penalized by a low recall and have lower F-scores, even if the word boundaries found are much more accurate.

	Term			Word Boundary		
	P	R	F	P	R	F
Baseline	45.3	38.5	38.8	22.8	2.8	4.7
Pause	47.1	40.9	40.9	24.1	2.5	4.2
Break 4	51.3	39.2	42.2	24.1	2.1	3.6
Break 3&4	**52.6**	35.8	40.4	24.4	1.7	3.0

Table 1: *Average precision, recall and F-score for discovered terms and word boundaries respectively, when the discard method is used.*

4.2. Experiment 2

In the previous experiment, we have observed that the method used for incorporating boundary information tends to persistently decrease the recall rate. This was due to the fact that the approach used consisted in discarding all terms found straddling a boundary. In this last experiment we wanted to compare this method to a different one which does not discard the terms spanning over several prosodic units, but shortens them ($truncate$). In this method, a term straddling a boundary would be truncated so it would include only the speech signal belonging to the prosodic unit having the highest overlap in time with the found term. The minimum term length constraint is applied after the truncation procedure.

	Term			Word Boundary		
	P	R	F	P	R	F
Baseline	45.2	42.4	40.3	23.0	2.9	4.9
Pause	46.5	**43.1**	41.6	26.3	**3.2**	**5.2**
Break 4	49.1	41.6	**42.4**	27.5	3.1	**5.2**
Break 3&4	51.3	38.5	41.9	**28.3**	3.0	5.1

Table 2: *Average precision, recall and F-score for discovered terms and word boundaries respectively, when the $truncate$ method is used.*

Table 2 illustrates the results obtained with this approach of incorporating prosodic information for the various types of information added. It contains the same type of information as Table 1. As we expected, the approach which truncates terms straddling a boundary gives a better recall than $discard$, at the expense of a slightly lower precision. In terms of F-score, an overall increase in performance is observed for all conditions.

The results in Table 2 show a small advantage in terms of word boundary F-score when boundary information is used. We detailed these results in Figure 4, by plotting the F-score over the range of ϵ_{DTW} values tested. It seems that for lower values of the DTW threshold, the baseline performs slightly better than the other systems, but, as the system becomes more permissive, the boundary information becomes more useful for discriminating words. Thus, it encourages the use of prosodic breaks information in conjunction with higher DTW thresholds for improved performance of UTD systems.

Interestingly, we found that the system using intonational phrase boundaries generally outperforms the system using smaller breaks (intermediate boundaries), which correspond to phonological phrase boundaries within the prosodic hierarchy [20]. Smaller breaks give better precision but this, in turn, is compensated by a worse recall which yields a slightly lower F-score, also for the $truncate$ case. This stands in contrast to findings in psycholinguistics studies where smaller breaks do seem to play a role, both for processing online speech in adults and for boosting speech segmentation in babies [11, 8, 9, 10]. We speculate that this may be due to the fact that our system imposes a 500 ms limit on the size of the discovered terms, which could affect proportionally more the breaks 3 and 4 compared to breaks 4. In order to prove this, we looked at the length of fragments delimited by boundaries. We discovered that when level 4 breaks are considered, 0.6% of the total speech fragments are shorter than 500 ms, the minimum term length employed in this study. This proportion increases to 3.7% when both level 3 and level 4 boundaries are taken into account, but it is equal to 0% for pauses. It means that for a percentage of the corpus no terms can be found. In this case, it would be interesting to investigate whether a lower limit for minimum term length will boost the recall rate, while not affecting too much the precision.

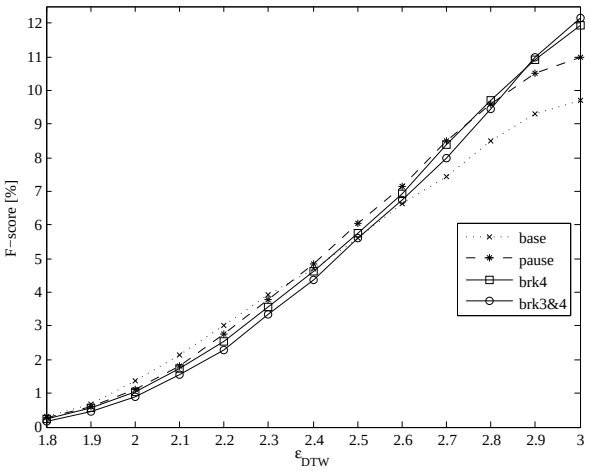

Figure 4: *Word boundary F-score obtained for different values of ϵ_{DTW} and various type of information used: baseline, pause information, level 4 boundaries, and level 3 and 4 prosodic boundaries.*

5. Conclusions

We have presented in this paper a preliminary study regarding the usefulness of prosodic boundaries for unsupervised term detection. Our findings show that boundary information, either intonational boundaries or intermediate and intonational boundaries, increases the performance of the system. The better results obtained are mainly due to increasingly accurate found terms, reflected in an improved precision. We have also compared prosodic boundaries against pauses, a prosodic cue which is generally easier to detect automatically. The system employing pauses outperformed the one using both level 3 and 4 boundaries, but it behaved worse than the system having knowledge of level 4 boundaries. We have discovered this advantage of pauses over level 3 and 4 boundaries to be due to a much lower recall, caused in part by constraints imposed for the length of the terms found.

The results we obtained encourage us to further continue our investigation by planning to use in a future study automatically extracted prosodic boundaries. In order to achieve this, we are currently focusing on methods of prosodic boundary detection based exclusively on acoustic cues. A second direction to pursue would be extending the study to several other languages. While unsupervised term discovery was applied until now only to less than a handful of languages we would expect prosodic boundary information to bring a consistent improvement in any language.

Abstract

This papers presents GlóRí - the glottal research instrument. GlóRí is a speech analysis interface which offers a flexibility and multiplicity of approaches to voice analysis. The system allows for fully automatic processing, for instance for analysis of large corpora. However, for more fine-grained studies, which may require precise voice source measurements, the systems facilitates manual optimisation of parameter settings. The present paper highlights the main features of the GlóRí system and provides illustrations of the usefulness of this approach.

Index Terms: Glottal source, voice source, phonetic features, voice quality

1. Introduction

The research being carried out by the voice processing group at the Phonetics and Speech Laboratory in Trinity College Dublin is concerned with the development of robust voice source processing methods and analysing the function of the voice source in prosody. As part of this endeavour, we have been developing our speech analysis methods so as to be able to handle the inherently different acoustic characteristics of the speech signal and to be adaptive and flexible according to the phonetic and prosodic context. This paper presents GlóRí - the glottal research instrument. Note that [glo:ˌi:] is the Irish (Gaelic) word for *voices*. GlóRí is the voice analysis system within which our ongoing developments in voice source analysis and data visualisation will be integrated.

The ability to derive precise and robust measurements of the voice source is becoming increasingly important for speech technology applications (e.g., speech synthesis [1, 2], emotion classification [3, 4]), as well for linguistic analysis on the prosody of the voice [5, 6] and also for voice pathology and voice function assessment [7]. Ideally, one would wish to be able to derive robust parameterisation of the voice source completely automatically. However, this process typically involves three non-trivial steps.

The first step, in order to allow glottal pulse-synchronous analysis, is to estimate glottal closure instants (GCIs, [8]). After several decades of research state-of-the-art GCI detection is at a sufficiently high level of performance for the analysis of neutral read speech. Despite this, a recent study [9] demonstrated how different phonation types (and in particular creaky voice) deteriorated GCI detection performance. For disordered voices, where there is indeed a significant excitation within each glottal cycle, the deterioration is likely to be significantly more.

The next step, typically involves glottal inverse filtering, the process of compensating for the effect of vocal tract resonance from the speech signal. The most commonly used vocal tract model is an all-pole model, which can be estimate by linear predictive analysis, or similar methods. For nasals consonants and nasalised vowels there are generally zeros present in the vocal tract spectrum, making the all-pole model less suitable and this has negative effects on subsequent voice source parameterisation [10]. For speech with a low first formant frequency (F1), discrimination of F1 from the glottal formant can be problematic. This is particularly true when combined with a high f_0, which has the additional effect of having more widely spaced harmonics making the vocal tract spectral envelope more difficult to estimate effectively.

Finally, once an estimate of the voice source has been derived, for many purposes one typically then requires a parametric description of the signal. The two main approaches to this are to either take measurements from the voice source estimate directly or fit a mathematical model to the individual glottal pulses. Quotients characterising the timing of important events in the glottal cycle are generally thought to be the most salient parameters, regardless of which of the two approaches are used. One critical event is the instant of glottal opening, a reference point required for most time-quotient parameters. Localisation of this time instant is extremely difficult, not least because the glottal opening does not always display a significant discontinuity (e.g., in lax phonation). For the direct measure approach, the more commonly used parameters are generally amplitude-based [11, 12] or frequency domain correlates of time quotients [13].

From the three steps described above there is clearly wide scope for the introduction of significant errors, particularly in the case of natural, expressive speech or indeed even moderately disordered speech. In many instances, an experienced speech science researcher may be able to make adjustments to the automatic process and improve the overall effectiveness of the analysis. With this firmly in mind, the newly developed analysis system, GlóRí, has been designed to allow both fully automatic analysis while also facilitating manual intervention and optimisation at various stages in the analysis. From the outset there are three main characteristics that are fundamental to our system design.

1. **Adaptive** The system should allow a multiplicity of approaches, e.g., for research on large corpora fully automatic analysis can be deployed, but for more fine-grained analysis the researcher should be able to manually optimise the analysis to ensure maximal precision. Furthermore, the analysis should be adaptive to the phonetic and prosodic context, e.g., allowing glottal inverse filtering with an adaptive vocal tract modelling.
2. **Modular** Ongoing development of various voice source and speech analysis algorithms should be easy to incor-

porate into the system. To this end we created the interface in the Matlab programming environment. As our algorithm development (as well as much of the signal processing development in the speech research community) is done using this environment, it facilitates newly developed algorithms being easily incorporated.

3. **Knowledge** We intend for the system to incorporate various sources of *knowledge* in the analysis. This can be considering the given phonetic class being analysed and adapting the analysis accordingly (e.g., using a vocal tract model which included pole-zeros for nasal regions). It can also include incorporating knowledge from speech production theory, e.g., precluding parameterisation which is outside the physical boundaries of human speech.

1.1. Existing voice source analysis systems

There are a small number of interfaces for voice source analysis available in the literature. The APARAT system is one interface which facilitates automatic glottal inverse filtering and voice source parameterisation using a range of existing parameters from the literature [14]. The system is available under an open-source licence[1] and has encourage using voice source feature extraction in a range of speech-related areas.

Another freely available interface for voice analysis is the Voice Sauce program[2] [15]. Voice Sauce enables a wide range of voice-related speech analysis including f_0 and harmonic extraction, formant tracking and the formant compensation proposed by Hanson [13], harmonic and subharmonic to noise ratio, energy and cepstral peak prominence extraction. Voice sauce also includes a facility for analysis of electroglottographic (EGG) waveforms.

Although there is some overlap with these interfaces, GlóRí is a useful complement and there are several major differences compared with existing systems. First, GlóRí allows manual intervention and optimisation. Second, GlóRí includes some very recently developed voice quality related analysis methods. A third major difference is that we are intending for the system to allow incorporation of speech production knowledge and to involve pre-processing steps which could be used to contrain possible analysis settings and also, where necessary adapt the analysis (e.g., the structure of the vocal tract model) to more closely match the acoustic structure of the given speech segment. Furthermore, GlóRí includes resynthesis and data vizualisation components that facilitate construction of stimuli for perception experiments as well as allow to represent the analysed data for visual inspection in a number of ways.

2. System features

This section serves to illustrate the main system features of the GlóRí system. The system was designed to be user-friendly and to allow manual analysis, if it is deemed necessary, or completely automatic voice source feature extraction.

2.1. Manually-optimised analysis

Voice source analysis, including the possiblity for manually-optimised analysis, can be carried out using the analysis window shown in Figure 1. When a speech sample is loaded into

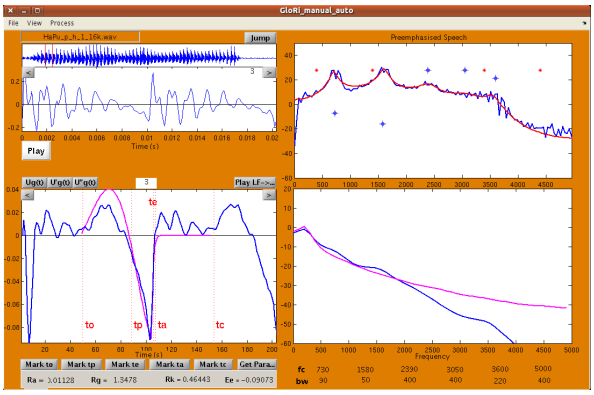

Figure 1: Screenshot of the manual analysis interface of the GlóRí system. Users can choose from a selection of parameterisation approaches, derived from the voice source estimate, using parameters derived from model-fitting and parameters derived from the speech signal.

system, it is resampled to 10 kHz. GCIs are located automatically using our recently developed algorithm (SE-VQ, [9]) and GCIs detected in unvoiced regions are excluded. GCI locations can then be manually edited later if required using the GCI editor. Locations that are judged to be false can be deleted and undetected locations can be added. Although state-of-the-art GCI detection has reached a mature level of performance, this can still degrade when analysing speech involving wide variation in phonation type [9] or the voice is disordered. Allowing a facility for manual intervention here may enable more precise analysis for these types of speech.

For each GCI-centred two pulse length frame, the vocal tract model can be constructed by setting the formants frequencies and bandwidths. The frequency and bandwidth of each formant can be adjusted using the keyboard arrow keys, and a time and frequency domain representation is available to assess the effect of the inverse filter. As each anti-formant nears its optimal location, the oscillations of the corresponding formant will be dampened in the time domain (see bottom left panel of Figure 1), and the formant peak will be largely attenuated in the frequency domain (see bottom right panel). Once the speech signal has been inverse filtered the user can then move to the parameterisation step. The manually optimised system allows parameterisation of the estimated voice source signal by fitting the Liljencrants-Fant (LF) voice source model [16] to the individual glottal pulses. An LF model can be fitted to the inverse-filtered pulse by manually adjusting the time-points of the model (see bottom left panel of 1). Fitting is facilitated with both the time and frequency domains displays in the two adjacent panels, allowing the user to achieve accurate time-point matches while also ensuring close spectral fitting.

2.2. Fully automatic analysis

In contrast to the manually-optimised analysis, a fully automatic analysis approach is included in the GlóRí system (see Figure 2). The analysis relies entirely on the use of automatic algorithms, without any intervention from the user. A folder of speech samples is loaded through the interface, and the desired analysis parameters are selected.

These fall under three categories. The category title "Glottal params" is further subdivided into two different types. Un-

[1] http://sourceforge.net/projects/aparat/
[2] http://www.ee.ucla.edu/~spapl/voicesauce/

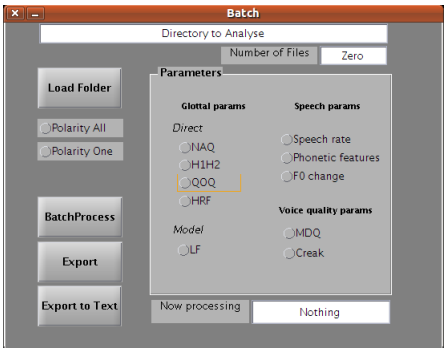

Figure 2: Screenshot of the fully automatic analysis interface of the GlóRí system. Users can choose from a selection of parameterisation approaches, derived from the voice source estimate, using parameters derived from model-fitting and parameters derived from the speech signal.

der "Direct" one can select parameters which are derived using direct measurements of the glottal inverse filtered signal. These include: the normalised amplitude quotient (NAQ; [12]), the difference between the amplitude of the first two harmonics (H1-H2; [13]), the quasi-open quotient (QOQ; [11]), and the harmonic richness factor (HRF; [19]). Under "Model" one can select to have the glottal inverse filtered signal parameterised by fitting LF-model pulses to the individual glottal pulses using our recently developed automatic fitting algorithm [20]. Note that prior to estimation of these parameters, the inputted speech signal is inverse filtered using iterative and adaptive inverse filtering (IAIF, [21]).

Under the category "Voice quality parameters", one can select the maxima dispersion quotient (MDQ; [22]) and Creak [23]. MDQ is a wavelet based algorithm which discriminates breathy and tense voice quality by assessing the dispersion of peaks across a range of frequency bands relative to the GCI. The Creak parameter gives the binary output of a decision tree classifier, using two input features derived from the Linear Prediction (LP) residual signal.

Finally, the "Speech params" category allows selection of parameters related directly to aspects of the speech signal. Phonetic feature extraction selected and this outputs a continous score on the likelihood of the presence of a range of phonetics features {voiced, syllabic, nasal, liquid, fricative, plosive}. This is done using the algorithm recently proposed in [24]. Note that this algorithm provides important information on the underlying manner of articulation is various speech regions which can facilitate analysis strategies which are adaptive to the phonetic context. This algorithm can also be harnessed for deriving a 'speech rate' measurements, in terms of syllables per second.

2.3. Synthesis interface

Once a given speech signal has been analysed, using either manual or automatic methods, one can then load the exported analysis file into a synthesis interface. As shown in Figure 3 a user is provided with parameter contour displays. The user can modify parameter contours by clicking new points on the panel, as has been done for the f_0 parameter (top panel). It is then possible to resynthesise the speech using the modified parametric setting. This is a useful facility for stimuli generation to be used in perception experiments.

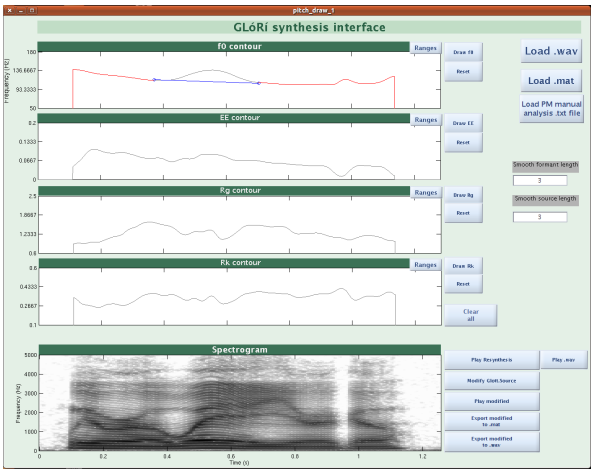

Figure 3: Screenshot of the synthesis interface of the GlóRí system. Users are shown display of parameter settings and can make alterations to these contours and resynthesise the speech.

2.4. Visualisation interface

An interface is also included for easy visualisation of extracted parameter contours. By loading in an analysis file, again either using manual or automatic systems, one can select combinations of parameters to be plotted together with the speech spectrogram. We have also begun to experiment with novel visualisation approaches for showing high dimensional parameter data in a clear single plot, e.g., using spidergrams (illustrated below). These novel developments are incorporated within this interface component of the GlóRí system.

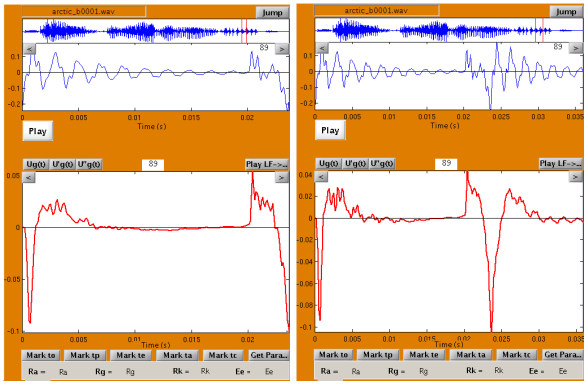
3. Illustrations

This section serves to provide illustrations of how the system features of GlóRí may be beneficial for a range of analysis purposes.

The first illustration highlights the importance of allowing manual intervention to improve the precision of the analysis in certain cases. In the left panel of Figure 4 one can observe the negative impact of a false positive GCI, as often occurs in creaky voice (see [9]), on the overall analysis. The main glottal excitation should be located close to the centre of the analysis panel, and, hence, the false positive observed here will preclude the possiblity of obtaining sensible parameter values if a completely automatic approach was used. However, by exploiting the ability for manual intervention, in this case facilitated by the manual GCI editor, one can easily delete this false positive and proceed to effective voice source modelling as shown in panel (b) of Figure 4.

One crucial intention in the development of the GlóRí system is to facility incorporating knowledge (in its various forms) to help constrain and augment the analysis. In particular, it is desired to facilitate analysis that is sensitive and adaptive to the phonetic environment of the speech signal. As mentioned previous, our phonetic feature extraction algorithm can provide us with initial information on the underlying manner of articulation in a given utterance [24]. Figure 5 shows the output of this feature extraction for a sample utterance.

The information yielded by these phonetic feature extractors may be beneficial for a range of purposes in the analysis



(a) GCI false positive (b) Corrected GCI false positive

Figure 4: Screenshot of analysis of a creaky voice pulse involving a false positive GCI (a) and with the false positive corrected (b).

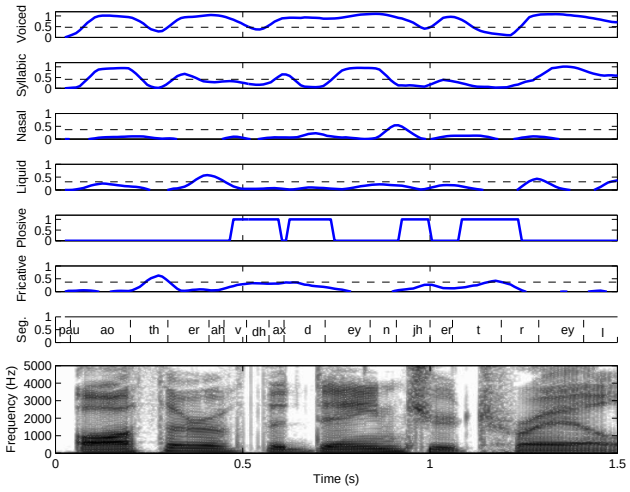


Figure 5: Illustration of phonetic feature extraction for the utterance “Author of The Danger Trail ...”, spoken by an American male.

interface. For voice source feature extraction for the purpose of voice quality classification one may choose to exclude certain phonetic regions known to cause problems for analysis (e.g., areas of frication, or nasality). Another usage could be for adaptive glottal inverse filtering, where the vocal tract model could be adapted to the given region, e.g., in nasalised regions pole-zeros could be incorporated into the vocal tract model. Besides these uses, the phonetic feature extraction may also provide a useful guide for the researcher when carrying out manually-optimised voice source analysis.

Another important component of the GlóRí system is data visualisation. A frequently used approach when analysing voice source parameters is to reduce the data, often to a single shape parameter. However, this approach may at times be premature and may involve losing important information to do with the glottal pulse shape. In order to avoid premature data reduction and to display the voice source parameter data in an accessable form the GlóRí system allows plotting of the data as a “spider-

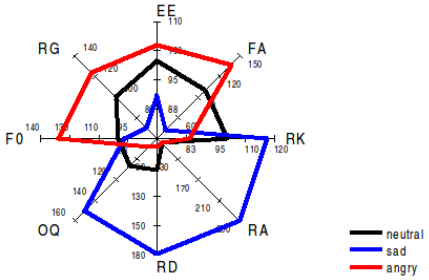

Figure 6: Spidergram plot summarising high dimensional voice source data into a single plot. Note that the axes are the parameter values in percentage relative to neutral.

gram” as shown in Figure 6 [4]. In the spidergram, parameters are arranged in such a way that increased parameter levels above the horizontal axis typically indicate a tenser phonation. Similarly, levels extending below the horizontal axis point to a laxer phonation. The illustration in Figure 6 shows an example spidergram for a sentence spoken with three types of affective colouring: neutral, sad and angry. The blue web for *sad* with it’s increased parameter levels below the horizontal line provides strong evidence of a laxer phonation type, whereas *angry* (with the red web) indicates a tenser phonation.

4. Discussion & conclusion

This paper presented the new voice analysis system, GlóRí. The system is shown to facilitate completely automatic voice source feature extraction, and incorporates a range of state-of-the-art voice source analysis developments as well as existing parameters from the literature. The automatic system may be extremely useful for studies across a range of speech-related disciplines when analysing large corpora, and could in particular be useful for allowing voice source feature extraction for researchers from a non-technical or non-voice related background.

A further benefit of the GlóRí system over existing analysis systems, is that it facilitates manually-optimised analysis. This may be critical for very fine-grained analysis studies which require precise voice source parameter data. Manual intervention here may help reduce the effect of error introduction in the various stages of analysis.

The GlóRí system is intended to be a constantly work-in-progress development. One main direction for ongoing and future research is to bring to bear our knowledge of speech production so we can constrain possible vocal tract model and voice source parameterisation solutions. Our newly developed fully automatic techniques (for instance for deriving information to do with breathy, tense and creaky voice, as well as the underlying phonetic features) can provide prior information that can be used to constrain vocal tract filter and voice source modelling. We intend to make this system publicly available in the near future.

Speech segmentation is modulated by peak alignment: Evidence from German 10-month-olds

Bettina Braun, Muna Pohl & Katharina Zahner

Department of Linguistics, University of Konstanz, Germany
{bettina.braun, muna.pohl, katharina.zahner}@uni-konstanz.de

Abstract

In two headturn preference experiments, we tested whether German infants' speech segmentation skills are sensitive to the position of the pitch peak relative to the stressed syllable. Specifically, we compared target words with medial-peak accents (where the pitch peak is aligned with the stressed syllable, i.e. H* accents) and early-peak accents (where the pitch peak is early with respect to the stressed syllable, i.e. H+L* accents). Such differences in accent type signal mostly pragmatic distinctions in German, such as the difference between contextually new and recoverable information. We familiarized infants with target words produced with one of the two intonation conditions; target words were embedded in sentences. We measured looking times to lists of trochaic part-words that were either embedded in the target words or were novel to them. Results showed a novelty effect only in the medial-peak condition, suggesting that German infants at 10 months of age are very sensitive to pitch information for segmenting running speech.

Index Terms: speech segmentation, pitch, metrical prominence, headturn preference procedure, German

1. Introduction

The ability to segment units from continuous speech is a vital skill for infants to build up their mental lexicon. Research has shown that the segmentation skills in the second half of the first year of life correlate positively with later vocabulary size [1, 2]. The focus of our investigation is on infants' use of metrical stress for segmentation. Previous findings suggest that stressed syllables are preferred word onsets for infants whose mother tongue is a stress-timed language (English [3, 4], German [5], Dutch [6]), but not for infants who are exposed to syllable-timed languages such as French [7]. Although the exact timeline has not been determined yet, it seems that infants shift their attention from statistical to prosodic cues and that by 9 months of age stress cues outweigh distributional cues in segmentation [8]. In stress-timed languages, metrical prominence is generally signaled by a wide variety of acoustic cues: Stressed syllables are longer and louder than unstressed syllables [9, 10], they are produced with increased vocal effort [11] [see 12 for an overview] and often have more peripheral vowel qualities [13]. When stressed syllables additionally receive phrase-level prominence (pitch accents), they are additionally produced with audible pitch movement. However, in intonation languages, the actual type of pitch accent (and hence the alignment of the pitch peak with regard to the stressed syllable) can vary. For instance, the pitch peak can be early, medial or late with respect to the stressed syllable, resulting in distinct accent types [14, 15]. These are described as H+L*, H* or L*+H in the framework of autosegmental metrical phonology [16, 17]. Factors that determine the realization of pitch accents are, among others, utterance position (prenuclear accents are realized with later peaks than nuclear accents, cf. [18]) as well as the information status of the accented referent (non-identifiable referents are preferably associated with medial-peak accents and identifiable referents with early-peak accents, cf. [19]) and information structure (new information is associated with medial-peak accents, inferable information with early-peak accents, cf. [14]). Hence, while a prominence-lending pitch movement in general is a salient cue for metrical stress, the exact position of the pitch *peak* is not a reliable indicator for the position of the stressed syllable in a given word. It must be pointed out that the distinction between early, medial and late pitch peaks is not only signaled by the position of the pitch peak but also in the duration and intensity distribution over the stressed and neighboring unstressed syllables [20]. Specifically, in early-peak accents, the contrast in duration and intensity between the pre-accented (high-toned) syllable and the accented (low-toned) syllable was reduced compared to medial-peak accents. [21] further showed that listeners also use duration and intensity for pitch accent type interpretation. These changes in the intensity and duration distribution suggest that it is more difficult to identify the stressed syllable in early-peak accents than in medial-peak accents. In the present study we investigate if peak alignment affects German 10-month-old infants' segmentation of trochaic part-words (which are salient to young infants) as a function of peak position (early vs. medial peak accents).

High pitch may play a crucial role in segmentation as infants are highly sensitive to pitch information. Specifically, they show a strong listening preference for f0-patterns in infant-directed speech over amplitude and duration patterns [22] and the preference for high pitch and expanded melodic contours is present very early in infancy [23-25]. [26] suggest that this early sensitivity to pitch information might be caused by its phonetic salience and by its distribution across languages. Regarding salience, [27] hypothesize that acoustic salience affects speech perception and infants indeed seem to be especially salient to pitch contrasts, even earlier than to other acoustic features, such as duration [28]. Regarding the distribution of pitch contrasts, [29] claims that melodic contours are present in all languages, either in form of lexical tone, lexical pitch accent or intonation. It has been shown that such common and salient acoustic distinctions as falling vs. rising pitch contours are discriminated early in infancy [26].

Previous segmentation studies have not manipulated peak alignment when familiarizing infants with test words. It can be assumed that the infant-directed speech samples used in these studies have a high proportion of medial-peak accents [30], but there is not enough information in the literature to know whether peak alignment modulates infants' ability to segment words or part-words that start with metrically strong syllables. In the present study, we used the headturn preference procedure [3] with a familiarization phase, in which infants hear two out of four possible passages containing the target words. In the test phase, infants listen to lists of isolated words, half of which already occurred in the familiarization

phase and half of which were novel to the infants. The crucial manipulation was the intonational realization of the target words in the familiarization phase: In Experiment 1, the target words were presented with a medial-peak accent, in Experiment 2, they were presented with an early-peak accent. We hypothesize that infants associate high pitch with metrical prominence and hence show different looking times to familiar and unfamiliar test lists only in the medial-peak condition and not in the early-peak condition.

2. Experiment 1

Experiment 1 investigated whether infants are able to segment embedded trochees from continuous speech when the stressed syllable carries the pitch peak. The target words were presented with a medial-peak accent in the familiarization phase. This is the intonational realization that was most likely used in earlier segmentation studies [3] and we expect to see differences in looking times to familiar and unfamiliar part-words. The target words were all trisyllabic with penultimate stress. This word-prosodic structure was chosen as it allowed us to present the pitch accent on the target word in both intonation conditions (in disyllabic trochaic words, the pitch peak would have been placed on different other words in the early-peak condition, as the target words were presented within whole sentences in the familiarization phase). The trochaic part of the target words (i.e., the last two syllables) served as test words, since infants are very good at segmenting trochees from running speech (see Introduction). Thus, compared to other segmentation studies in which infants were tested on their ability to detect trochees in fluent speech (e.g., [2]), the task demands are more challenging here: Since infants have to extract *embedded* trochees, they cannot rely on acoustic cues to word onsets, and statistical co-occurrences are not helpful either in that they would suggest to extract the complete trisyllabic target word. While the lexical activation of embedded words in adult listeners (e.g., *date* from *sedate* or *bone* in *trombone*) is often disputed [31], the task is different for young infants who are not affected by lexical competition (and inhibition) in the same way as adults are.

2.1. Methods

We conducted a headturn preference study, in which infants were familiarized with target words that were embedded in sentences (see [3]). In the test phase, infants heard word lists consisting of isolated disyllabic trochees that were either part-words of the target words in the familiarization phase or not.

2.1.1. Participants

We tested 21 infants between 37 and 41 weeks from monolingual German-speaking homes and who had not been exposed to languages other than German. All infants were born full-term. For the analysis, we could only include those 16 infants (7 male, 9 female) who finished the familiarization phase and all 12 test trials. They had an average age of 38.9 weeks (SD = 1.26 weeks). Parents were reimbursed for public transport fees and received a small present for the child.

2.1.2. Materials

We chose four low-frequency trisyllabic words (less than 0.1 occurrences per million in the CELEX word form dictionary, cf. [32]) with open syllables as target words (*Kanone* [kaˈnoːnə], 'cannon'; *Lagune* [laˈguːnə], 'lagoon'; *Kasino* [kaˈsiːno], 'casino'; *Tirade* [tiˈʁaːdə], 'tirade'). All were stressed on the second syllable. Note that in all these target words, the unstressed initial syllable is not reduced to [ə] but produced with a full vowel. For each target word we constructed six carrier sentences, such that the target word appeared in different lexical contexts and different sentence positions (twice each in sentence-final position, four times early in the sentence following an article or prenominal adjective). We used naturally produced auditory stimuli in our experiments since the perception of stress is influenced by a variety of acoustic cues that are distributed over the stressed and neighboring unstressed syllables [e.g., 33]. A native female speaker of German recorded the 24 target sentences with a medial-peak accent on the target words. To achieve equally salient f0-movements across target words, the average f0-excursion was matched across the four sets of target words (average f0-excursion was 9.34st, SD = 1.51st). The pitch contour of an example sentence is provided in Figure 1.

The four test words consisted of the second and third syllable of the target words: [ˈguːnə] (taken from *Lagune*), [ˈsiːno] (taken from *Kasino*), [ˈnoːnə] (taken from *Kanone*) and [ˈʁaːdə] (taken from *Tirade*). These disyllabic trochees were recorded approximately 30 times. For the experiment we chose 15 items of each disyllable, such that the average f0-excursion of the pitch fall and the average duration did not differ across test words (average f0-excursion = 10.0st, SD = 1.8st, average duration = 791ms, SD = 72ms). Two consecutive tokens in the test lists were separated by 800ms silence.

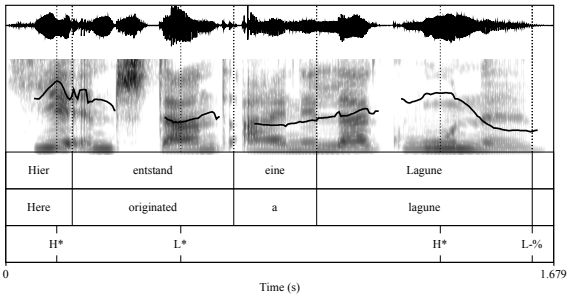

Figure 1: *Example pitch track of a target sentence in the medial-peak condition (f0-range is shown between 100 and 300Hz).*

2.1.3. Procedure

Half of the infants were assigned to the *Kanone* and *Tirade* familiarization trials and the other half to the *Kasino* and *Lagune* familiarization trials. All infants listened to three randomized repetitions of the four test lists (twelve test trials in total). Infants were tested in a three-sided experimental booth at the University of Konstanz. The infants sat on a caregiver's lap. The caregivers wore headphones and did not hear the auditory stimuli the infants were exposed to. Each trial started with a green blinking light at the center of the screen. As soon as the infant oriented towards the center light, a red light to the right or left of the child started blinking. When the infant turned his/her head towards the sidelight, an auditory word list started playing. It played as long as the infant oriented towards this side. If the child looked away for more than 2 seconds, the next trial started. In the familiarization phase, the two passages were presented randomly from the left or the right side until the child had

listened to each of the two paragraphs for at least 45 seconds. In the test phase also, the word lists played randomly from the left or the right side. Looking times were coded online by an experimenter who monitored the child via a video camera and controlled the experiment. The experimenter wore headphones and was not aware of the condition that was played (familiar or novel word list). Prior to testing, parents filled in a questionnaire regarding the infant's language background. The experimental session lasted approximately 5 minutes.

2.2. Results

Looking times in seconds were averaged by familiarity condition for each infant. Log-normalized looking times were analyzed using linear-mixed effects regression models with *familiarity* (familiar vs. novel) as fixed factor and *participants* and *lexicalization* as crossed random factors, allowing for random adjustments of intercepts and slopes for within-group factors [34, 35]. Data points with residuals beyond 2.5 SD of the mean were removed and the model was refitted. p-values were calculated on the basis of model comparisons, using the anova()-function in R [34]. In other words, only when a model with a given main effect improved compared to a simpler model without that effect, the main effect was considered to be significant. Results showed a significant effect of *familiarity* (ß = 1.13, SE = 0.05, t = 2.3, $p < 0.05$), see left-hand bars in Figure 3. Participants fixated on average 1.1 seconds longer to novel test lists (9.3 sec) than to familiar ones (8.2 sec).

2.3. Discussion

Participants looked significantly longer to the novel than to the familiar word lists, suggesting that they were able to segment the trochaic part-words from the trisyllabic words that were used in the familiarization phase. German 10-month-olds can hence segment trochaic syllable sequences from fluent speech even if they are embedded in trisyllabic carrier words, and thus contain neither probabilistic nor acoustic cues to word onsets. Our findings replicate earlier studies on the metrical segmentation strategy in German and English [3-5]. Importantly, we found evidence for segmentation with familiarization and test stimuli that had comparatively small f0-excursions. This suggests that infants are able to segment strings from fluent speech even when exposed to adult-directed speech.

3. Experiment 2

Experiment 2 examined whether a misaligned pitch peak affects infants' segmentation of embedded trochees.

3.1. Methods

3.1.1. Participants

Another group of 19 infants took part in Experiment 2. They fulfilled the same criteria as the infants in Experiment 1. The data of 16 infants could be analyzed (9 male, 7 female, mean age = 38.7 weeks, SD = 1.18). There was no significant difference in age across experiments ($t(30) = 0.3$, $p > 0.7$).

3.1.2. Materials

The four test words were identical to Experiment 1. The same speaker as in in Experiment 1 recorded the 24 sentences again, this time with an early-peak accent on the target word (Fig. 2).

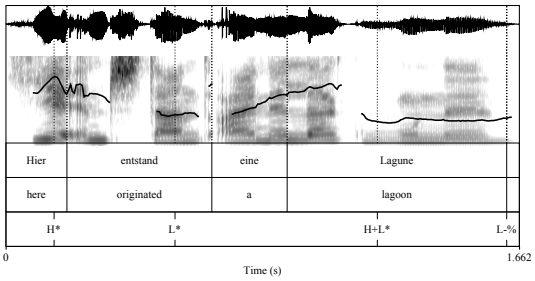

Figure 2: *Example pitch track of a target sentence in the early-peak condition (f0-range is shown between 100 and 300Hz).*

The target sentences were recorded until the productions did not differ from the recordings in the medial-peak condition for Experiment 1 in terms of f0-excursion of the pitch fall, total duration of the target word, the duration of the stressed syllable and the onset consonant of the stressed syllable (mean values are shown in Table 1). Also, the intonation conditions did not differ with respect to the spectral realization of the vowels in the first and second syllable (measured in terms of the Euclidian distance in the F1/F2 space between a particular vowel and the average over all 15 [ə]s in the target words, see (1)).

$$(1)\ \sqrt{(F1_{vowel} - F1_{[ə]})^2 + (F2_{vowel} - F2_{[ə]})^2}\ ).$$

Yet, since the target words were all naturally produced, there are some differences in the materials of the two experiments, mirroring the effects of early- and medial-peak accents described in [20].

3.1.3. Procedure

The procedure was the same as in Experiment 1.

3.2. Results

Looking times were analyzed in the same way as for Experiment 1. Results showed no effect of familiarity ($p > 0.8$), see right-hand graphs in Figure 3.

To statistically corroborate the differences across experiments, we calculated a single linear mixed effects regression model with *intonation condition* (early vs. medial) and *familiarity* as fixed factors and *participants* and *lexicalization* as crossed random factors. The results of this model showed no main effects, but a significant interaction between *intonation condition* and *familiarity* (ß = 0.16, SE = 0.08, t = 2.2, $p < 0.05$).

3.3. Discussion

Looking times did not differ significantly for familiar and unfamiliar disyllables in Experiment 2, in which high pitch was misaligned with the stressed syllable. This suggests that in this intonation condition infants were not able to segment the part-words starting with a stressed syllable. Taken together, the results of the two experiments indicate that trochees could only be successfully extracted from the speech stream when the pitch peak was aligned with the stressed syllable but not when the peak preceded the stressed syllable.

Table 1. *Acoustic realization of target words in the familiarization phase for both intonation conditions.*

Acoustic variable	medial-peak condition	early-peak condition	p-value (paired t-test, df =23)
F0-excursion of the pitch fall	9.3st	9.6st	n.s.
Duration of 1st, unstressed syllable	182ms	193ms	$p < 0.005$
Duration of 2nd, stressed syllable	253ms	256ms	n.s.
Duration of onset consonant of 2nd, stressed syllable	81.3ms	80.6ms	n.s.
Intensity in middle of initial vowel	67dB	66dB	n.s.
Intensity in middle of stressed vowel	71dB	64dB	$p < 0.001$
Euclidean distance of 1st vowel from [ə]	293.3Hz	307.8Hz	n.s.
Euclidean distance of 2nd vowel from [ə]	837.9Hz	737.7Hz	n.s.

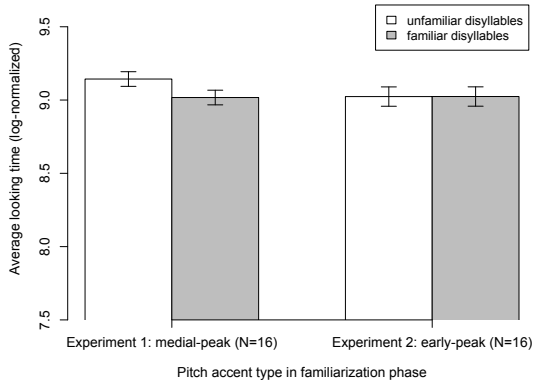

Figure 3: *Average looking time in the medial- and early-peak condition split by familiarity. Whiskers represent standard errors*

4. Discussion and Conclusion

The present study shows that German infants at 10 months of age are able to segment trochaic part-words from trisyllabic target words. However, this is only possible when the familiarization phase provides target words in which the pitch peak is aligned with the stressed syllable (medial-peak condition in Experiment 1) and not when the peak precedes the stressed syllable (early-peak condition in Experiment 2). We see four possible explanations for this finding. First, under the assumption that German 10-month-olds treat stressed syllables as preferred word onsets [36], stress perception appears to be partly linked to high pitch. When the stressed syllable carried a low tone, the segmentation of the trochaic part-words failed. This may be interpreted as an effect of cue strength, in analogy to findings showing that infants are able to distinguish different phrasings only when the prosodic phrase boundary is signaled by phrase-final lengthening and pitch movement, but not, when one of these cues is missing [37]. Second, recent research within the framework of the iambic/trochaic law [38, 39] showed that Italian infants at 7 months group high-low sequences as trochaic patterns while ignoring information on duration [28], suggesting that intonation may be a stronger cue to metrical stress than other stress cues. Third, high-pitched syllables may be likely word-onset markers per se, irrespective of their perceived metrical prominence. Fourth, our effects may not be related to the acoustic salience of pitch at all but may be explained in terms of frequency of occurrence. In infant-directed speech medial peaks are more frequent than early peaks [30]. Thus, infants' segmentation abilities displayed in the medial peak condition might correlate with the relative frequencies in the input.

To investigate the role of pitch on the perception of metrical stress more closely, we test infants' attention to the first two syllables of the target words, produced with a trochaic stress pattern (e.g., ['la:gu] for *Lagune*, ['ka:no] for *Kanone*). If high pitch is the most salient cue to metrical prominence, an effect of familiarity is expected only in the early-peak condition, but not in the medial-peak condition. Furthermore, we plan to use resynthesized stimuli to be able to focus on the role of f0-information in speech segmentation.

The Perception of Korean Boundary Tones by First and Second Language Speakers

Hae-Sung Jeon

School of Language, Literature and International Studies, University of Central Lancashire, UK

HJeon1@uclan.ac.uk

Abstract

This paper reports an experiment which investigated the perception of prosody in Korean or non-word utterances by native Korean speakers and English learners of Korean. Listeners rated the degrees of positivity and excitement of resynthesized utterances with different pitch ranges and durations. The results revealed no significant differences between the two groups of listeners. The variations in pitch range and duration had systematic effects on the ratings. However, the interactions between various factors suggest that the mapping between prosodic shapes and their paralinguistic meaning is not straightforward.

Index Terms: prosody, second language, emotion

1. Introduction

Intonation has linguistic and paralinguistic (e.g. emotional, attitudinal) functions which are important in social interactions [1]. There seems to be much cross-linguistic similarity in the paralinguistic (more specifically 'emotional') meaning of prosody; for example, a large pitch movement or an overall increase in the acoustic parameters is related to emotional arousal, e.g. [2]. However, cross-dialectal or -language differences in linguistic or paralinguistic uses of intonation are reported [e.g. 3, 4, 5]. Second language (L2) learners need to acquire the phonology of their target language intonation. Also, linguistic or paralinguistic meaning of prosody can be misinterpreted by speakers of foreign languages.

This study was motivated by English learners' impressionistic comments that Korean prosody often sounds like 'child-whining'. This is probably due to the frequent use of complex boundary tones and significant phrase-final lengthening. Jun [6] identifies nine Intonational Phrase (IP) boundary tones in Korean, and previous studies reported significant lengthening in the IP- or utterance-final syllable, i.e. the IP- or utterance-final syllable is longer than the medial syllable by a factor of 1.6-1.8 (see Ch. 2., [7] for a review). The previous studies mainly dealt with declarative sentences ending with a L or H tone; final-lengthening is likely to be even greater when there are multiple tones associated with the right edge of the phrase or utterance.

The aims of the study were to investigate: 1) whether emotional interpretation of prosody differs between native Korean speakers and English speakers learning Korean; 2) the potential effect of the lexical cue on the emotional interpretation of prosody; 3) the relationship between utterance-final lengthening or pitch range expansion and the emotional interpretation of prosody; and 4) whether different boundary tones are associated with different emotional interpretations.

2. Boundary tones in Korean

The nine tones in [6] include L%, H%, LH%, HL%, LHL%, HLH%, LHLH%, HLHL% and LHLHL% which are transcribed at the L(ow) and the H(igh) targets in the F0. These boundary tones are associated with the right edge, particularly the final one or two syllables, in the IP or utterance. Although [6] and [8] list the tone types and their use, they acknowledge that it is difficult to pinpoint the basic meaning of each boundary tone, since the same shape of pitch movement could signal different meanings depending on the context (e.g. [9]).

The descriptions of intonation in [6] and [8] (the transcription in [8] follows the British Framework) can be summarised as follows:

- L%: declaratives; neutral, formal, as-a-matter-of-fact, polite-apologetic
- H%: seeking information as in yes/no questions
- LH%: questions, continuation rises, explanatory endings in declaratives; annoyance, irritation, disbelief
- HL%: declaratives, wh-questions; kind, polite, apologetic
- LHL%: intensifying the meaning of HL%; persuasive, insisting, confirmative; annoyance, irritation
- LHLH%: intensifying some of the meaning of LH%, i.e. annoyance, irritation, disbelief
- HLHL%: intensifying the meaning of confirming and insisting on one's opinion; nagging, persuading
- LHLHL%: similar to LHL%, signalling more annoyance

That is, L% and H% are described as emotionally relatively neutral in a statement or a question respectively, and it is only HL% which may signal speakers' positive feelings in declaratives. Complex tones are associated with irritation or annoyance; similarly, [10] suggests that the tones with three or more targets do not have a distinct meaning of their own but they are used to intensify the meaning of the less complex tones, e.g. HLHL% intensifies the meaning of HL%.

In this experiment, eight boundary tones, L%, H%, LH%, HL%, LHL%, LHLH%, HLHL% and LHLHL%, were employed. These were chosen intentionally to balance the number of relatively simple tones (L%, H%, LH% and HL%) and complex tones (LHL%, LHLH%, HLHL% and LHLHL%). HLH% was excluded in the main experiment, since the stimuli with this tone sounded unnatural compared to the others. HLH% was used in the practice session preceding the main experiment, together with HLHLH% (see Section 3. 1. 2).

3. Experiment

3.1. Method

3.1.1. Materials

There were four types of trisyllabic stimuli, two Martian (non-word) utterances and two Korean utterances. For the Korean materials which were created first, the experimenter (a trained phonetician, female native Korean speaker) recorded two utterances, [migugɛ] ('in the USA' which can be either declarative or interrogative) and [hatsima] ('don't do it', imperative or interrogative) in the ten boundary tones (L%, H%, LH%, HL%, LHL%, LHLH%, HLHL% and LHLHL% for the main experiment; HLH% and HLHLH% for the practice sessions). The recording took place in a sound-attenuated booth in the Phonetics Laboratory, University of Cambridge (digital recording with a sampling rate of 44.1 kHz). Then all resynthesis was performed with [11] using the PSOLA method. The F0 contours of the recorded utterances were stylised to create source utterances for further resynthesis; the L and H targets were identified and the F0 between two adjacent targets was interpolated. The experimental materials were created by resynthesising F0 (PITCH, two levels; Natural, Expanded) and DURATION (three levels; Shortened, Neutral, Lengthened). For the Natural condition, no additional manipulation of F0 was done. To create the Expanded condition, the H peaks were increased by 2 ST; the only exception was with L% in which the valley was lowered by 2 ST. For the Lengthened duration condition, the utterance-final vowel was lengthened by 50%; for the Shortened condition, the vowel was shorted by 50%; the original duration was maintained in the Neutral condition.

The Martian stimuli ([sesapʰa], [samuda]) were created by concatenating syllables from Finnish utterances spoken by a female speaker. None of the syllables were adjacent to each other in the original utterances. After the concatenation, their pitch and duration properties were resynthesised to be identical to the Korean counterparts ([samuda] and [migugɛ], [sesapʰa] and [hatsima]). In Korean, phrase-initial [s, h] are often associated with H and [m] with L [6]. However, Korean listeners are insensitive to the violation in the tone-segment type association [12] and all stimuli sounded natural.

The paper-and-pencil method was used to collect listeners' responses. A two dimensional model of emotion with valence (i.e. the degree of positivity) and arousal (i.e. the degree of excitement) was employed, with answer sheets from the Self-Assessment Manikin (SAM) rating system [13]. This method is particularly useful for cross-cultural studies when the interpretation of emotional words can be culture-specific. Although there is a third dimension, dominance, it was not included since its reliability has been questioned and it was necessary to keep the experiment simple. The answer sheets had pictures representing five steps of valence (the continuum between smiling face and sad face) and five steps of arousal (the continuum along the excitement scale). Listeners could put a mark on a picture or between two pictures, and therefore a 9-step scale for each dimension was provided. High scores for valence and arousal indicate a high degree of happiness and excitement, respectively. Following the descriptions in [6], [8], and [10], it is expected that the complex tones will show lower positivity (valence) and higher excitement (arousal) than the simple tones, although HL% is likely to be positive with lower excitement.

3.1.2. Experimental procedure

Thirty eight participants without speech or hearing problems participated in the experiment (19 native Korean speakers at the Korea National University of Education, South Korea, age Mean = 21.68 years, SD = 2.75; 19 native British English speakers at the University of Central Lancashire, UK, age Mean = 20.68, SD = 1.59). English speakers were students in a Korean language class at beginner level who had been learning Korean for six months for 2 hours a week. Although their command of Korean was at a basic level, they could understand the experimental materials presented in Korean.

All participants in the same first language (L1) group were tested together. Participants sat in a quiet classroom and the stimuli were played on loudspeakers connected to a PC. Participants were told that they would hear a Martian speaking and their task was to guess the degree of positiveness/negativeness (valence) and the degree of excitement (arousal) from the speech. They were instructed to make full use of the nine-degree scale. They were informed that there would be Korean utterances only after the completion of the Martian part. The presentation order was: [samuda], [sesapʰa], [migugɛ] 'in the USA' and [hatsima] 'don't do it'. Within each stimulus type, the main experiment was preceded by a short practice session which allowed participants to familiarise themselves with the task. In the practice sessions, stimuli with HLH% and HLHLH% in two pitch conditions (Neutral, Expanded) with natural duration were played. Each stimulus was played three times and the presentation order was randomised. The experiment took approximately 35 minutes. In total, 192 utterances were played in the main experiment (4 STIMULUS TYPE × 8 TONE TYPE × 3 DURATION × 2 PITCH).

3.2. Results

3.2.1. Overall patterns

Figures 1-4 show the ratings for each TONE TYPE. Overall, there is little difference between the two L1 groups (as supported by the ANOVA results reported below), although the valence ratings seem slightly higher (more positive) in the English group. For valence, the ratings were relatively high (more positive) for the simple tones (L%, H%, LH%, HL%) than for the complex tones. The valence is particularly high for H%, which was probably interpreted as a yes-no question with a relatively neutral emotional state. As predicted, HL% has a high rating for valence; however, contrary to the description in Section 2, LH% also shows high valence. For arousal, the complex tones (LHL%, LHLH%, HLHL%, LHLHL%) were rated higher (more excited). Pitch range expansion (Figs 1 and 2) led to a higher degree of valence and arousal than the natural pitch contour, although the arousal rating seems less affected than valence rating. For duration (Figs 3 and 4), lengthening seems to be associated with lower valence and higher arousal.

A series of mixed ANOVAs were conducted for valence and arousal respectively, with a between-subject factor, L1 (Korean, English), and within-subject factors, STIMULUS TYPE (ST: [migugɛ], [hatsima], [samuda], [sesapʰa]), TONE TYPE (TT: L%, H%, LH%, HL%, LHL%, LHLH%, HLHL%, LHLHL%), DURATION (D: Neutral, Short, Long) and PITCH RANGE (P: Natural, Expanded) (Greenhouse-Geisser correction applied, α level adjusted to 0.01 after Bonferroni correction).

The L1 main effect was not significant as for either valence or arousal. For valence, complicated interactions involving ST were statistically significant together with the main effects of TT, P and D; significant effects were revealed with ST, TT, P, D, ST × TT, TT × P, ST × D, ST × T × D, and P × D. The mean rating was highest for [sesapʰa] (Martian, M = 4.76, SE = 0.14) and lowest for [hatsima] 'don't do it' (Korean, M = 4.1, SE = 0.12) ([migugɛ] M = 4.73, SE = 0.83; [samuda] M = 4.42, SE = 0.12). For arousal, again, the interaction effects involving ST were significant (ST: [migugɛ] M = 4.73, SE = 0.16; [hatsima] M = 4.87, SE = 0.14; [samuda] M = 4.78, SE = 0.14; [sesapʰa] M = 4.68, SE = 0.15). The statistically significant effects included TT, P, D, ST × TT, TT × P, ST × T × P, ST × D, TT × D, ST × TT × D, TT × P × D and ST × T × P × D. Due to the interactions involving ST, further analyses were carried out with the data split by ST ([migugɛ], [hatsima], [sesapʰa], [samuda]). The results of the further ANOVAs are summarised in Table 1. The table shows that there are few effects involving L1, whilst the effects of TT, P, D and TT × D tend to be significant across the STs. Figures 5 and 6 allow an examination of the TT × D interaction.

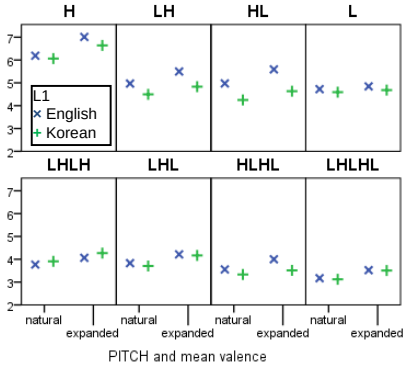

Figure 1: *Valance rating for PITCH. Panels in descending order for mean rating.*

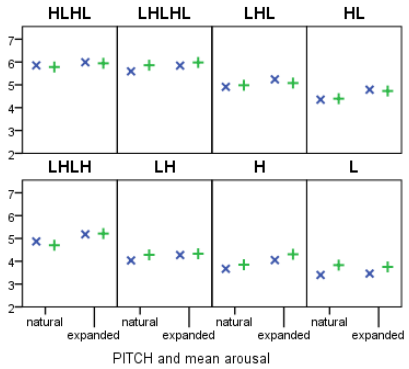

Figure 2: *Arousal rating for PITCH. Panels in descending order for mean rating.*

In Figure 5, [hatsima] ('don't do it') shows little variation across the DURATION conditions with relatively low valence ratings. The other Korean utterance, [migugɛ], shows patterns similar to the Martian utterances in general. Other notable points are: for H%, the valence rating is consistently high for all STs; and for HLHL%, the Korean materials show differences from the Martian materials in that little variation across the DURATION conditions is observed in the Korean materials.

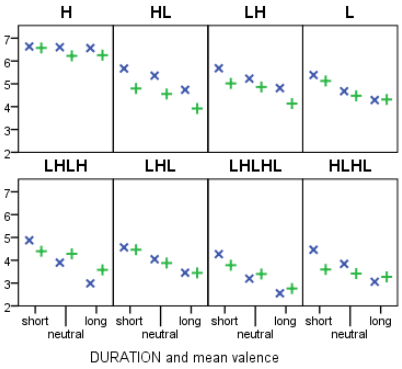

Figure 3: *Valence rating for DURATION. Panels in descending order for mean rating.*

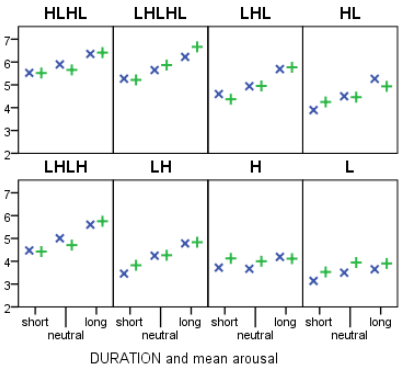

Figure 4: *Arousal rating for DURATION. Panels in descending order for mean rating.*

TT × D × L1	-	-	-	-	-	-	*	-
P × D	-	-	-	-	-	-	-	-
TT × P × D	-	-	-	-	-	*	**	-
P × D × L1	-	-	-	-	-	*	-	-
T × P × D × L1	-	-	-	-	-	-	-	-

Table 1. *ANOVA results (α level = 0.01), ST: K1 [migugɛ], K2 [hatsima], M1 [samuda], M2 [sesapʰa]. significance codes: ** p < 0.001, * p < 0.01, and - not significant*

In Figure 6, there seems to be a positive correlation between the degree of lengthening and the arousal rating, particularly for Martian, although there are exceptions such as the results for H% and LHL%. For Korean, although the two STs show similar patterns in general, listeners' response patterns differed notably between the two for L%, HL% and HLHL%.

4. Discussion

4.1. Effect of L1

The results show that the emotional interpretation of prosody did not differ between native Korean speakers and native English speakers. English speakers were leaners of Korean at beginner level with a very limited command of Korean and they had been attending the classes for 6 months.

Although the English speakers' valence ratings appeared generally higher than those of the Koreans, the between-L1-group difference did not reach statistical significance. The results seem to support the theory that there is a cross-culturally shared component in the paralinguistic interpretation of prosody related to the expansion of pitch range and durational variations (e.g. [2]). But the generally higher valence ratings by English speakers and the slightly different response patterns between the two groups in some cases (e.g. HLHL% in Fig 3) show that there may also be a language-specific part to be learned which deserves further investigation. Another possibility is that English learners were quick at acquiring the paralinguistic meaning of the Korean boundary tones. Although prosody at the sentence or discourse level is little discussed in the language classroom, students had been exposed to authentic Korean speech through TV shows, films, etc.

4.2. Effect of lexical cue

The fact that listeners' ratings of the Martian utterances did not show a random distribution implies that it is possible to interpret paralinguistic meaning only from prosody without any lexical cues. However, complicated interactions between the STIMULUS TYPE and the TONE TYPE can be seen in Figures 5 and 6, particularly for the Korean utterances, although details are not discussed in the present paper. For example, the Korean sentence whose basic meaning entails annoyance in the declarative, [hatsima] ('don't do it'), received the lowest valence score, and showed less variation in score compared to other types of stimulus. Therefore, the same prosody would signal different paralinguistic meaning depending on the lexical content of a given utterance. A strict and straightforward mapping between semantics and prosody must not be assumed.

4.3. Duration and pitch

For both emotional dimensions, pitch range expansion tended to be associated with intensification, i.e. a greater degree of positivity and excitement. Lengthening was associated with low valence (negativity) but high arousal (excitement).

4.4. Boundary tones

The results generally support the observations that, other things being equal, the complex boundary tones are likely to signal negative emotions and a high degree of arousal, such as irritation or annoyance. However, the effects of lexical cue and variations in duration and pitch span suggest that it would be counterproductive to assume a straightforward mapping between the type of boundary tone and its basic meaning, whether it is linguistic or paralinguistic. In addition, the pitch movement at the boundary and final lengthening would interact with more global characteristics of speech, such as overall pitch register and variations in speaking rate (e.g. [2]).

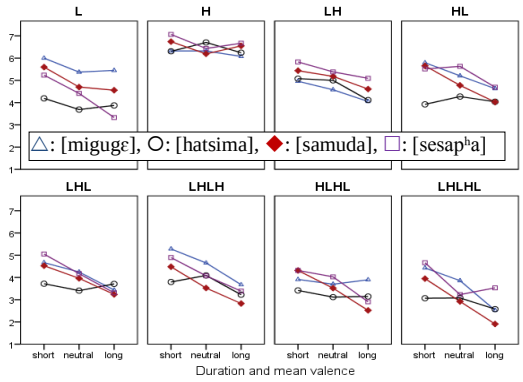

Figure 5: *Valence rating for DURATION. Each line represents a different Stimulus Type*

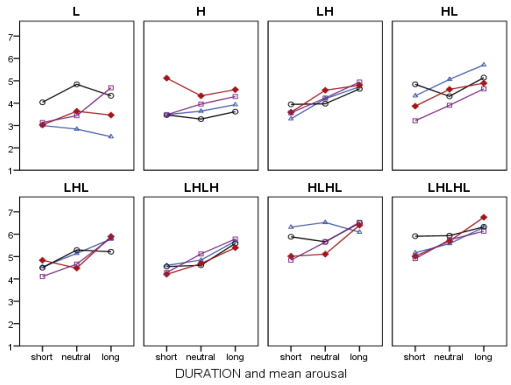

Figure 6: *Arousal rating for DURATION. Each line represents a different Stimulus Type*

5. Conclusions

The emotional interpretation of eight Korean boundary tones did not differ between the two listener groups (native Korean speakers vs. native English speakers learning Korean). The complex boundary tones tended to be perceived as more negative and excited than the simple tones. An increase in pitch span signalled higher positivity and excitement, whilst lengthening signalled higher negativity and excitement. However, the complicated interactions between tone type, utterance-final lengthening, and the lexical cue suggest that the mapping between the type of boundary tone and its paralinguistic meaning is not straightforward.

6. Acknowledgements

I would like to thank Prof. Hyunsong Chung for his help with the experiment in Korea and the members of the Phonetics Laboratory, University of Cambridge, for their help in recording. Thanks are also due to the students in the Beginner's Korean language class 2012-2013 at the University of Central Lancashire who willingly participated in the experiment.

Abstract

As part of a broader study of voice prosody in speech communication, this paper looks at intonation in turn-taking. It examines the distribution of pitch patterns and communicative types in the interpausal units (IPUs) preceding pause or gap silences extracted from a corpus of spontaneous speech of Irish English. IPUs preceding speaker change ('Gaps') and IPUs preceding silence where the same speaker continues talking ('Pauses') were selected in the course of automatic extraction of pause/gap silences in dyadic dialogue interactions. A listening test was conducted to establish 'human predictable' pause/gap data sets which were subsequently manually annotated in terms of pitch patterns and communicative types. Overall, the Gaps and Pauses subsets show differentiation in terms of both their communicative types and pitch tunes. Declaratives and Questions are mainly found in Gaps, whereas in Pauses we mainly find Hesitations and Incomplete Declaratives. Gaps are generally characterised by falling or rising pitch patterns, whereas in Pauses a large proportion of speech samples are realised with level pitch. Classification experiments reveal discrimination of pauses and gaps for both prosodic and functional annotation labels. Follow-up work aims to relate intonational characteristics of turn taking with voice quality and temporal dynamics, to provide a holistic view of the processes involved.

Index Terms: dialogue speech, pause, gap, intonation, communicative type

1. Introduction

This paper is part of a broader study of the interaction of intonation and voice source parameters in prosody at the Phonetics and Speech Lab, Trinity College Dublin. The present study complements parallel research exploring voice source [1], f_0 and temporal features (see, for example [2] on the role of prosodic features as well as [3] on f_0 range declination trends in turn-taking organisation). In this paper we describe intonational (pitch patterns) and functional (communicative types) annotation of the interpausal units (IPUs) preceding pause or gap silences extracted from a corpus of spontaneous speech of Irish English.

Robust prediction of turn-taking is crucial for dialogue systems. To date, prediction is largely based on the duration of pause or gap silent intervals, and on the speech interval immediately preceding them. The present detailed analysis of both functional and intonational characteristics of pre-silence chunks for a corpus of Irish English, aims to establish their linkage to turn-taking, and their potential for discriminating speaker changes vs. holds. It further aims to provide the intonational baseline with which we can later correlate voice source and temporal features.

The decision on whether and when we begin to speak in a conversation depends on numerous factors, e.g., lexical and syntactic [4], prosodic [5], vocal effort and audible respiratory cues [6], as well as gestural signals (e.g., head movement, gaze [7] etc.). The importance of lexical-syntactic features for turn-taking management has been emphasised since the early scientific work in this field [4, 8] as well as in more recently reported work [9]. In fact, the perceptual experiment carried out in [9] showed that artificially flattening intonation contours had less of an impact on the predictability of 'end-of-turn' compared to artificially removing the intelligibility of the utterance (by low-pass filtering).

Nonetheless, many researchers focus entirely on prosodic features, an approach which is somewhat justified given that previous studies (e.g., [2, 10, 11]) have found significant discriminative power of prosody-related features, and that this has direct relevance for prosody-only turn prediction (e.g., [12]) in dialogue systems. The role of prosodic patterns in turn-taking has been discussed in [5, 9, 13], see also references therein. For a number of languages (English, German, Dutch, Japanese and Mandarin Chinese), it has been reported that level pitch accents or flat contours at the end of an utterance are indicative of a pause (silent interval within the speech of the same speaker) while any other terminal contours such as rises and falls are indicative of a gap (silent interval between the speech of different speakers) [14-19].

However, the picture emerging is not always as clear cut. In some studies, similar intonation contours have been found for both turn-taking and turn-holding. In [20], 51% of the rising intonation patterns co-occurred with speaker changes while 49% of rises were associated with speaker holds. Furthermore, most studies report a high level of inter-speaker variability.

Other researchers have suggested that turn-taking is likely to be positively affected by the number of prosodic cues present [21, 22]. In addition to pitch contours, prosodic features reported as contributing to turn-management include voice quality (e.g., creaky voice [23]), speech rate and final lengthening [24]. At the level of prosody, we feel it is the dynamic patterning of the voice as a whole (the combination of intonation, voice quality and temporal aspects) that effectively cues speaker changes and holds. While the focus of this paper is on the formal and functional aspects of pitch contours as relating to turn-taking, the bigger picture is a longer term objective.

2. Speech data

2.1. Recordings

The speech data for annotation is taken from the Dublin Institute of Technology Emotional Speech Corpus [26] which consists of seven 10-minute dyadic (male-male and female-female, Irish English) interactions. Six dyadic interactions involving six male and six female speakers were selected from

the original corpus to ensure gender balance. The interactions were elicited in a shipwreck scenario game where participants were presented with 15 items and were given 10 minutes to jointly rank them in order of usefulness for their survival. Recordings were made with participants in separate booths using a professional Neumann microphone connected to an Apple Mac-based Digidesign Pro-Tools Mbox2 recording system. The audio signal was recorded using Pro-Tools software as two separate audio streams and digitised at 96 kHz/24 Bit. Audio was then downsampled to 16 kHz/8 Bit.

2.2. Extraction of the IPUs preceding pause and gap silent intervals

Automatic identification of pauses and gaps was carried out on the speech data using an approach similar to that described in [27]. Binary voice activity detection (VAD) using the VAD algorithm proposed in [28] was carried out on both speaker channels for each dyadic interaction. The threshold for silence interval duration was set to 200 ms to avoid false detection of pauses for speech events like plosives. Silent intervals below this threshold were bridged. Fig. 1 illustrates schematically the output of the VAD process. Overall, 460 gaps and 410 pauses were identified automatically.

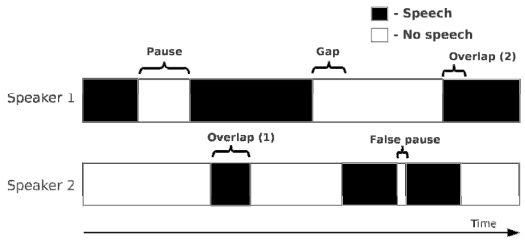

Figure 1. *Schematic representation of a dialogue interaction illustrating pauses, gaps and overlaps. The 'false pause' indicates a silence which is below the threshold (here set to 200 ms).*

As one of our goals is to establish whether and to what extent prosodic characteristics of the speech-chunks immediately preceding pause or gap silent intervals allow automatic prediction of turn-taking in human-machine interaction, we (in a previous study [2]) selected a subset of data where pauses and gaps were clearly predictable by human listeners. A listening test was conducted in which the IPUs (n=870) preceding automatically identified pause and gap silent intervals were presented individually to three raters in random order. Each rater was to indicate, on a 5-point scale, whether in their opinion a pause (same speaker continues) or a gap (speaker change) follows. The rating scale was defined as follows: (1) Very certain the CURRENT speaker continues, (2) Quite certain the CURRENT speaker continues, (3) Don't know! (4) Quite certain the OTHER speaker begins, (5) Very certain the OTHER speaker begins. The raters had an option to indicate that there was an error in the automatic extraction of stimuli, e.g., due to premature truncation of utterances. In total, 6% of the stimuli were marked as an error by the raters. The inter-rater agreement was measured using Krippendorff's α [29]. Analysis revealed fairly high inter-rater agreement (α = 0.74). Only the samples which all three raters identified as being followed by a pause or a gap were retained to form the ultimate 'human predictable' dataset. In total, 302 IPUs preceding gaps and 288 IPUs preceding pauses were retained, which amounts to 70% of the original dataset. This 'human predictable' data set was subsequently manually annotated to explore the distribution of pitch patterns and communicative types of the utterance in the speech-chunks immediately preceding pause and gap silent intervals. For simplicity, we will refer to the IPUs immediately followed by gaps (speaker change) as 'Gaps' and the IPUs immediately followed by pauses (same speaker continues talking) as 'Pauses'. The terms 'Pauses' and 'Gaps' are therefore used to refer to speech-chunks immediately before silent intervals rather than the silent intervals themselves. The data samples in the 'human predictable' data set represent male and female speakers in fairly equal proportion, however the amount of data selected from individual speakers is not necessarily balanced.

3. Annotation of the selected data

The selected Gaps and Pauses data were annotated separately. The aim of this preliminary annotation was to explore the patterns in the distribution of communicative types and pitch tunes in these two data subsets. The manual annotations involved auditory analyses of the extracted data and were initially done by one annotator. Pitch patterns were independently analysed by a second annotator, and the two annotators agreed on 71% of the data. The labels used for the annotation are described in the sections below.

COMMUNICATIVE TYPES: A variety of approaches exist in dialogue speech annotations, e.g., [30-32] and annotation schemes usually include both communicative types of the utterance and functional analyses of dialogue acts. Here we report only the results of communicative type annotation. Since the IPUs were obtained by automatic extraction using a predefined minimum pause threshold, they may contain more than one sentence. An example of such IPU would be *I still like the life jacket. You could drown, like.* In such cases, only the sentence closest to the pause/gap silence (in this example, *You could drown, like*) was analysed. The following communicative type labels were used:

Declarative - grammatically complete/well-formed declaratives, e.g., *Yeah, but I mean we've already lost so many points.*

Incomplete Declarative - grammatically incomplete fragmented declaratives, e.g., *…starting from the most important. Seven…er… a knife.*

Yes/No-Q - grammatically complete/well-formed Yes/No questions, e.g., *Does that mean we picked right every other one?*

WH-Q - grammatically complete/well-formed WH-questions, e.g., *What's the knife gonna do?*

Incomplete Q - grammatically incomplete questions, e.g., *I'd say radio next? …the survival guide and the knife, does it?*

Alt Q - alternative questions, e.g., *Did you say compass or map again ?*

Dec Q - declarative question, e.g., *Yep, flare sounds good to me, so flare's for four?*

Tag Q - tag questions, e.g., *We did do, didn't we?*

Exclamation - [largely based on the intonation with which these utterances were produced], e.g., *Binoculars! Binoculars! Oh god! We did so well!*

Imperative - e.g., *So, do you wanna rank them? Mac, please!*

Hesitation - filled pauses, e.g., *erm, ahm, er,* repetitions and self-corrections, or markedly prolonged words, e.g., *And th[e:]n….*

Backchannel - short acknowledgements such as *sure, yeah, uhum, yep.*

Other labels included '**?**' for uncertain cases and '**n/a**' for the IPUs with no propositional content (e.g., only laughter).

PITCH PATTERNS: In the annotation of pitch patterns in Pauses and Gaps subsets we described the nuclear tunes (each containing the intonation-phrase final pitch accent and its associated boundary tone) using the IViE system [33]. The following tune labels were used:

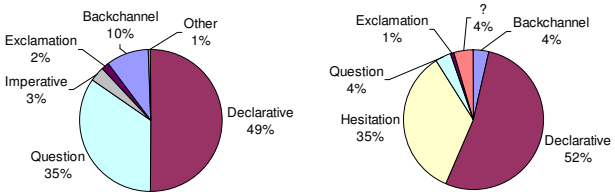
H*+L 0%	fall
H*+L H%	fall-rise
L*+H 0%	low rise
H* H%	high rise
L*+H L%	rise-fall
!H* 0%	downstep (e.g., in item lists)
H* 0%	level (no change/movement of pitch)**.**

Analysis of the pitch patterns reported below was conducted on the final intonational phrase in the sentence closest to the pause/gap silent intervals rather than on the whole IPU.

4. Results and discussion

4.1. The distribution of communicative types

The distribution of communicative types in the Gaps and Pauses subsets is shown in Figure 2. Due to space limitations, the different types of questions are pooled into one category and the same is done for well-formed and incomplete declaratives.



(a) Gaps (b) Pauses

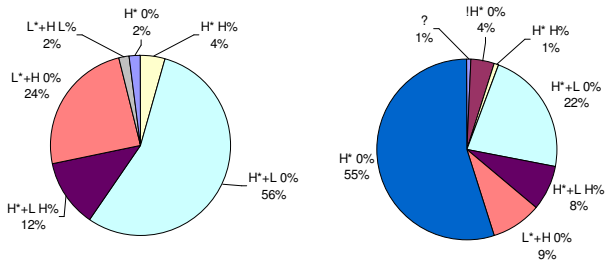
Figure 2. *The distribution of communicative types in the Gaps (a) and Pauses (b) subsets.*

As is clear from Figure 2, almost half of the IPUs in the Gaps subset are Declaratives (of which about a quarter are incomplete). Questions comprise 35% of the Gaps subset, with Incomplete Questions and Yes/No Questions making up the majority of the question types. Among the remaining communicative types, Backchannels are the most frequent (10%), with only 5% of IPUs classified as either Imperatives or Exclamations.

Similar to Gaps, a large part of the Pauses subset is made up by Declaratives (55%). However, the majority of the declaratives in Pauses are incomplete (74% of all declaratives). A fairly large proportion of the IPUs from the Pauses subset are classified as hesitations, a communicative type that does not appear in the Gaps set. The proportion of questions in the Pauses subset is 4% which is substantially lower than in the Gaps set. The proportion of Backchannels is also lower in Pauses, only 4%. The least common communicative type occurring in Pauses is Exclamation (1%). In 4% of the cases the communicative types of the extracted IPUs in the Pauses set were ambiguous and were not annotated.

4.2. The distribution of pitch patterns

The overall distribution of pitch patterns in the Gaps and Pauses data subsets is given in Figure 3 (the data is pooled across all communicative types). More than half of the intonation phrases (IPs) preceding gaps (56%) are realised with a falling pitch, H*+L 0%. Rises L*+H 0% (24%) and fall-rises H*+L H% (12%) are the next most frequent tune types in Gaps. The most frequently occurring pitch pattern in the IPs preceding pauses is level tone H* 0% (55%). The second most common tune type here is fall H*+L 0%, although its proportion in the Pauses subset is substantially lower (22%) than in the Gaps subset (56%). Generally speaking, Gaps are characterised overwhelmingly by pitch movement, whereas Pauses have level tone in the majority of cases. These findings corroborate what has been described in the literature, e.g., [5, 17]. A more detailed analysis of pitch patterns that characterise communicative types most frequently found in Gaps and Pauses is given in the sections below (although not all are illustrated due to space limitations).



(a) Gaps (b) Pauses

Figure 3. *The distribution of pitch patterns in the Gaps (a) and Pauses (b) subsets (across all communicative types).*

A closer look at the pitch tunes in different communicative types found in the Gaps set reveals similar pattern for Declaratives, Incomplete Declaratives, WH Questions and Backchannels: in about 60-70% of the cases, the H*+L 0% tune (fall) is used, followed by L*+H 0% (low rise) as the next most frequent tune type. The proportion of rises is the lowest in Declaratives (10%), it is higher in Incomplete Declaratives and WH questions (17%), and is the highest in Backchannels (24%). In Incomplete Questions, the pitch is predominantly rising (only 12% of samples here have falling pitch). In Yes/No Questions, both falling and rising pitch pattern is used, with a slight preference for rises (about 54% in total).

The distribution of pitch patterns in the Pauses subset is examined mainly for Declaratives and Hesitations which comprise 98% of this data set. Overall, Hesitations are realised predominantly with level pitch (H* 0%), with only a small proportion (14%) having a falling pitch. Incomplete Declaratives are realised with either level or rising pitch (in 80% of the cases), with falls occurring in only 20% of the cases. The proportion of falling pitch is higher in [well-formed] Declaratives (41%), however, in the majority of cases the pitch is either rising or stays level.

4.2.1. *The distribution of tunes: a case of Declaratives*

We compare here in some detail the distribution of tunes in declaratives which make up about 50% of communicative types in each of these two data sets (see Figure 2). The tunes found in Declaratives and Incomplete Declaratives are shown in Figure 4 separately for Gaps (left panel, a) and Pauses (right panel, b). Note that the proportion of incomplete and complete declaratives is reversed in the Pauses set compared to the Gaps set: well formed/complete declaratives constitute 76% of all declaratives in Gaps, but their proportion is reduced to only 26% in Pauses.

There is relatively little difference in the distribution of tunes between complete and incomplete declaratives in the Gaps set. A striking feature of incomplete declaratives in Pauses is a high number H* 0% (level) tunes.

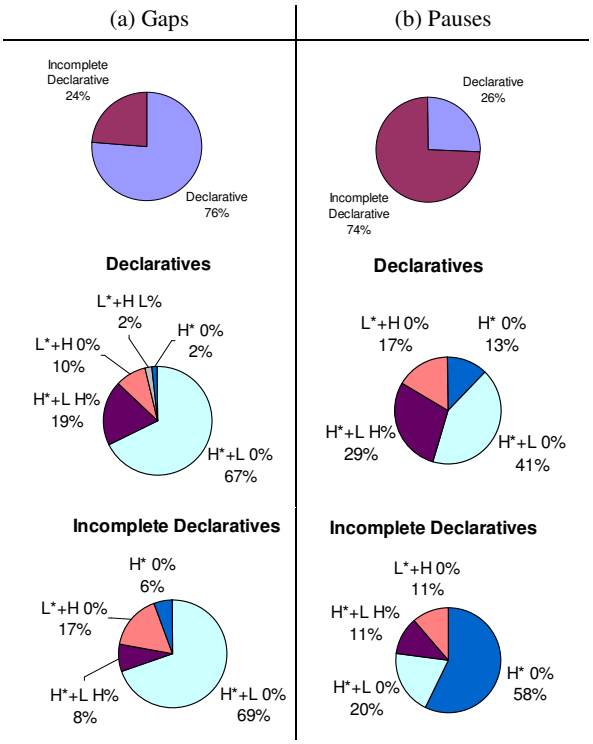


Figure 4. *The distribution of pitch patterns in Declaratives and Incomplete declaratives in the Gaps (a) and Pauses (b) subsets.*

4.3. Intonation and communicative type annotation in classification experiments

In order to investigate the combined discriminative power of functional and intonation labels (derived from speech-chunks immediately preceding pause and gap silent intervals) for differentiating pauses and gaps we carry out a speaker independent classification experiment. For this we utilise a support vector machine (SVM) based classifier with a radial basis function kernel. As input features we use the manually obtained annotation labels, separated into multiple binary features (e.g., the feature for H*+L 0% would have all samples with this annotation label assigned the value of 1 and all others 0). Classification is carried out using a leave-one-speaker-out procedure where the data of a single speaker is held out solely for testing, with the remainder of the data used for training the SVM classifier. This procedure is repeated for all 12 speakers with classification error (%) retained each time.

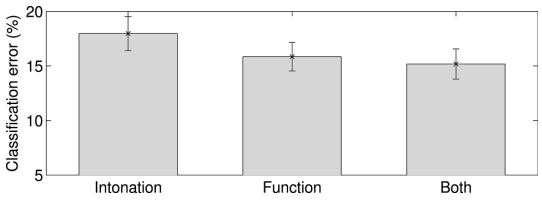

Figure 5. *The results of the support vector machine-based classification experiment. Shown are mean and standard error values.*

The results of this analysis are summarised in Figure 5 and are shown for intonation and functional label features separately and combined. The overall classification error is strikingly low for what is an extremely difficult discrimination problem. Using intonation labels alone one achieves a mean classification error of around 18%. The result provides a strong motivation to produce robust automatic characterisation of such intonation patterns.

Functional labels provide an even lower mean classification error (~15%). This also suggests that detection of functional labels would be beneficial for the prediction of pauses and gaps. However, deriving such information automatically would require the combination of an automatic speech recognition component as well as a subsequent text analytics procedure both of which are liable to introduce significant errors. The combination of the intonation and functional labels brings only a minor reduction in mean classification error and suggests a high level of redundancy between the two classes of labels.

5. Conclusions

In this paper we examined the distribution of communicative functions and pitch tunes in the 'human predictable' Pauses and Gaps subsets selected from the Dublin Institute of Technology Emotional Speech corpus. Overall, Gaps and Pauses subsets show differentiation both in terms of their communicative types and pitch patterns. Declaratives and Questions are commonly found in Gaps, whereas in Pauses it is mainly Hesitations and Incomplete declaratives. Gaps are mainly characterised by falling or rising pitch patterns (pitch movement), whereas in Pauses a large proportion of speech samples are realised with level pitch. Results suggest that including information on pitch patterns in the speech-chunks immediately preceding pause and gap silent intervals appears to enhance automatic discrimination of pauses and gaps. Our future work will exploit the findings of this study to examine other prosodic dimensions, voice quality and temporal characteristics, and their interaction with intonational features.

Realization of Narrow Focus in Hong Kong English declaratives—a Pilot Study

Holly Sze Ho Fung, Peggy Pik Ki Mok

Department of Linguistics and Modern Languages, The Chinese University of Hong Kong
hollyfung@cuhk.edu.hk, peggymok@cuhk.edu.hk

Abstract

Narrow focus, i.e., focus on one word, is realized differently in native English and Cantonese. While it is signaled primarily by on-focus F0 changes such as F0 range expansion in English, it is marked essentially by lengthening of duration in Cantonese. Another difference is the pitch of the post-focus elements. While native English demonstrates post-focus F0 compression, Cantonese shows no significant post-focus pitch change. To investigate how narrow focus is realized in Hong Kong English (HKE), an emergent variety of English spoken by native speakers of Cantonese in Hong Kong, a controlled production experiment was conducted with 8 HKE speakers. Results showed that while the HKE speakers did realize foci with significant on-focus F0 range expansion, they exhibited no post-focus compression.

Index Terms: Hong Kong English, focus, post-focus compression

1. Introduction

Focus, as defined by Crystal [1], is information that is "at the center of their [speakers'] communicative interest". It can be classified as narrow or broad depending on its scope. First introduced by Ladd [2], the term "narrow focus" was defined as focus on "a particular constituent or a small set of constituents", and "broad focus" as that on an entire utterance, or any constituent larger than that of a narrow focus [3].

Early acoustic studies of focus realization in English found that narrow focus is signaled by multiple prosodic cues including raised F0 peak and mean F0, expanded F0 range, lengthened duration and increased intensity [4][5]. More recent studies, while confirming these findings, suggested a broader temporal domain of focus prosody. Instead of being solely signaled by on-focus cues, narrow focus was also found to be marked by post-focus F0 lowering and F0 range suppression, which were also referred to as post-focus compression (PFC) [6][7].

Similar to native English, narrow focus was found to be signaled by multiple cues in Cantonese including an increase in duration and intensity [8][9][10] as well as pre-focal pause insertion [8]. As for whether F0 is an acoustic correlate of Cantonese narrow focus, opinions diverged. On the one hand, Man [6] found significant F0 range expansion that was local to the focused syllable. Gu and Lee [8] found both F0 heightening and expansion in a broader scope spanning from the syllable before the sentence-medial focus to the end of the utterance, with the heightening effect more prominent on high-tone target. On the other hand, in a more recent study by Wu and Xu [10], which is more reliable regarding the larger sample size and the method of focus elicitation used, no significant on-focus or post-focus F0 variations was found.

While pitch is surely an important acoustic correlate of focus in native English, its role in focus-marking is in doubt in Cantonese. Regarding such difference, a legitimate question to ask about Hong Kong English (HKE), a non-native variety of English that emerges from the interaction between the two languages, is whether pitch is an acoustic correlate of focus in it. To answer this question, and to assess the role of transfer from Cantonese to HKE, a controlled production experiment was conducted.

2. Method

2.1. Materials

10 English and 6 Cantonese declarative sentences were used in the experiment. All the 10 English sentences (see Table 1) contain the carrier frame __ *gave a* __ *to* __, in which the empty slots were filled by different keywords. The keywords, all sonorants for continuous F0 contours, were controlled for their number of syllables and stress pattern. Half of them were monosyllabic and the other half disyllabic, all stressed on the first syllable.

Table 1. *List of English sentences (keywords underlined)*

Monosyllabic keywords	
1.	Ann gave a mole to Wayne.
2.	Lee gave a ring to Wong.
3.	May gave a ram to Lynn.
4.	Ron gave a wheel to Ray.
5.	We gave a yam to Nell.
Disyllabic keywords	
6.	Alan gave a lemon to Laura.
7.	Larry gave a melon to Luna.
8.	Mary gave a lolly to Annie.
9.	Mummy gave a warning to Molly.
10.	Willy gave a ruler to Emma.

Similarly, the Cantonese sentences also contained keywords in the sentence-initial, medial and final positions. In addition, to examine the effects of focus on different lexical tones (see Table 2), each of the sentences contained keywords of one of the six lexical tones in Cantonese. Table 3 is a list of the Cantonese sentences used.

Table 2. *Summary of Cantonese lexical tones*

	T1	T2	T3	T4	T5	T6
Tone shape	high level	high rising	mid level	low falling	low rising	low level
Tone code	55	25	33	21	23	22

Table 3. *List of Cantonese sentences (keywords underlined)*

Tones	Sentence in *Jyutping* with English translation
T1	*maau1 mi1 maai5 zo2 jyun1 joeng1 sung3 bei2 wu1 aa1*. 貓咪買咗鴛鴦送畀烏鴉。 'The cat bought tea coffee for the raven.'
T2	*waa2 min2 gin3 dou2 jyun2 jyun2 sik1 jin2 jiu2 neoi2*. 畫面見到婉婉飾演妖女。 'It is shown on the screen that Jyunjyun plays a banshee.'
T3	*aa3 jin3 keoi5 ge3 ngoi3 hou3 ling6 jan4 jim3 wu3*. 阿燕佢嘅愛好令人厭惡。 'Aajin's interest is disturbing.'
T4	*maa4 maa4 fan1 fu3 jung4 jan4 heoi3 maai5 jau4 jim4*. 嫲嫲吩咐傭人去買油鹽。 'Granny asked the maid to buy oil and salt.'
T5	*lou5 ng5 deoi5 doi6 mei5 neoi5 fei1 soeng4 jau5 lai5*. 老五對待美女非常有禮。 'Loung is very polite to beauties.'
T6	*wu6 wai6 ting3 cung4 ming6 ling6 zeon1 hang4 jam6 mou6*. 護衛聽從命令進行任務。 'The guard went for a mission on command.'

To compare the F0 and duration of focused and non-focused keywords, each of these 16 sentences were produced in four conditions, one with neutral focus (i.e., no focus) and the other three with focus in the sentence-initial, medial and final positions. To elicit these focus conditions, two sets of stimuli were prepared. The set for eliciting neutral focus contained the 16 sentences in plain font, and the other for eliciting narrow focus consisted of 48 sentences (16 sentences x 3 focus positions) with focused keywords in different positions highlighted in bold.

The reason for choosing this method over the more commonly adopted one using prompt questions was that although the latter was successful with native speakers of English in some previous studies [4][5][12][13][6][7], it did not work for the HKE speakers in our earlier pilot test. The pilot speakers (whose data are not presented here) did not realize any focus on the pieces of information being asked for, i.e., their answers were the same as those with neutral focus. Moreover, the speakers also reported that they found the prompt questions rather irritating. As a result, in this study, narrow focus was elicited instead by highlighting the keywords in bold and directly asking the speakers to emphasize them, conveying them as the most important information in the sentences, but no instruction was given to them on how they should emphasize them phonetically. Thus, the focus realized by them was particularly emphatic.

In addition, 12 practice sentences similar to the focus-eliciting stimuli were prepared to familiarize the speakers with producing narrow focus in various positions.

2.2. Speakers

3 male and 5 female native Cantonese speakers aged between 22 and 24, who acquired English as their second language, were recruited as subjects. All were undergraduates of local universities who received pre-tertiary education at local primary and secondary schools, where they were exposed to native English for 3 to 6 years from their native-speaking English teachers. Two of them have been to an English-speaking country before, one to the US for four days and the other to Australia and New Zealand for two weeks and six months respectively. As for their oral English proficiency, five attained grade C in the oral paper of Use of English (UE) in the Hong Kong Advanced Level Examination (HKALE). Among the rest, two received grade D and one grade E.

In addition to the HKE speakers, two native American English (AmE)-speaking exchange students from New York, aged 20 and 21, were recruited as control subjects. Only two control subjects were used because the patterns of narrow focus in English were already well established in the literature.

2.3. Procedures

The experiment for the HKE speakers was divided into two sessions. In the first session, the speakers were shown and recorded reading the sentences without focus. They were reminded to avoid placing emphasis on particular words in order to elicit neutral focus successfully. The sentences were arranged randomly into three blocks, the first with the Cantonese test sentences and the other two with the English sentences with monosyllabic and disyllabic keywords respectively. Each sentence was recorded twice.

The second part of the experiment began with a training session, in which the speakers were asked to read the practice sentences with foci in different sentence positions after they were told that the words in bold were the most important pieces of information to be emphasized. After becoming familiar with the procedure, they were then recorded reading the Cantonese and English test sentences with narrow foci, which were arranged into two and four blocks respectively. Each block was read in two repetitions.

As for the American English speakers, the experiment procedures were basically the same, except that they were not asked to read the Cantonese stimuli.

2.4. Data Analysis

Extraction of utterances and labeling of individual syllables of the keywords were done using Praat. For the disyllabic keywords in English with the CVCV(C) structure, syllables were segmented between the first vowel and the second consonant, i.e., CV/CV(C). For example, the keyword *lemon* was segmented as "le/mon", rather than "lem/on".

Each labeled syllable was then measured for its: 1) F0 range and 2) mean F0, which were calculated from F0 values obtained from 10 equal-distant points along the pitch contour of the target syllable.

3. Results

3.1.1. American English

Figures 1 and 2 show the mean F0 ranges and mean F0s of the disyllabic keywords produced by the two AmE speakers. (Given the admittedly small sample size, no statistical analysis was performed on the AmE data.) The abbreviation *s* stands for the stressed syllable and *us* for the unstressed syllable of a keyword. As expected, on-focus F0 range expansion occurred regardless of sentence position in AmE. On-focus F0 heightening, although insubstantial, was also observed consistently in all sentence positions. The data also confirmed the presence of post-focus compression (PFC) in native English, since both mean F0s and F0 ranges of keywords were found to decrease in the post-focus condition. (Data of the

monosyllabic keywords, which show the same pitch pattern as the disyllabic ones, are excluded here owing to page limit. Details of them are available upon request.)

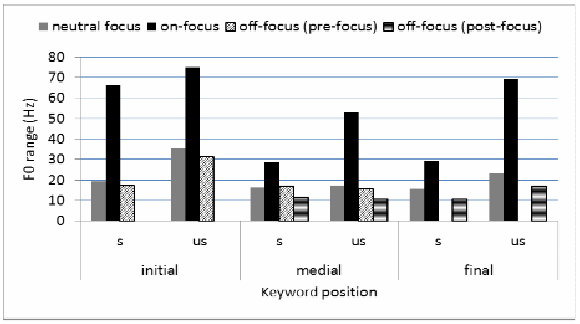

Figure 1: *Mean F0 ranges of English disyllabic keywords produced by AmE speakers*

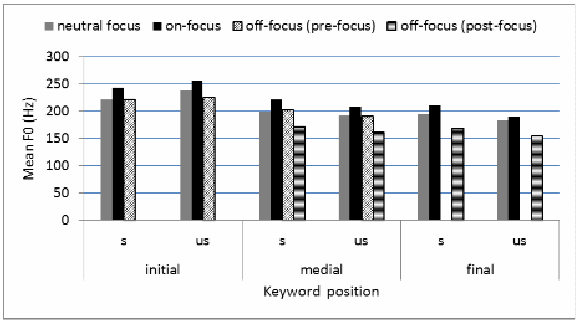

Figure 2: *Mean F0s of English disyllabic keywords produced by AmE speakers*

3.1.2. Cantonese

Among the data of all the six lexical tones collected, only those of T1, T3 and T6 were analyzed. The reason was that since we wanted to compare the Cantonese and the HKE data to evaluate the influence from the former on the latter (if any), and that HKE was suggested to be tonal with H, M and L tones [14][15][16], analysis of the three level tones in Cantonese would best suit the purpose.

One general observation of the Cantonese data is that there some insubstantial increases in mean F0 of the keywords in focus. As an example, Figure 3 shows the mean F0 of the T1 keywords produced by the female speakers. In a two-way ANOVA test, focus (neutral versus on-focus) was found to have significant main effect on mean F0 of the keywords of T3 (p=0.018) and T6 (p=0.011) produced by the female speakers, and those of T1 (p=0.027) and T6 (p=0.021) produced by the male speakers. The results suggest that the speakers demonstrated some on-focus F0 heightening, but not in a consistent manner.

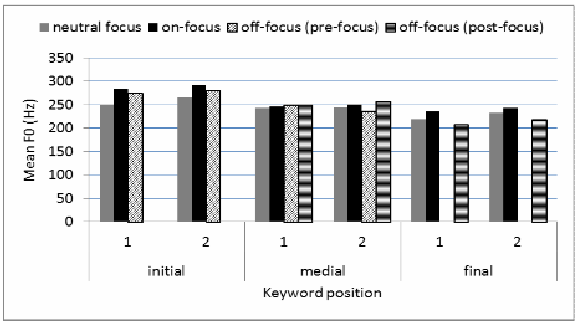

Figure 3: *Mean F0s of T1 keywords produced by female HKE speakers (abbreviations: 1—1st syllable; 2—2nd syllable of the disyllabic target)*

As for F0 range, on-focus expansion of it was found only sporadically. In addition to the result that focus had a significant main effect on F0 range only in the T1 foci produced by the female speakers (p=0.04), no strong evidence was found to support that F0 range expansion is a cue to Cantonese focus.

Neither was PFC found in the data. No significant effect of focus was found on either mean F0 or F0 range of post-focus keywords. The result confirmed Wu and Xu's [10] suggestion that PFC does not exist in Cantonese.

3.1.3. HKE

The mean F0 range of the English monosyllabic foci produced by the HKE speakers displayed in Figure 4 and Figure 5 show that for both gender groups, a keyword was produced with remarkably larger F0 range in the on-focus condition than in the neutral focus condition regardless of its position. In a two-way ANOVA assessing two main effects, namely focus (neutral focus and on-focus) and word position (initial, medial and final), focus was found to have significant effect on F0 range in monosyllabic keywords produced by both male (p=0.009) and female speakers (p=0.025), suggesting that the expansion of F0 range was focus-induced.

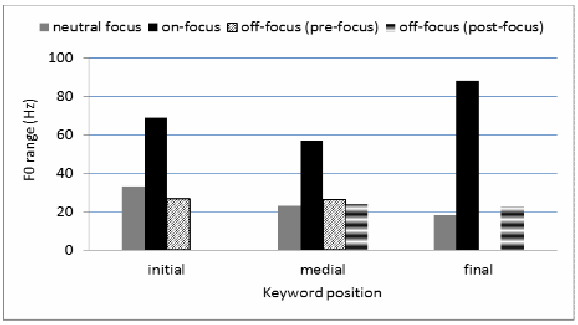

Figure 4: *Mean F0s of English monosyllabic keywords produced by male HKE speakers*

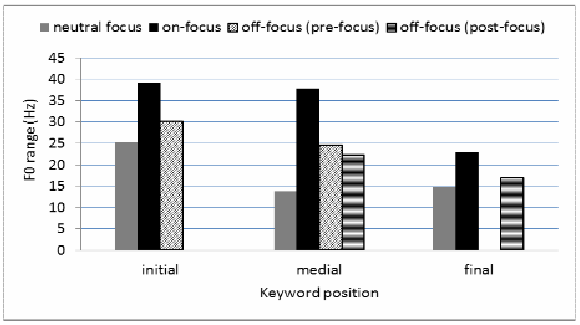

Figure 5: *Mean F0s of English monosyllabic keywords produced by female HKE speakers*

Substantial on-focus F0 range expansion was also found in the disyllabic foci, as shown below in Figure 6 and 7. In a three-way ANOVA analysis with the focus (neutral focus and on-focus), lexical stress (stressed and unstressed) and word position (initial, medial and final) as the factors, focus was again found to have a significant effect on F0 range of keywords produced by both male (p=0.009) and female (p=0.000) speakers. The results suggest that F0 range expansion is a cue to narrow focus in HKE.

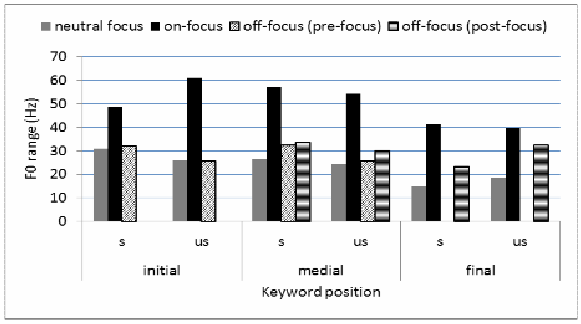

Figure 6: *Mean F0 ranges of English disyllabic keywords produced by male HKE speakers*

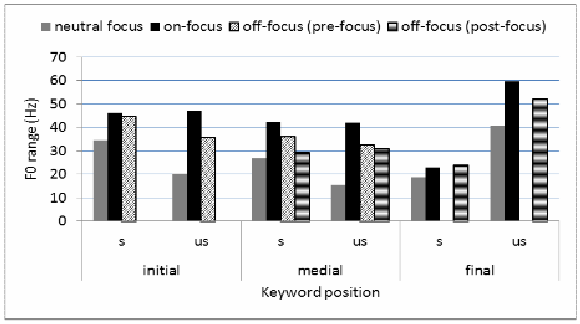

Figure 7: *Mean F0 ranges of English disyllabic keywords produced by female HKE speakers*

On the other hand, only random mean F0 heightening was found. A two-way ANOVA test found that focus had no significant effect on the rises. Therefore, mean F0 is unlikely an on-focus cue to narrow focus in HKE. The random increases of F0 might simply be the by-product of F0 range expansion.

Same as in Cantonese, no post-focus F0 lowering or F0 range suppression was found in HKE. In fact, noticeable expansion of F0 range was found in off-focus keywords, both pre-focus and post-focus ones, as shown above in Figures 6 and 7, meaning that the speakers actually had global F0 range expansion for the entire utterance with narrow focus. One possible reason for the finding is that since the subjects were asked explicitly to produce focus, they might as a result have spoken with a more exaggerated register which rendered more rise and fall in the pitch contour. Further tests are needed to verify this.

4. Discussion

Based on the results in Section 3.1.3, pitch does seem to be an acoustic correlate to narrow focus in HKE. Despite the absence of consistent on-focus F0 heightening and PFC, substantial on-focus F0 range expansion in both monosyllabic and disyllabic keywords located in all sentence positions suggests that HKE speakers do signal narrow focus with manipulation of pitch.

The absence of PFC in the HKE data can be attributed to cross-linguistic influence from Cantonese. As mentioned in Section 3.1.3, none of the HKE speakers exhibited PFC in Cantonese. If there were no influence from Cantonese, we would expect them to demonstrate PFC in their English like the two AmE speakers did. In fact, the absence of PFC in HKE is not at all surprising. Similar to HKE, English spoken by native speakers of Taiwan Mandarin, another language without the post-focal feature, was found not to have it either [17]. Its absence in HKE may provide an additional piece of evidence for that PFC in L2 English is susceptible to transfer from L1.

On the other hand, the presence of on-focus F0 range expansion in HKE cannot be explained simply by transfer from Cantonese. As mentioned, on-focus F0 range expansion occurred only sporadically and insubstantially in Cantonese. This seems to suggest that HKE speakers have two distinct intonation patterns for focus marking in Cantonese and HKE.

Based on our preliminary findings, focus intonation of HKE was found to be a "hybrid" of that of its parent languages: native English and Cantonese. While it shows on-focus F0 range expansion like native English does, it exhibits no PFC, similar to Cantonese. In other words, pitch is an acoustic correlate of narrow focus in HKE, although it is limited to the local domain, i.e., the word in focus. It has to be emphasized, though, that the conclusions are drawn from results obtained by a non-canonical way of focus elicitation involving the use of text in bold and explicit instruction to produce a focus instead of the more common one using prompt questions. Further studies employing various focus elicitation methods are needed to corroborate the results here.

Altering speech synthesis prosody through real time natural gestural control

David Abelman[1]*, Robert A.J. Clark*[2]

[1]School of Informatics, University of Edinburgh, Edinburgh, UK
[2]The Centre for Speech Technology Research, University of Edinburgh, Edinburgh, UK
robert@cstr.ed.ac.uk

Abstract

This paper investigates the usage of natural gestural controls to alter synthesised speech prosody in real time (for example, recognising a one-handed beat as a cue to emphasise a certain word in a synthesised sentence). A user's gestures are recognised using a Microsoft Kinect® sensor, and synthesised speech prosody is altered through a series of hand-crafted rules running through a modified HTS engine (pHTS, as described in [1]). Two sets of preliminary experiments are carried out. Firstly, it is shown that users can control the device to a moderate level of accuracy, though this is projected to improve further as the system is refined. Secondly, it is shown that the prosody of the altered output is significantly preferred to that of the baseline pHTS synthesis. Future work is recommended to focus on learning gestural and prosodic rules from data, and in using an updated version of the underlying pHTS engine.

The reader is encouraged to watch a short video demonstration of the work at ***http://tinyurl.com/gesture-prosody***.

Index Terms: speech prosody, pHTS, real time control, gesture

1. Introduction

Despite the significant advances made in speech technology in recent years, producing speech that is both **expressive** and **reactive** to a user's input or local environment is a significant challenge facing speech synthesis today, and one on which there has been limited research to date [1] [2].

This work aims to construct a system to alter speech prosody in a limited number of ways, based on a user's real time gestural input. Future extended systems of this type would have various potential applications. A primary use may be in text-to-speech communication aids of those with vocal disorders. More natural expression and prosody may be 'conducted' by the user in real-time, either through a set of standard natural gestures, or through a set of custom-designed gestures for those with physical disabilities (for example, eyebrow or finger movements).

Additionally, technology developed as part of this system may be incorporated within potential 'sign-language synthesis' systems of the future [3] [4]. In addition to synthesising words based on sign-language hand movements, the manner in which the gestures are performed may indicate to the system a certain expressive or emphatic style in which to synthesise the speech.

Finally, other potential applications may exist within the entertainment industry. For example, the technology may be adapted for use within synthesised singing voices, or perhaps within future 'instrument-voice hybrids' that people may wish to control through body gestures. Ultimately, any situation in which it would be useful to improve expressiveness of a voice-like synthesis in real-time would benefit from the research that this work undertakes.

2. Background

This project is built upon a modified HTS engine 'pHTS' (*performative* HTS) [1]. This technology allows HTS synthesis to be reactive to its environment - whether adapting to surrounding conditions, or being controlled expressively by a user (as is the case here). In order to make the system reactive, the phonetic context required in calculating the synthesis parameters is reduced from that of the whole sentence to a much smaller window. This change requires two main modifications. Firstly, the context used in training the model is reduced to just the current and surrounding phonemes, and the current and previous syllable. Secondly, during synthesis, the generation of parameters occurs on a sliding window of two labels.

A variety of potential applications for pHTS have been outlined and developed by the group. These include *HandSketch*, a pen-based musical instrument prototype [5], speech synthesis based on face-tracking [6], and accent interpolation through an interactive map application [7]. Meanwhile, non-pHTS examples of hand-controlled prosodic modification include [8].

Finally, [2] incorporates skeleton tracking (using Microsoft Kinect) into the pHTS system to create a reactive speech synthesiser, in which pitch and duration are controlled by the vertical position of both hands. It is found that meaningful expressiveness is difficult to simulate when pitch and duration modulations are controlled in this particular way. It is this work that this project intends to build on, incorporating gesture recognition and more constrained prosodic modification rules.

3. Design

3.1. Preliminary decisions

A number of preliminary decisions were made to constrain the scope of the project. Future iterations of the work should revisit these in order to extend the system's abilities. Decisions included:

- Limiting the system's prosodic vocabulary to contrastive emphasis, general emphasis, yes/no questions and wh-questions only
- Realisation of prosodic shifts through manual parameter shifts on a single speech database, as opposed to switching between multiple recorded databases for different effects without explicitly shifting speech parameters
- Alteration of pitch and duration only, as the two primary parametric drivers of prosody (i.e. volume, spectral energy, pause models etc. are left untouched)

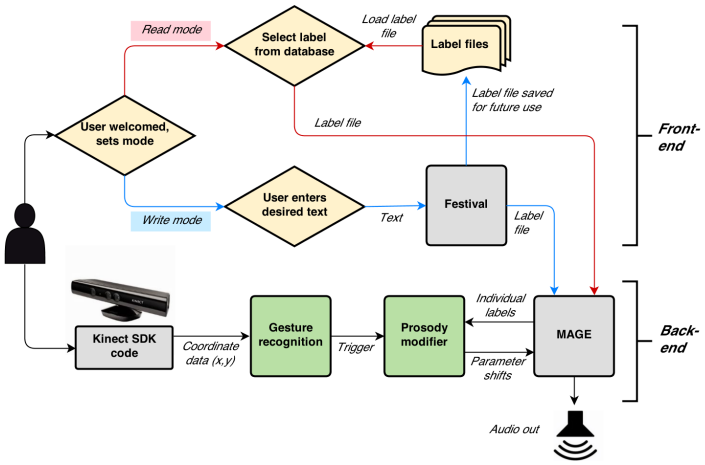

Figure 1: *System setup.*

- Magnitudes of pitch/duration shifts are manually encoded, as opposed to being learnt through data
- Gesture recognition implemented in a rule-based fashion, as opposed to being learnt through data
- Limiting the system's gesture recognition to one handed beats (contrastive and general emphasis, different hand for each), head tilts (yes/no questions and wh-questions, different side for each)
- Constricting emphasis to content words (not function words) and to stressed syllables within these words only. Future iterations may use a more flexible or intelligent natural language model to bias the prosodic effects towards the most likely syllables given the semantic meaning of the text, and the user's timing

A number of small-scale tests were carried out in order to optimise values for parameter shift magnitudes, and gesture tracking rules. Details may be found in [9]. The final set of rules implemented in terms of skeletal coordinates and pHTS parameter shifts are laid out in Section 3.3.4 of [9], with an illustrative example (contrastive emphasis) shown in this paper in Section 3.3.

3.2. System setup

A schematic for the system set up is laid out in Figure 1. The system has two modes, **read** and **write**. Both modes create a temporary label file which the backend loads into MAGE. **Write** mode passes the user's textual input (currently entered using a keyboard) to **Festival** Speech Synthesis System v2.1[1] in order to create the label file, whereas **read** mode allows the user to select a label file previously created by this process. The format of the label file required by the system is that outlined within [10].

The backend is built in C++ on top of MAGE and the work already carried out as part of [2]. OpenFrameworks[2] is used as the graphical and audio framework. The main application loop repeatedly calls an 'update' function (15 times per second), in which pre-existing **Kinect SDK code** tracks *x* and *y* coordinate data for the user's skeleton.

[1] http://www.cstr.ed.ac.uk/projects/festival/download.html
[2] http://www.openframeworks.cc/

The skeletal coordinate data are used within the **gesture recognition** stage. A simple set of if-else rules act as triggers for initiating prosodic effects, as described in [9]. Once some gesture has been recognised, the **prosody modifier** must allocate the prosodic effect to a specific syllabic unit (or set of syllabic units). Prosodic adjustments are carried out using a set of if-else rules, as also described in [9].

The parameter shifts are sent to the **MAGE** engine, and are used to shift parameter trajectories as appropriate via the pHTS engine. This functionality pre-exists within the MAGE platform code.

In addition to the resulting audio output, the application provides a visual representation of the user's skeleton as part of the application interface. Flashing text and graphical meters indicate to the user when a gesture has been recognised, and how the pitch and duration of the synthesis is being shifted.

3.3. Contrastive emphasis example

This section briefly outlines the set of rules implemented to enable the system to add *contrastive emphasis* to a synthesised sentence. Similar sets of rules exist for *general emphasis*, *yes/no questions* and *wh-questions*, and can be found in [9].

Gestural rules: As the Kinect recognises the left hand moving above the left hip, a 'contrastive window' of ∼0.5 seconds (8 frames) is triggered. (Note that due to latency issues it has not been possible to fine control the placement of this window for any hand movements above the hip, though this would be desirable in an improved system).

Prosodic rules: A pitch accent is applied if a content word's stressed syllable falls within this 0.5 second window. The pitch accent consists of a raised pitch (28%) and a reduction in speed (-10%). Following this, the remainder of the sentence is lowered in pitch (-14%) and increased in speed (14%). The final syllable of the sentence is raised in pitch (10%) to counter the default falling accent provided by pHTS.

4. Experiment 1 - Generation test

Two experiments have been carried out, the first being a generation test to investigate the accuracy to which users can control the system.

4.1. Experimental setup

In total, 12 native English speakers were tested using the system. Each user was asked to add some form of emphasis to 31 different synthesised sentences through gestural control, with each sentence being repeated eight times consecutively. Each sentence contains one or two gestures, leading to a total of 264 gestures that have been performed and tracked for each user, taking around 50 minutes in total.

A script was placed within the user's view. For each sentence the user was told which word to emphasise, and with what action (normally contrastive emphasis, as this is the most obvious to the ear). The author was able to track each attempt as being correct, early / late (missing the intended syllable but not emphasising an unintended syllable) or very early / very late (emphasising an unintended syllable). Immediately after each attempt and prior to the next, the subject was told by the author if they had gestured correctly, early or late (although it was often already clear to the user without prompting). This feedback is justified, as we would expect a fully-developed system to pro-

vide the user with some kind of explicit feedback on where their attempted emphasis fell.

The sentences are split into five primary sections. These sections are presented to each subject in the same order (avoiding learning bias over the session), but sentences within each section are presented in different orders according to various Latin Squares. Full sentence lists may be found in the original work's appendix [9].

4.2. Experimental results

A selection of findings are presented here. Two-tailed binomial tests are used to mark 95% confidence intervals in tables. The mean of the binomial distribution is set to the proportion of correct emphases out of all attempts. Chi-squared tests are used to calculate p-values for significance when confidence intervals overlap.

Spread of false positive and negative gesture timings: Considering just the *first attempt* across all sentence types in the 50 minute experiment, correct emphasis is applied 50% of the time. The user emphasises *no* word 30% of the time (gesturing only slightly too late or early), and the *wrong* word 20% of the time. These results are shown in Table 1. Note that when *all eight attempts* are considered, the application of correct emphasis improves from 50% to 65% (as users improve with practice on each sentence).

Table 1: *Spread of emphasis gesture timings (1st attempt only)*

Emphasis	% of time
Very early (wrong emphasis)	$7 \pm 3\%$
Early (no emphasis)	$4 \pm 2\%$
Correct emphasis	$50 \pm 6\%$
Late (no emphasis)	$26 \pm 5\%$
Very late (wrong emphasis)	$12 \pm 4\%$

Improvement over session: Users were requested to add emphasis onto individual words within a sentence at the start of the experiment, and onto individual words in sentences of similar rhythm after 25 and 45 minutes of practice. Results show that users do improve between 0 and 25 minutes ($p<0.01$), though not significantly between 25 and 45 minutes, suggesting that accuracy levels plateau with reasonably little experience. These results are shown in Table 2.

Table 2: *Accuracy improvement over the session*

Time since experiment start	Avg. accuracy (8 attempts)
0 minutes	$52 \pm 7\%$
25 minutes	$64 \pm 7\%$
45 minutes	$67 \pm 7\%$

Other results: Other results found include the following:

- A user emphasising *two words per sentence* will on average obtain a lower accuracy rate for the second word, in comparison to emphasising that same word *alone* in a sentence, if the words are in close enough proximity.
- Users have a significantly lower accuracy rate emphasising *words at the start and end of sentences*. Emphasising a word at the beginning of a sentence may be expected to be more challenging, as the user can be caught off-guard. There is less clear reason for words at the ends of sentences to be harder to emphasise - this may be due to a quirk of the sentences chosen within this experiment (for example, the 'rhythm' with which the synthesiser recites them).
- A user *speaking the text out loud* at the same time as gesticulating to control the synthesiser does not find his/her accuracy altered significantly, on average. It had been hypothesised that gestures may be performed more naturally at the correct moments if the user was speaking out loud whilst gesticulating. However, given this result, this wouldn't be a technique that is recommended to users in any future system.
- The *naturalness* (or unnaturalness) of the word to be emphasised does not affect a user's accuracy rate significantly.

5. Experiment 2 - Listening test

A listening test has been carried out to investigate the extent (if any) by which the output is perceived to be more natural, or have a different meaning, relative to baseline pHTS. Null hypotheses assumes a listener chooses an option from the forced choice test with equal probability - i.e. the options are equivalent. Two-tailed binomial tests are used to calculate p-values, and 95% confidence intervals are shown in tables.

5.1. Experimental setup

In total, 33 subjects were recruited for a listening test, lasting 20-30 minutes depending on the subject, under controlled conditions. All subjects identified themselves as being native English speakers, and received £6 in compensation. Each user was presented with 92 sentences split across 7 sections, and asked to select one of two options in a forced-choice test. This choice involved selecting either a preferred audio clip or a preferred textual option, depending on the question. Similarly to the generation test, sections were presented in a consistent order, but questions and options within each section were appropriately randomised. Once again, a full list of test sentences may be found in the original work's appendix [9].

5.2. Experimental results

A selection of findings regarding **contrastive emphasis** are presented here.

Perceived naturalness of contrastive emphasis: A question narrated by the author and pairs of synthesised responses were played to listeners. The sentences were of a defined form - see [9] for details. One of the responses would be a neutral pHTS synthesis, the other would have a word emphasised using the reactive synthesis system. This emphasis may be appropriate (correct word emphasised) or inappropriate (incorrect word emphasised). The participant must choose which of the two responses seems more natural. To illustrate, the user was hypothesised to prefer the 'appropriately' emphasised (first) response in this case:

'Did Jess have trout for her breakfast yesterday?'

1. *'No, Jess had **SALMON** for her breakfast yesterday.'*
2. *'No, Jess had salmon for her breakfast yesterday.'*

whereas the user was hypothesised to prefer the neutral pHTS baseline (second) response where an 'inappropriately' emphasised response was presented:

'Did Jess have trout for her breakfast yesterday?'

1. *'No, Jess had salmon for her **BREAKFAST** yesterday.'*
2. *'No, Jess had salmon for her breakfast yesterday.'*

Indeed, it has been found that listeners significantly prefer contrastive emphasis over neutral prosody when the emphasis is delivered on the appropriate word, and significantly prefer the neutral prosody over contrastive emphasis when the emphasis is delivered on an inappropriate word ($p<0.01$). Both of these results are as hypothesised, and are shown in Table 3.

Table 3: *Contrastive emphasis - naturalness*

Listener preference:	Emphasised	Neutral
Appropriately emph'd synthesis	**86 ± 4%**	14 ± 4%
Inappropriately emph'd synthesis	22 ± 7%	**78 ± 7%**

Effect on semantic interpretation of sentence by contrastive emphasis: Two textual options were presented to participants in writing, along with a single synthesised audio response. For example, a pair of textual options used was:

1. *The black dog was lying on the mat*
2. *The white mouse was lying on the mat*

with the single synthesised audio response being:

*'No, the **WHITE** dog was lying on the mat.'*

Since the emphasis is on *'WHITE'*, we would expect the listener to select the first of the two textual statements as the more appropriate, given the response. (If the emphasis had been on *'DOG'* we would have expected the user to choose the second textual option). Indeed it was found that these expected choices were made the majority of the time: the position of the synthesised emphasis significantly changes the user's semantic interpretation of the response ($p<0.01$). Results are shown in Table 4.

Table 4: *Contrastive emphasis - semantics*

Emphasis perceived to be on:	1st word	2nd word
When neutral synthesis	32 ± 7%	**67 ± 7%**
When 1st word emph'd in synthesis	**94 ± 6%**	5 ± 6%
When 2nd word emph'd in synthesis	8 ± 5%	**92 ± 5%**

Other results: Other results found include the following:

- As described above, within a defined sentence structure, appropriate contrastive emphasis is considered more natural than neutral synthesis. However, a separate section of the listening test showed that appropriate contrastive emphasis placed on the *final* syllable of a sentence is *not* perceived to be more natural by listeners. The hypothesised reason is that a final syllable emphasised contrastively needs to rise *and* fall in pitch within the same syllable. However, contrastive emphasis built into the current system only raises the emphasised syllable, resulting in an unnatural effect. This issue should be addressed in any future iterations of the work.
- Although contrastive emphasis was set as described in Section 3.3 using a 28% pitch rise on the emphasised syllable for most of the listening test, alternative values for the magnitude of the pitch rise were evaluated against one another within a short section of the test. A rise of roughly 20% was found to be optimal according to listeners' choices. Future iterations of the system may tweak parameters through tests such as these to optimise perceived naturalness.
- The experiment also evaluated listeners' perceptions of interrogative prosody, in addition to contrastive emphasis as outlined here. The reader may consult the original work for details [9].

6. Discussion

This work presented does suggest that it is possible to improve prosody of speech synthesis in real time through gestural controls. Users can control the emphasis with some accuracy, and listeners overwhelmingly prefer correctly emphasised sentences over baseline pHTS. It should be noted however that no analysis of the benefit of a correct emphasis versus the cost of an incorrect emphasis (from the listener's point of view) has been carried out within this work.

Future work should enable the user to control the system with a much superior accuracy rate to that obtained here. The largest obstacle to accurate control within this iteration of the work was relatively poor latency, caused by audio buffering. Future iterations of the work will use MAGE 2.0 [11] rather than MAGE 1.0, which the current system is based on. This will improve audio buffering times, meaning that the system has the potential to react to more granular gesture timings. For example, rather than triggering a window for potential emphasis as a user raises their wrist above their hip, the system may apply emphasis within an instant of recognising that the user's hand has reached the apex of an emphatic 'beat' trajectory. This should improve accuracy rates significantly. Additionally this would allow prosody to be affected *before* the user reaches this apex if required, for example by decreasing the speed of a syllable immediately preceding a contrastively emphasised syllable.

Future iterations of the system should implement machine learning based techniques for gestural recognition, as opposed to the current rule-based setup. This will result in a more flexible system going forward, in which new gestures can be recorded more easily, added or modified by a user, and customised to those with accessibility requirements. Similarly, learning prosodic parameter shifts through data (as opposed to the hard-coded rules currently used) will allow the system to scale more easily to a larger repertoire of available prosodic effects. A final modification that may improve the system's accuracy would be to incorporate a discourse model to aid prediction of where the user intends to apply emphases and similar prosodic effects. Even if the user's timing is slightly out, the system may then intelligently factor in prior probabilities of words most likely to be emphasised given the discourse context.

In summary, the work presented is in its early stages, but improvements such as these will lead to a novel and natural method of altering speech synthesis prosody in real time.

Body size projection by voice quality in emotional speech—Evidence from Mandarin Chinese

Xiaoluan Liu, Yi Xu

Department of Speech, Hearing and Phonetic Sciences, University College London, UK
xiaoluan.liu.12@ucl.ac.uk, yi.xu@ucl.ac.uk

Abstract

This study attempts to extend the line of research on using body size projection theory to account for emotional speech. It is predicted by the theory that anger is expressed by projecting a large body size with low pitch, rough voice and long vocal tract; happiness is expressed by projecting a small body size with high pitch, breathy voice and short vocal tract. Ten native speakers of Mandarin with drama training background recorded sentences in happy, angry, disgust and neutral emotions. We used multiple measurements to assess voice quality, formant dispersion (as an indicator of vocal tract length) and pitch. The results show clear support for the body size projection theory in voice quality, with anger and disgust associated with pressed and rough voice while happiness with breathy voice. But the results of formant dispersion and pitch demonstrate no clear directions. While the study is the first to show clear speech production support for the body size projection theory with voice quality data, the equivocal results of formant and pitch call for improvement in the method of emotion elicitation in the laboratory.

Index terms: emotional speech, body size projection theory, Mandarin Chinese

1. Introduction

Speech is one of the most important means of expressing emotions. While there have been many studies on the acoustic characteristics of emotional speech, the findings have generally been mixed [12]. One particular line of research, based on the body size projection theory, however, has taken a rather different theoretic approach to emotional speech. Originally proposed by Morton [8] for explaining animal calls, and later extended by Ohala [11] to human speech, the key idea is that vocal emotional expressions are a mechanism evolved under a selection pressure to influence the behaviour of other individuals in social interactions. For example, an angry expression is to project a large body size to scare off the opponents in case of confrontation; a happy expression is to project a small body size to attract the listener. Recently, this idea has seen support from a series of perception research in which the speech stimuli are synthetically manipulated in terms of pitch, vocal tract length and voice quality to simulate body size projection [3, 17, 18]. It is shown that listeners hear speech with synthetic parameters that project a large body size both as being spoken by a large person and as expressing anger. And they hear speech that projects a small body size as spoken by a small person and expressing happiness and friendliness [10, 17, 18].

In Xu et al. [17] an extension to the body size projection principle is proposed to incorporate additional "bio-informational dimensions" that may also serve to influence listener behaviour. These include dynamicity, audibility and association. One of these dimensions, namely, dynamicity, has been tested and shown to be relevant to the perception of a number of emotions [17, 18]. So far, however, there has not been systematic testing of either size projection or any of the other bio-informational dimensions in production studies. Thus, despite the demonstrated listener sensitivity to some of them, it is not yet known whether and how consistently speakers use any of them in the production of emotional speech. Also, the bio-informational dimensions have been tested on anger, happiness, sadness and fear [17], but not yet on disgust, which is also considered as one of the basic emotions [4].

Identifying acoustic properties that are clearly emotion-relevant from production data has not been easy, however, partly because it is generally difficult to elicit genuine emotions in the laboratory, even from trained actors and actresses. Recently, however, an emotion portrayal method has been developed for inducing emotions, and it is argued that the method can induce reliable and natural emotions in laboratory conditions because it reflects people's daily strategy to control and display emotions [12,13].

The present paper reports the results of a production study to test the bio-informational dimensions of emotion, using the emotion portrayal as the induction method, and Mandarin Chinese as the target language. Three emotional expressions are examined—anger, disgust and happiness, with the aim to find out whether the predictions of the theory can be confirmed in speech production, and how effective emotion portrayal is as a method of emotion induction in the laboratory.

2. Methodology

The basic design of the study is to have native speakers of Mandarin produce sentences with anger, disgust, happiness and neutral emotion using emotion portrayal as the induction method.

The stimuli, as shown in Table 1, consist of four Mandarin sentences with the target words *mao* and *men* imbedded in sentence-medial and sentence-final positions. The selection of *men* and *mao* is for the ease of phonetic segmentation while minimizing consonantal perturbation of F_0. To test for interaction between tone and emotion, we assigned the key word *mao* with four lexical tones: High tone *mao1* for sentence 1, rising tone *mao2* for sentence 2, low tone *mao3*

for sentence 3 and falling tone *mao4* for sentence 4. The syllable *men* following *mao* is assigned with tone 5 (neutral tone) for semantic/pragmatic naturalness of the sentences constructed. Note that *xiaomaomen* in the sentences is a compound word with three syllables, denoting the name of a brand and their album, although *mao* and *men* when used separately have their own independent meanings.

Table 1. Stimuli of the experiment. The number in each syllable represents the lexical tone: 1 for H (High tone), 2 for R (Rising tone), 3 for L (Low tone), 4 for F (Falling tone), and 5 for N (Neutral tone).

xiao3 little	*mao1* cat	*men5* particle	*yue4dui4 fa1xing2 le5*	*xiao3* little	*mao1* cat	*men5* particle
	mao2 fur				*mao2* fur	
	mao3 mortise		band release particle		*mao3* mortise	
	mao4 hat				*mao4* hat	
The band *Xiaomaomen* has released the album *Xiaomaomen*.						

Ten native Mandarin speakers with drama training background were recruited as subjects. They reported no speech or hearing problems. Emotion portrayal method was used to induce emotion, i.e., having subjects imagine themselves being in an emotional state as vividly as possible when saying each sentence [12, 13]. The recording was conducted in a sound-controlled booth. All the sentences were repeated 3 times by 10 subjects in anger, disgust, happiness and neutral emotion, resulting in 4 (*mao1/2/3/4*) * 4 (emotions) *10 (subjects) *3 (repetitions) = 480 sentences.

A customized version of Prosody Pro [16], running under Praat [1], was used to extract and analyse F0 contours, voice quality and formant dispersion (as indicator of vocal tract length [5]). Segmental boundaries were labelled by hands with visual inspection and listening validation. Given the difficulty in assessing voice quality, we obtained multiple measurements used in previous studies as follows:

H_1-H_2*, H_1-A_1*, and H_1-A_3* (H_1 and H_2 refer to the amplitude of the first and second harmonics of voiced segments; A_1 and A_3 refer to the amplitude of the first and third formants. The * symbol indicates that the measurements are estimates based on frequency bands without literally tracking harmonics and formants.);

Centre of spectral gravity—A measure for how high the frequencies in a spectrum are on average [1];

Energy of voiced segments below 500Hz and 1000Hz [14];

Hammarberg index—Maximum energy difference between the range of 0-2000 Hz and the range of 2000Hz to 5000Hz in the voiced section of the speech under examination [7];

Skewness—A measure for how much the shape of the spectrum below the centre of gravity is different from the shape above the mean frequency [1].

The above five measurements are indicators of spectral slope which is directly related to voice quality [6].

Jitter—Mean absolute difference between consecutive periods, divided by the mean period [6];

Shimmer—Mean absolute difference between the amplitudes of consecutive periods, divided by the mean amplitude [6];

Harmonicity—Harmonics-to-noise ratio measuring "the extent of acoustic periodicity expressed in dB" [6].

The above three measurements are indicators of voice roughness. Each of them indicates in one way or another the amount of aperiodicity in the voice.

Formant dispersion—Mean frequency differences between adjacent formants, which is an indicator of vocal tract length [5, 11].

The perception test by Xu et al. [18] shows that anger is associated with smaller formant dispersion than happiness. Therefore, this is a vocal dimension worth examination as well in this study.

F0 values were measured in semitones to reduce the bias towards higher pitch range over lower pitch range.

3. Results

The measurements used in statistical analyses were taken from the target syllables *mao* and *men* (both sentence medial and final across the four emotions). A series of three-way repeated measures ANOVAs were performed on the measurements of voice quality, formant dispersion and F0 of these syllables. The independent variables were emotion (anger, disgust, happiness and neutral), tone of *mao* (high, rising, low and falling), and sentence position (medial and final). A series of post-hoc Tukey HSD tests were also conducted to examine which pair of the emotions was significantly different.

The ANOVA results on tone, sentence positions and the interaction between tone, sentence positions and emotion are non-significant (hence not displayed), suggesting that tone and sentence position of the target syllable (*mao* and *men*) do not affect the acoustic characteristics of the emotional speech. In contrast, emotion is found to affect all features except formant dispersion (Table 2a-2b).

Table 2a. Means and *p* values of ANOVAs for H_1-H_2*, H_1-A_1*, H_1-A_3*, centre of gravity (COG), formant dispersion (FD), jitter (JI), shimmer (SH) and harmonicity (HA) of the four types of emotional speech (A=anger, D=disgust, H=happiness, N=neutral).

	H1-H2*	H1-A1*	H1-A3*	COG	JI	SH	HA
A	-3.1	-3.9	21.9	882.7	0.06	0.22	8.9
D	-2.6	-3.8	22.8	876.6	0.05	0.21	9.11
H	-0.1	-1.8	26.1	811.6	0.05	0.2	10.24
N	-0.3	0.7	31.1	608.4	0.04	0.19	11.58
p	<.05	<.05	<.05	<.05	<.05	<.05	<.05
F	3.84	3.92	4.01	4.06	4.35	3.65	3.98
df	3,27	3,27	3,27	3,27	3,27	3,27	3,27

With regard to H_1-H_2*, H_1-A_1*, and H_1-A_3*, it has been reported [18] that the decrease in the values of the three parameters results in not only an increase in perceived body size but also a change of perceived emotion from happiness to anger. This is in the same direction as the results of this study. As can be observed from Table 2a, the smallest values all correspond to anger, indicating an exaggerated

body size. As the values go up, the emotions produced change gradually from anger to disgust, happiness and neutral emotion.

Table 2b. Means and *p* values of ANOVAs for energy below 500/1000Hz (E<500Hz, E<1000Hz), Hammarberg index (HI), skewness (SK), formant dispersion (FD) and F0 (semitone) of the four types of emotional speech (A=anger, D=disgust, H=happiness, N=neutral).

In terms of centre of spectral gravity, the prediction from perception findings [10, 18] is that it should show a decrease in values from anger to happiness. This is confirmed in Table 2a: Anger and disgust both have higher values than happiness, again indicating a larger projected body size while happiness has a low value, indicating a smaller projected body size.

Jitter and shimmer show higher values for anger than happiness (Table 2a), which, though not specifically predicted before, is in line with Morton's [8] hypothesis that aggressiveness is associated with rough voice.

Harmonicity (Table 2a) is the highest for neutral emotion and lowest for anger, with happiness in the middle having slightly higher values than disgust. Table 2b shows that energy below 500Hz and 1000Hz of happy speech is higher than that of angry speech, and that the tendency is also true with regard to Hammarberg index. As for skewness, happiness has the highest degree of skewness, followed by neutral and disgust emotion, with anger having the smallest skewness (Table 2b). These measurements are, therefore, consistent with the results of H_1-H_2*, H_1-A_1* and H_1-A_3* and hence with the body size projection theory.

The difference between anger and disgust is non-significant in most of the parameters mentioned above (Table 3), indicating a tendency of anger and disgust being positioned towards the same end of the body size dimension.

The differences in formant dispersion, however, are non-significant between different emotions (Table 2b and 3). Also, Table 2b shows that anger has a higher pitch than happiness and neutral emotion, with disgust having the lowest pitch. This is not consistent with the findings of previous perception studies.

4. Discussions

The results of voice quality are consistent with the body size hypothesis in that anger is found to project a large body size with pressed (as indicated by all the spectral tilt measurements) and rough (as indicated by higher jitter and shimmer but lower harmonicity) voice. Happiness, in contrast, is found to project a small body size with breathier and more harmonious voice. As argued in [18], with its greater spectral tilt, a breathy voice approximates a "pure tone" voice which is observed by Morton in animal calls associated with appeasement and sociability [8]. So this study is the first to show clear speech production support for the body size projection theory with voice quality data. Somewhat surprisingly, however, neutral emotion shows greater breathiness than happiness, which has not previously been predicted. It is possible that voice quality is affected not only by body size projection, but also by vocal effort, because anger, happiness and disgust are all more *activated* than neutral voice.

The non-significant difference in formant dispersion across the emotions is somewhat puzzling. It could be that the prediction of the body size projection theory is wrong, but it could also be due to the possibility that emotion portrayal method implemented in this study is not powerful enough to make speakers alter their vocal tract length when trying to produce emotional prosody. If so, it may suggest that voice quality is the most easily elicited emotion-relevant acoustic changes in speakers. But this needs confirmation from future research.

The higher pitch in anger than in happiness, as shown in Table 2b, may present a problem for the body size projection theory. But many previous studies have found that anger is associated with a higher pitch than neutral emotion [9, 12, 15]. This suggests that anger also projects high dynamicity through vocalization [17]. As speculated in [17], high dynamicity may serve to convince the listeners of the high energy the signaller possesses, thus helping to frighten them away. On the other hand, however, there are also different types of anger. As the participants in this study were instructed to portray "hot anger", nearly all of them managed to achieve it. In contrast, the happiness portrayed by the participants was more similar to calm happiness/pleasantness than to elation. This may further explain why the average pitch is higher for anger than for happiness.

The current results also show that disgust is similar to anger in terms of voice quality. This, together with the fact that the F_0 of disgust is the lowest among the four emotions, suggests that disgust involves the projection of a large body size, as has been speculated in [17].

5. Conclusions

In this study, we have used speech production experiments on Mandarin to test the body size projection theory of emotional speech. The results suggest that, firstly, tone and sentence position do not contribute significantly to the acoustic characteristics of emotional speech; secondly, disgust is similar to anger in terms of body size projection; thirdly and most importantly, among the features of emotional speech, only voice quality is fully consistent with the predictions of the body size theory: Pressed and rough voice, both projecting a large body size, is associated with anger; breathy voice, which projects a small body size, is associated with happiness. Pitch and formant dispersion did not generate results either in support or opposition to the body size projection theory. This could be due to insufficient authenticity of emotional speech under laboratory conditions, for which solutions need to be sought in future research. Overall, nevertheless, it is interesting, and in fact slightly surprising that voice quality turns out to be the vocal dimension that is the most easily elicited by the emotion portrayal method in this study. Naturally, further explorations in future research are needed.

Scaling of Final Rises in German Questions and Statements

Jan Michalsky

Department of German Studies, University of Oldenburg, Germany

j.michalsky@uni-oldenburg.de

Abstract

Although certain intonation contours occur more frequently with German questions than with German statements, there is evidence that the semantics of intonational phonology operates on a more abstract level [1][2][3][4]. Hence, it is unlikely that there are pitch patterns in German that are exclusively used in interrogatives. Rather, intonational signaling of interrogativity can be regarded as resulting from the interaction between tonal and phonetic features. The tonal structure provides abstract semantic features, which are modified by paralinguistic features through phonetic realization [5]. This paper deals with the question which phonetic features may serve as cues to interrogativity in German. We report a reading task that was designed to elicit utterances that have phonologically identical nuclear rising pitch contours but differed by pragmatic function, serving either as a question or a statement. The observed absolute and relative scaling of nuclear and prenuclear tonal targets suggests that questions differ from statements by larger f0 excursions of nuclear rising contours, whereas the scaling of prenuclear accents does not substantially contribute to the expression of interrogativity. We conclude that phonetic cues to interrogativity in German are mainly realized through scaling and are restricted to the nuclear part of the intonational phrase.

Index Terms: intonation, interrogativity, questions, phonetic implementation, scaling, German

1. Introduction

There are two distinct levels of intonation to look at for specific features of German interrogatives: the categorical tonal structure and the continuous phonetic realization [6]. If interrogativity is regarded as a discrete pragmatic function, it may be assumed to be signaled by categorical intonational structure [7]. This view is prevalent in early descriptions of English [8], Dutch [9], and German [10], which attempt to identify pitch patterns that are linked to specific sentence types. Von Essen [10], for example, reports for German that most types of statements occur primarily with falling intonation, while certain question types occur primarily with rising intonation.

Spontaneous speech data suggest a less clear-cut distribution of pitch patterns in German: although certain intonation contours occur more frequently with specific types of questions than with statements, every sentence type may be realized with any contour of the German intonational inventory depending on the pragmatic context[11][3]. This finding is compatible with the majority of recent theories on the semantics of intonational phonology, where more abstract meanings are assigned to different intonation contours. Explanations regarding the phonology of question intonation and the difference between rising and falling contours in questions or across question types range from semantic features like *assertiveness* [12][13], over pragmatic features like *bias* [14][15] to discourse functions [11] and attitudinal features [16]. On a more abstract level, rising contours ending with a high boundary tone can be described as signaling pragmatic openness or incompleteness of the corresponding intonational phrase [17][2][3][18]. Hence, interrogativity cannot unambiguously be signaled by a specific choice of intonation contour. Rather, semantic features of intonation contours restrict the potential meanings of the associated utterance in a way that e.g. the feature of incompleteness suggests an interrogative interpretation in a certain context. This can explain why this type of intonation occurs more often with interrogative utterances like polar questions and to a certain degree wh-questions, but there is no immediate connection between the contour and the specific pragmatic function. However, if the phonology of intonation can signal certain aspects of interrogativity but not interrogativity itself the question arises whether this is the only contribution intonation can make to signal interrogativity in German, or whether there are other intonational cues, in particular at the level of phonetic realization.

According to Gussenhoven [5], intonational signaling of pragmatic functions may result from an interaction between phonological structure and phonetic realization. For example, emphatic focus may be signaled by a combination of a phonological pitch accent and an increase in its scaling. In this way, continuous variation in the phonetic realization can modify the abstract meaning of the phonological structure. This assumption is in accordance with reports that different types of increased pitch rather than a specific tonal pattern like a final rise were found as a potential universal feature of questions [19][20][21].

Evidence for the relevance of phonetic variation for the signaling of interrogativity has been found for several languages like Swedish [22][23], Finnish [24], Danish [25][26][27], and French [28] amongst others. For Dutch question intonation, Haan [29] identified several phonetic features such as higher f0 onset, raised register level, and differences in the scaling of the nuclear accent, which results in a shift in the overall global trend from declination to inclination. Eventually, phonetic effects of interrogativity were also found for German. Oppenrieder [30] observed the absence of overall declination in German questions, Brinckmann and Benzmüller [31] found differences in pitch range and f0 onset and Niebuhr et al. [32] suggest differences in shaping and alignment of prenuclear accents. Note, however, that in these experiments the potential phonetic features were not investigated independently of the phonological structure. A change of pragmatic function was always accompanied by a change in intonation contour like falling intonation in statements against rising intonation in questions [30][31][29][32]. Hence, an effect of the chosen contour on the phonetic realization cannot be excluded.

There are also several possibilities regarding the type of phonetic features involved and the domain of phonetic variation. Most research yielded effects in the scaling of tonal targets [22][23][27][24] but there is also some evidence for the

relevance of the shape of the transitions between tonal targets and of alignment relative to segmental landmarks [32]. As for the size of the affected constituent, there is evidence for the relevance of global parameters such as declination [25][26][28][30], pitch range [33][24][34], or register level [22][23], or local effects such as the scaling of the nuclear [29] or prenuclear peaks [32].

We report a reading task that was designed to investigate the phonetic effects of interrogativity in Standard German while keeping the tonal and grammatical structure constant. Since grammatically identical statements and questions can't be reliably elicited with the same intonational contour in utterance-final position we chose continuous statements and alternative questions were the nuclear rising contour occurs at the end of an intonational phrase with grammatically identical material but within an utterance. A possible generalization of the reported findings to utterance-final rising contours remains to be investigated.

In particular, we were interested in the identification of the relevant phonetic dimensions (scaling, shaping, and alignment) and domains of f0 variation (global, prenuclear or nuclear) that may be used for the distinction between questions and statements independently of grammatical and tonal structure. In the present paper we report results on the scaling of tonal targets only. Neither the phonetic variation of transitions between tonal targets nor their alignment or variation in pitch range or register level turned out to covary systematically with pragmatic function so far and remain open for further investigation.

2. Method

2.1. Speakers

The reading task was conducted with 21 speakers, 11 females and 10 males, aged between 18 and 30. The subjects were students from the University of Oldenburg and were born and raised in the northwestern part of Lower Saxony. All subjects were monolingual speakers of German.

2.2. Material

Two types of test sentences were constructed, questions and statements. Each sentence was designed to elicit two intonational phrases with the same intonation contour on the first phrase while keeping the grammatical structure identical. For the questions we used alternative questions and for the statements continuous statements with V1 word order. Subject and object items were filled with proper names to elicit two accents, a prenuclear and a nuclear one. The following examples illustrate both sentence types (for intonational annotation conventions see 2.4).

Alternative question:

(Will X nachher zu Y gehen)$_{IP}$, (oder bei Z bleiben?)$_{IP}$

H*L L*H H%|0%

Does X want to go to Y later, or stay with Z?

Continuous statement:

(Will X nachher zu Y gehen)$_{IP}$, (kann sie nicht bei Z bleiben.)$_{IP}$

H*L L*H H%|0%

If X wants to go to Y later, she cannot stay with Z.

Using a number of artificial proper names of the type *Mone* [ˈmoːnə] and *Mine* [ˈmiːnə] as accented words in the prenuclear and another set of artificial proper names of the type *Suse* [ˈzuːzə], *Söre* [ˈzøːʁə], *Neewe* [ˈneːvə] and *Narne* [ˈnaːnə] as accented words in the nuclear position we created 16 lexical variants of each sentence type. The proper names were segmentally controlled such that only voiced segments were used and all words ended in schwa to ensure a disyllabic production. We obtained a total of 32 target sentences, which were interspersed with 192 filler sentences and presented in a pseudo-randomized order.

2.3. Procedure

The test sentences were presented visually via a PowerPoint presentation with one sentence per slide. A line break was inserted after every potential intonational phrase to elicit a phrase boundary. The subjects were instructed to familiarize themselves with the sentence material in silence before they read them out aloud. Recordings were made in a sound booth in the speech laboratory at the University of Oldenburg with a portable digital recorder (Tascam HD P2) at a sampling rate of 48khz and 16bit resolution via a head mounted microphone (DPA 4065 FR).

2.4. Acoustic analysis

Only the first intonational phrase was selected for acoustic analysis. This phrase was expected to be realized with one of two possible nuclear target contours: a half-completed rise or plateau-contour L*H0% or a low-rising-contour L*HH%. Contours are represented according to the ToDI system [35] and its adaptation for German [3][18]. Equivalent notations in the classical ToBi [36] and GToBi [37] systems would be L*H-L% for the plateau-contour and L*H-H% for the low-rising-contour. The phrases contained two possible pitch accents: a prenuclear H*L accent on the subject-item in X-position and a nuclear L*H with a final boundary tone of H% or 0% on the object-item in Y-position and the following verb. Only utterances realized with the described tonal structure regarding number and position of pitch accents as a reflection of focus structure as well as choice of contour were selected for acoustic analysis.

Four points of measurement were determined as illustrated in figure 1: the beginning of the prenuclear rise, the prenuclear peak, the onset of the final rise and the offset of the final rise. From these measurements the following variables were calculated: The excursion of the rise to the prenuclear peak (*prenuclear rise excursion*), the excursion of the final rise (*final rise excursion*), the difference in the excursions (*excursion difference*) and in the peaks (*peak difference*). The excursions were determined by calculating the difference in frequency from prenuclear onset to prenuclear peak for the *prenuclear rise excursion* and from final rise onset to final rise offset for the *final rise excursion*. The *excursion difference* was calculated by subtracting the *prenuclear rise excursion* from the *final rise excursion*. The *peak difference* was calculated by subtracting the prenuclear peak from the final rise offset. For comparability of the two sexes the measurements were converted to a semitone scale.

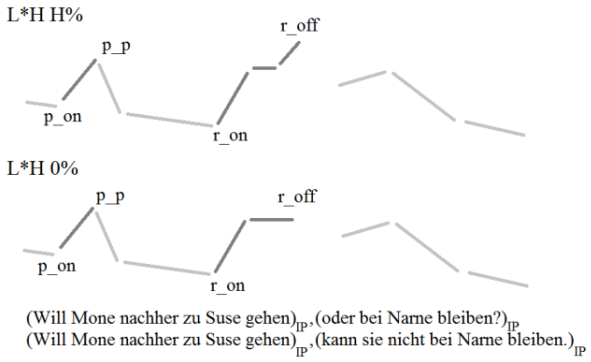

Figure 1: Points of measurement for the acoustic analysis for both target contours. (dark grey = prenuclear and nuclear rise excursion, p_on = onset of prenuclear rise, p_p = peak of prenuclear rise, r_on = onset of final rise, r_off = offset of final rise).

2.5. Statistical analysis

For the statistical analysis linear mixed effect models were used with PRAGMATIC FUNCTION (declarative / interrogative) and SPEAKER SEX (male / female) as fixed factors, and ITEM and SPEAKER as random factors. The dependent variables were *prenuclear rise excursion*, *final rise excursion*, *excursion difference*, and *peak difference*.

3. Results

Most of the intonational phrases were realized with the plateau-contour L*H0% or the low-rising-contour L*HH%. The female speakers produced 97 statements and 117 questions with plateau-contours, and 78 statements and 70 questions with low-rising-contours. The male speakers produced 159 statements and 140 questions with plateau-contours, and 65 statements and 83 questions with low-rising-contours. Four female speakers showed variation in their choice of contour while the other 7 female speakers and all 10 male speakers kept the chosen contours constant (see table1). The distribution of the two target contours shows that the choice of contour varies across speakers but doesn't systematically vary across pragmatic functions.

Speaker	Pragmatic Function	Plateau-contour	Low-Rising-contour
1	Statement	23 (67%)	11 (33%)
	Question	14 (66%)	7 (34%)
2	Statement	13 (48%)	14 (52%)
	Question	6 (40%)	9 (60%)
3	Statement	25 (81%)	6 (19%)
	Question	9 (45%)	11 (55%)
4	Statement	17 (54%)	14 (46%)
	Question	10 (45%)	12 (55%)

Table 1: Distribution of intonational contours across pragmatic functions for four female speakers.

Significant effects of PRAGMATIC FUNCTION were found for the excursion of the final rise in both L*H0% (declarative mean=5.9st, interrogative mean=7.9st, F=324.92, p<.001) and L*HH% (declarative mean=9.2st, interrogative mean=11.2st, F=109.24, p<.001) but not for SPEAKER SEX (L*H0%: female mean=6.7st, male mean=7.1st, F=0.34, n.s.) (L*HH%: female mean=8.9st, male mean=11.5st, F=2.01, n.s.), illustrated in figure 2.

No significant effects of PRAGMATIC FUNCTION could be found for the excursion of the prenuclear rise, neither for L*H0% (declarative mean=4.4st, interrogative mean=4.3st, F=0.06, n.s.) nor for L*HH% (declarative mean=4.1st, interrogative mean=4.0st, F=0.25, n.s.), and no effects of SPEAKER SEX (L*H0%: female mean=4.0st, male mean=4.6st, F=0.52, n.s.) (L*HH%: female mean=4.0st, male mean=4.1st, F=0.01, n.s.).

Consequently, there were significant effects of PRAGMATIC FUNCTION on the difference between final rise excursion and prenuclear rise excursion for L*H0% (declarative mean=1.5st, interrogative mean=3.6st, F=159.47, p<.001) and L*HH% as well (declarative mean=5.0st, interrogative mean=7.1st, F=68.10, p<.001) with no significant effects of SPEAKER SEX (L*H0%: female mean=2.6st, male mean=2.5st, F=0.001, n.s.) (L*HH%: female mean=4.6st, interrogative mean=7.5st, F=2.84, n.s.), illustrated in figure 3.

Finally, for the differences between the absolute final rise offset and the absolute prenuclear peak height, there were significant effects of PRAGMATIC FUNCTION for L*H0% (declarative mean=0.1st, interrogative mean=1.7st, F=200.51, p<.001) and L*HH% (declarative mean=3.4st, interrogative mean=5.2st, F=58.53, p<.001) with no significant effects of SPEAKER SEX in L*H0% (female mean=0.5st, male mean=1.0st, F=0.67, n.s.) but a small effect in L*HH% (female mean=2.7st, male mean=5.9st, F=7.67, p<.05), as illustrated in figure 4.

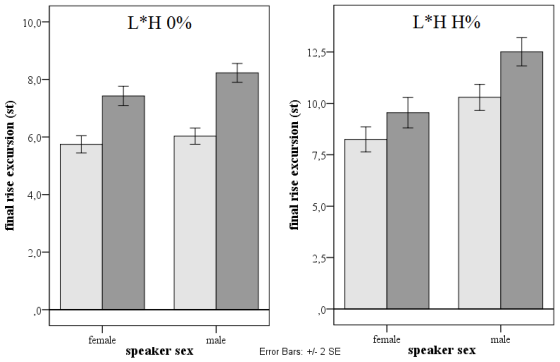

Figure 2: Phonetic effects of PRAGMATIC FUNCTION (light grey = declarative, dark grey = interrogative) and SPEAKER SEX on the *final rise excursion* in semitones for plateau- and low-rising contours.

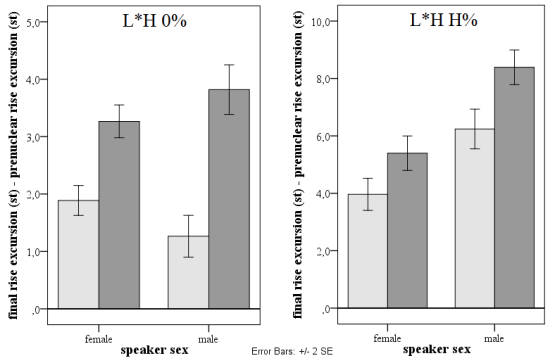

Figure 3: Phonetic effects of PRAGMATIC FUNCTION (light grey = declarative, dark grey = interrogative) and SPEAKER SEX on the *excursion difference* in semitones for plateau- and low-rising contours.

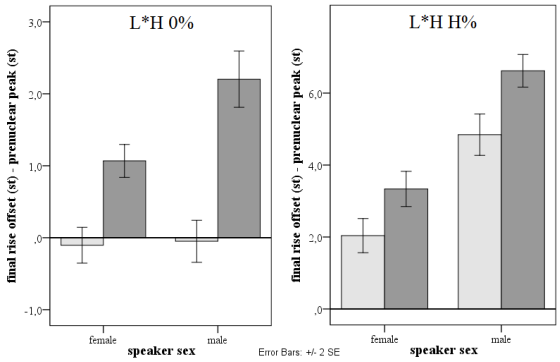

Figure 4: Phonetic effects of PRAGMATIC FUNCTION (light grey = declarative, dark grey = interrogative) and SPEAKER SEX on the *peak difference* in semitones for plateau- and low-rising contours.

4. Discussion and conclusion

The results suggest that the pragmatic function of interrogativity has significant effects on the scaling of intonation contours in German. This is in accordance with the assumption that in a typological perspective increased pitch is characteristic of interrogatives [19][20][21], as well as with experimental studies on several other languages [22][23][27][24][29].

The observed effects, however, were found to be restricted to the nuclear part of the utterance. This contradicts the majority of observations for other languages where interrogativity is found to either affect prenuclear and nuclear accents equally [22][23][27][24] or affect global parameters like declination [25][26][28], pitch range [33][24][34] or register level [22][23] in general. On the other hand, it is in accordance with Haan's [29] findings for Dutch. This suggests that Dutch and German may differ from other languages regarding the dimension of phonetic effects of interrogativity. It is, however, in contradiction to the observations of Niebuhr et al. [32] for German regarding both dimensions and types of effects. A first explanation for these differences may lie in the differences in keeping the phonological structure constant.

The variation of the nuclear part and the stability of the prenuclear part in interrogative utterances resulted in an increased difference between nuclear rise excursion and prenuclear rise excursion as well as between the absolute heights of the peaks of both rises. In other words, the local restriction of the phonetic effects also resulted in a global effect. The differences in absolute height of the peaks of both rises resulted in an even top-line for statements and an inclining top-line for questions. This is comparable to Haan's [29] upsweep, describing the amount by which the final rise exceeds the peak of the preceding nuclear accent peak. It is also compatible with the results from Brinckmann and Benzmüller [31] who observed a difference in the top-lines of statements and question-types.

Our results do not show, however, whether the actual perceptual relevant effect is 1) the difference in the excursion size of the final rise, 2) the relative difference of the excursion size of the final rise compared to the prenuclear rise, or 3) the difference in height of the peak of the final rise compared to the peak of the prenuclear rise. The first view would call for the listener's capability to compare the excursion size to some reference value in order to judge it as high enough to cue a question. The second view assumes the movement of both excursions as the perceptual cue. According to the third view, the perceptual cue would be whether the final rise's offset exceeds the prenuclear peak by a certain amount. The last two assumptions can but need not necessarily be connected because an increase in the excursion size of the final rise can be achieved by lowering the onset without increasing the height of the offset. To answer the question whether the extension of the final rise or the raising of the final offset alone provides sufficient cues to interrogativity, additional perception experiments will be carried out. It further remains to be tested whether the differences in excursion size of the final rise become more prominent when there is no prenuclear accent for comparison.

Processing Prosodic Boundaries in Natural and Filtered Speech

Grace Kuo

Department of Linguistics, Macalester College, St. Paul, USA
gkuo@macalester.edu

Abstract

The prosody of an utterance can carry information that is critically important to understand the meaning of a sentence. Previous studies have shown that listeners are able to detect major prosodic boundaries in their native language in stimuli whose segmental information has been removed, such as low-pass filtered [1][2] and hummed speech [2][3][4][5]. The present boundary strength rating study is conducted on native and non-native speakers to Swedish, in an attempt to observe non-native speakers' accuracy in judging the upcoming boundary size in natural and filtered speech. 18 Taiwanese and 18 American English speakers were recruited for the rating task whose stimuli consisted of Swedish utterances from three prosodic boundary types (word boundary, phrase/tone sandhi group boundary, and Intonation Phrase boundary). In Experiment 1, participants rated the upcoming boundary strength on a slider for natural speech stimuli. In Experiment 2, they rated the boundary strength for filtered speech stimuli. The results show that both native and non-native speakers could accurately predict the upcoming prosodic boundary type in both natural and filtered speech. The acoustic analyses of duration, f0 range, f0 median, spectral tile, and harmonics-to-noise ratio reveal that both native and non-native speakers use these prosodic cues to make their judgment; however, they put different emphasis on different cues when they were presented with stimuli of different qualities (natural vs. filtered) and lengths.

1. Introduction

Previous studies of speech prosody have shown that listeners are able to predict upcoming prosodic boundaries. For example, Grosjean and Hirst [6] had the subjects listen to some part of an English sentence and asked them to predict how long the remaining sentence was. The results showed that English listeners were very accurate at predicting the amount of the rest of the sentence. However, their French listeners could only tell if a sentence ended, unable to differentiate between different amounts to come. Carlson, Hirschberg, and Swerts [7], on the other hand, found that English listeners were able to predict the strengths of the upcoming boundaries as well as Swedish listeners when the subjects were asked to express their judgment about the upcoming boundary in Swedish on a 5-point scale. This suggests that prosodic, rather than syntactic/semantic information was being used as a primary cue. In addition, the result of their follow-up study with Mandarin listeners showed that the length of the presented stimuli matters – Mandarin listeners could hear different Swedish boundaries only when presented with 2-second fragments, whereas English and Swedish listeners could differentiate the boundaries with either 2-second or one-word fragments. This finding indicates that language background affects the listeners' judgments.

Experiment 1 in the current study replicates [7]' experiment by recruiting American English and Taiwanese listeners to participate in a rating task, where half of the stimuli were from natural Swedish speech and the other half were its low-pass filtered version. It is predicted that American English listeners will accurately predict the Swedish upcoming boundaries with both 2-second and one-word fragments (as reported by [7]), and that Taiwanese listeners, speakers of another tone language, will predict the boundaries accurately only when presented with 2-second fragments (similar to [7]'s result with Mandarin speakers).

Previous study such as [1] [2] [8] showed that native listeners were able to detect major prosodic boundaries in meaningless speech materials, including re-iterant speech, low-pass filtered speech and hummed speech. Since [7] found that non-native listeners could make use of the prosodic information (in the absence of the syntactic/semantic information) to predict the upcoming boundary, Experiment 2 has listeners participate in the same rating task as in Experiment 1, but the segmental information in the stimuli was absent/reduced (low-pass filtered). It is predicted that no rating difference will be found between the natural speech stimuli and the filtered speech stimuli in that both the American English and Taiwanese listeners are able to use prosodic information to make the accurate judgments.

2. Experiment 1: Natural Stimuli

2.1. Method

2.1.1. Stimuli

The Swedish stimuli were the same stimuli [7] used in their experiment. The stimuli were obtained from a 25-minute interview with a Swedish female politician and the interview was manually annotated for perceived boundaries by three experienced transcribers. Every word was marked as being followed either by an IP boundary, a phrase boundary, or a word boundary. Sixty 2-second speech fragments followed by either of the three boundary types were chosen: 20 word boundaries (labeled as "no break" in later analysis), 20 phrase boundary ("weak break") and 20 IP boundaries ("strong break"). All stimuli came in two lengths, 2-second fragment and one-word fragment. From each 2-second fragment, the last word was extracted to be the one-word fragment.

Therefore, there were 120 utterances in total (20 items x 3 breaks x 2 fragment lengths).

2.1.2. Participants

Eighteen Taiwanese native speakers and eighteen American English native speakers participated in this experiment. None of the American English and the Taiwanese listeners had previous knowledge about or prior experience with Swedish. Neither of them had hearing or language problems according to their self-report.

2.1.3. Procedures

The subject individually judged the upcoming boundary strength for each natural utterance with an onscreen slider, whose position was manipulated by listeners from left ("small break") to right ("big break"). During the task, the subjects could choose to hear each stimulus more than once, but were encouraged to make their judgments by instinct. To minimize any possible learning effect, the stimuli were presented in a randomized order.

2.1.4. Data Analysis

The position of the slider bar was recorded by the Matlab script on a scale from 0-100. These numerical values were converted into logarithmic values to reduce the skewing in the distribution. The logarithmic strength ("log strength" hereafter) were entered into the repeated measures ANOVA, with the two within-subject factors, "Break" (no break vs. weak break vs. strong break), and "Length" (2-second vs. one-word). Since different language background might result in different rating results, English listeners' data were separated from Taiwanese listeners' data.

2.2. Results – Boundary Strength Ratings

2.2.1. English listeners

Repeated measures ANOVA reveals significant effects of "Break" ($F(2, 2154) = 74.32$, $p < .05$) and "Length" ($F(1, 2154) = 231.4$, $p < .05$). In other words, (i) listeners tended to give higher ratings for bigger boundaries, and (ii) listeners gave higher strength ratings for 2-seond fragments than for one-word fragments. In addition, listeners were able to differentiate all three breaks in either 2-second or one-word fragments. The results are shown in Figure 1. These findings were the same as the results found in [7] – English listeners were able to accurately predict all three boundaries in a nonnative language such as Swedish when presented with natural speech stimuli.

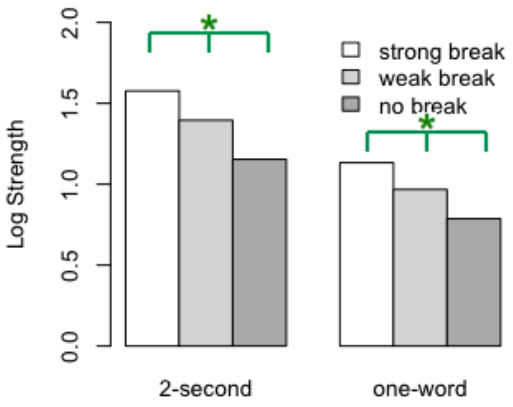

Figure 1: *English listeners' average logarithmic perceived boundary strength for Swedish Natural Stimuli. A significant difference between "Breaks" of either length is indicated with a line and asterisk above the bars.*

2.2.2. Taiwanese listeners

Significant effects were found not only in "Break" ($F(2, 2154) = 61.09$, $p < .05$) and "Length" ($F(1, 2154) = 196.88$, $p < .05$), but also in their interaction ($F(2, 2154) = 3.18$, $p < .05$). The results are shown in Figure 2. These findings were similar to [7]'s study with Mandarin listeners – tone language speakers were able to accurately predict the upcoming three boundaries only when they were presented with 2-seoncd fragments.

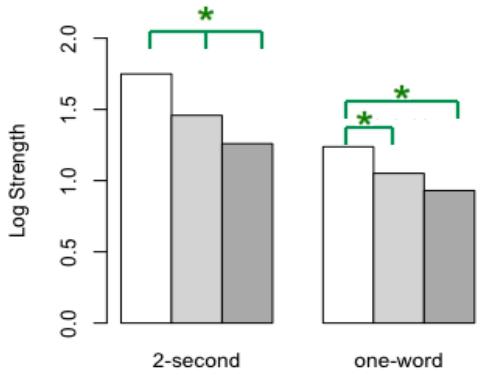

Figure 2: *Taiwanese listeners' average logarithmic perceived boundary strength for Swedish Natural Stimuli.*

3. Experiment 2: Filtered Stimuli

3.1. Method

The same 18 Taiwanese and 18 American English speakers participated in the boundary strength rating experiment. The stimuli were the low-pass filtered version of the 60 natural speech stimuli. They were generated by at a frequency cut-off of 400 Hz and 50 Hz smoothing, and the intensity was adjusted to 70 dB. The entire manipulation was done with a Praat [9] script. With low-pass filtering, most of the segmental information will be removed, yet the prosodic information, such as duration, f0, and some voice quality stay intact. Like Experiment 1, the stimuli also came in two lengths. Therefore, there were 120 utterances in total (20 items x 3 breaks x 2 fragment lengths). The experiment procedures were the same as those in Experiment 1.

In the analysis, the raw strengths are converted into the logarithmic strength, and the values were entered into the repeated measures ANOVA, which had "Break" and "Length" as the two factors.

3.2. Results – Boundary Strength Ratings

3.2.1. English listeners

The results with the English listeners show that when they were presented with filtered Swedish stimuli, they rated he three breaks differently, ($F(2, 2154) = 21.01$, $p < .05$). In addition, they were able to correctly predict all three breaks when presented with 2-second fragments, but not with one-word fragments. The results are shown in Figure 3. It seems that filtering has prevented listeners from identifying the phrase boundaries when the stimuli is short.

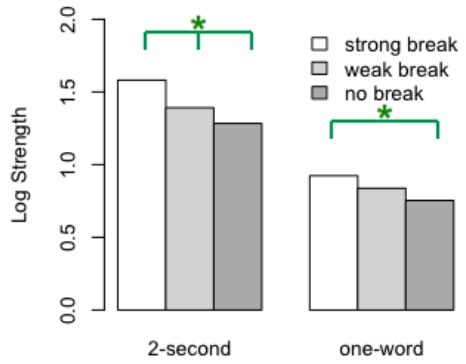

Figure 3: *English listeners' average logarithmic perceived boundary strength for Swedish Filtered Stimuli.*

3.2.2. Taiwanese listeners

Significant effects were found not only in "Break" ($F(2, 2154) = 15.67$, $p < .05$) and "Length" ($F(1, 2154) = 402.2$, $p < .05$), but also in their interaction ($F(2, 2154) = 3.31$, $p < .05$). Similar to the results with the English listeners, Taiwanese listeners were still able to accurately predict the upcoming Swedish breaks in 2-second fragments when the stimuli were low-pass filtered. However, when the filtered stimuli contained only one-word, there were no difference in ratings between the three breaks.

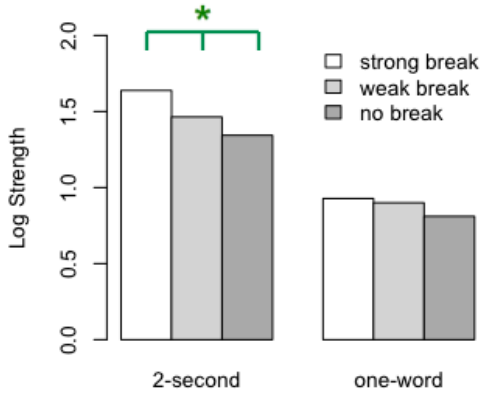

Figure 4: *Taiwanese listeners' average logarithmic perceived boundary strength for Swedish Filtered Stimuli*

4. Acoustic Correlates

In an attempt to identify the prosodic cues that could contribute to accurate boundary strength judgments in natural and filtered speech, we examined the acoustic measures from the last syllable of each stimulus: duration (=normalized vowel duration, and speech rate), pitch (including f0 range and f0 slope), harmonic amplitude/spectral tilt, harmonic-to-noise ratios, CPP, and Energy. The last syllable of each stimulus was labeled in Praat [9] and then the acoustic measures for the labeled portions were obtained using VoiceSauce [10]. The last syllable in Swedish contained usually part of a word.

As mentioned earlier, the filtered stimuli were a low-pass filtered version of the normal speech and the threshold was set at 400 Hz (as indicated with the vertical line in Figure 5), thus, any information beyond 400 Hz would have been filtered out. For the filtered stimuli, the main available voice measures were the amplitude of the first harmonic (corrected H1), HNR05 (frequency range <500 Hz) and CPP.

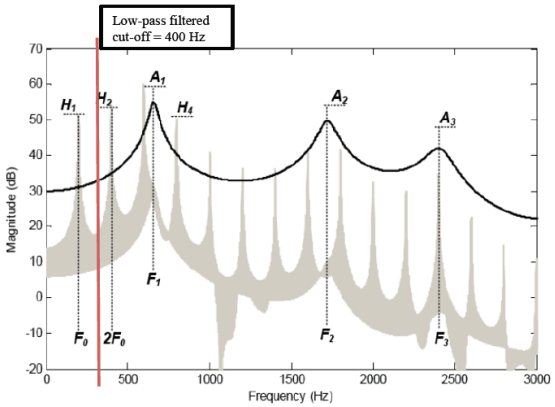

Figure 5: *An example spectrum. Adopted from [11]. The envelope in shade is the actual output from VoiceSauce [10]. The corrected values are obtained from this envelope.*

The regressions between the acoustic measures and the logarithmic boundary strength ratings are made. Multiple regression analysis was carried out for each type of stimulus (considering speech quality and the fragment length). The natural stimuli results are shown in Table 1 and the filtered stimuli results are shown in Table 2.

Table 1: *English and Taiwanese listeners listened to Swedish natural stimuli: marks show which acoustic measures contributed significantly to the regression equation.*

	English		Taiwanese	
	2-sec	1-wrd	2-sec	1-wrd
Duration				
Rate	✓	✓	✓	
F0 range	✓	✓	✓	✓
F0 median	✓		✓	✓
F0 mean	✓		✓	
H1*-H2*		✓		
HNR05				✓
CPP		✓		✓

The results show that for both English and Taiwanese listeners, when they were presented with 2-second natural stimuli, they would pay attention to durational and f0 cues. When the presented stimuli was one-word fragment, they would take voice quality into consideration.

Table 2: *English and Taiwanese listeners listened to Swedish filtered stimuli: marks show which acoustic measures contributed significantly to the regression equation.*

	English		Taiwanese	
	2-sec	1-wrd	2-sec	1-wrd
Duration			✓	
Rate	✓		✓	
F0 range			✓	✓
F0 median			✓	✓
F0 mean	✓	✓	✓	
H1*	✓	✓	✓	
HNR05	✓	✓	✓	✓
CPP				✓

The results reveal the significant correlations between the acoustic measures from the last syllable of the filtered utterances and the logarithmic boundary strength. It seems that English listeners rely on more voice quality cues for both lengths whereas Taiwanese listeners, who had better boundary strength when presented with 2-second fragments, tended to make use of more cues, including durational measures, to predict the upcoming boundaries. In addition, tone language speakers, such as Taiwanese, also used f0 range as a reliable cue when they were asked to predict upcoming boundary in a non-native language. Pitch is not only for lexical use for Taiwanese listeners.

5. Conclusion

In this study, we examined the perceived boundary strength indicated by Taiwanese and English listeners presented with Swedish natural and filtered stimuli. The distribution of the perceived boundary strengths shows that English listeners showed a three-way distinction in breaks in normal (both 2-seoncd and one-word) and filtered (only 2-second) stimuli. Taiwanese listeners also showed a three-way distinction in breaks in normal and filtered stimuli, but only when they were presented with 2-second fragments. These findings are consistent with [7]'s findings.

The acoustic analyses of normalized vowel duration, speech rate, f0 range, f0 slope, spectral tile, and harmonics-to-noise ratio reveal that non-native speakers use these prosodic cues to make their judgment; however, they put different emphasis on different cues when they were presented with stimuli of different qualities (natural vs. filtered).

6. Acknowledgements

The author would like to acknowledge Prof. Rolf Carlson, Julia Hirschberg and Marc Swerts for generously sharing their Swedish stimuli.

Constant Tonal Alignment in Swedish Word Accent II

Malin Svensson Lundmark

Linguistics and Phonetics, Lund University, Lund, Sweden
Malin.svenssonlundmark@gmail.com

Abstract

Studies on accentual tonal alignment of intonation languages suggest that L in rising (LH) pre-nuclear accents anchors with a specific point in the segmental string, while the timing of H varies. This study investigates if lexical accents, too, exhibit a constant alignment by testing the South Swedish word Accent II. When under the strain of tempo variability the L-target was found not to be anchored with syllable onset. The results were not fully conclusive regarding H, but no clear evidence was found against anchoring of H, which could mean that H is an important phonological event in Accent II, while L is not.

Index Terms: tonal alignment, segmental anchoring, word accent, pre-nuclear accent, speech rate

1. Introduction

Over a period of 15 years there has been an on-and-off debate within intonational phonology on whether or not accentual tonal targets (L, H) are constantly aligned with the segmental string. Most studies have focused on pre-nuclear rising accents in intonation languages and have found conclusive results on the start of the rise, the L-target. So far, a language with lexical accents has not been taken into account in the recent research on constant tonal alignment.

1.1. Tonal alignment

Tonal alignment might be seen upon as a wider notion for other concepts such as timing, tonal association or segmental anchoring. The *segmental anchoring principle* presupposes that tonal targets are constantly aligned, and thus anchored at specific points in the segmental string [1]-[3]. Studies that second the principle have focused on rising pre-nuclear accents in intonation languages. Previous studies in the field of constant tonal alignment have displayed an unambiguous case of the tonal target L aligning with syllable onset in pre-nuclear accents, though the precise timing seems to vary across languages. Results include the L-target occurring just before the onset of the accented syllable ([1] for Greek; [4] for Italian), at syllable onset ([5] for Dutch; [3] for English; [2] for German), or after syllable onset ([6] for Mandarin).

While the studies show anchoring of L with the beginning of the syllable, the same consistent result does not exist for the H-target. Some studies found H anchoring after syllable offset [1], [2], [6], or somewhere late in the syllable [3]. Caspers and Van Heuven [5] found that the end of the rise, the H-target, varied considerably under time pressure and thus rejected that it did anchor with the segment. However, they did also consider whether or not the variation had to do with segmental structure.

It can be concluded that the L-target appears to be more stable than the H-target in rising pre-nuclear accents in intonation languages. Niemann et al. [4] has suggested that the cross-linguistic variation of anchoring of L is systematic and can be explained by different phonological structures between the intonation languages. The inconclusive results on H have been highlighted by Niebuhr et al. [7] who addressed the effect of individual speaker strategies. They also proposed that instead other related features are responsible for the consistent results of segmental anchoring.

1.2. Swedish accents

In the prosodic typology of Swedish intonation provided by the Lund Model [8], [9], the two Swedish word accents are assumed to be represented by a fall associated with the stressed syllable in a prosodic word, where the two accents differ in the timing of the fall. There is a regional variation between the Swedish dialects. For example in the South Swedish dialect (South) both accents are timed considerably later than in the Central Swedish dialect (Svea): in South Swedish the high level in Accent I is associated with the stressed vowel and in Accent II with offset of the stressed syllable.

The original dialect typology has later been revised by Bruce [9], who identified, for all dialects, an LHL tonal gesture from which bitonal gestures are extracted; either a fall, H+L, or a rise, L+H. Bruce generalized for Accent II an association of a fall in the dialects with an early timing of the accents (Svea and Göta) and a rise in the dialects with a late timing (South, Gotland, Dala, North). For the South Swedish dialect, a late timed dialect type, Bruce made the specific assumption of a fall, an H+L pattern, for Accent I and a rise, an L+H pattern, for Accent II. The rise in South Swedish Accent II has indeed been shown to be relevant from a perceptual point of view [10].

As if by chance, there is a rough phonetic match between the timing of the lexical Accent II in South Swedish and the pre-nuclear accents in the already mentioned studies on tonal alignment in intonation languages. The research question formulated here is whether or not additional phonetic features are similar such as if L and H are anchored with a segment, as is assumed by the segmental anchoring principle.

The present study is a production study where the hypothesis of segmental anchoring is tested on the Swedish word Accent II. Speech rate is used as an experimental tool and is based on the idea that speakers will try to retain primary features of phonological properties, while they will let other features be modified under time pressure [5]. Speech rate has been used successfully by a number of researchers in studies concerning tonal alignment [3], [5], [6]. Because the Lund Model (revised by Bruce [9]) assumes that both L and H in the rising L+H gesture of Accent II are phonologically relevant, anchoring of L and H is expected.

2. Method

2.1. Speakers and recording

The material was initially collected for a different study in which two age groups were recorded. For this study only the older speakers were tested due to technical issues. There were

seven speakers, four males and three females, and the average age of the speakers was 72 years. All speakers were voluntary and spoke the same variety of the South Swedish dialect. A criterion for speaker selection was that they had all lived most of their lives in the same area in the northeastern part of the South Swedish region. Moreover, their parents also had to have lived most of their lives in the area.

All of the recordings were made in people's homes. An IMG Stage boundary microphone (table-microphone) with phantom power was used (ECM-302B) since it is non-invasive and the speakers were expected to be naïve with no prior recording experiences.

The material was read twice by each speaker at three different speech rates: normal, slow and fast. The recording leader set the pace of the speech rate with the leading question and the speaker was asked to answer the question and to follow the speech rate of the recording leader.

2.2. Speech materials and data processing

The materials consisted of three test sentences with the same test word: *många*, meaning 'many' in English. The materials were mixed with 37 further sentences not investigated here. The test word, in its three sentence contexts, fits the following criteria: an unbroken tonal curve, a word Accent II, identical segmental surroundings ([9 syllables] bisyllabic target word [2 syllables]) and that neither syllable and vowel onset, nor syllable and vowel offset coincided. The leading question sought to that the target word *många* [ˈmɔŋːa] 'many' occurred before nuclear accent in all three sentences. The F0 contour of an example sentence can be seen in Figure 1.

The author performed segmentation and annotation in Praat [11]. Since each speaker was recorded twice, the material consisted of 126 items (3 sentences x 2 repetitions x 3 speech rates x 7 speakers). Each target word was segmented into syllables, and in addition, the boundaries of the accented vowel were determined. The boundary between the two syllables was defined as the temporal midpoint of the long, ambisyllabic consonant. The tonal curve has been semi-automatically annotated for the tonal targets L and H by the author (Figure 2). Extracted measures were the start and the end of the rise (L and H), syllable onset and syllable offset.

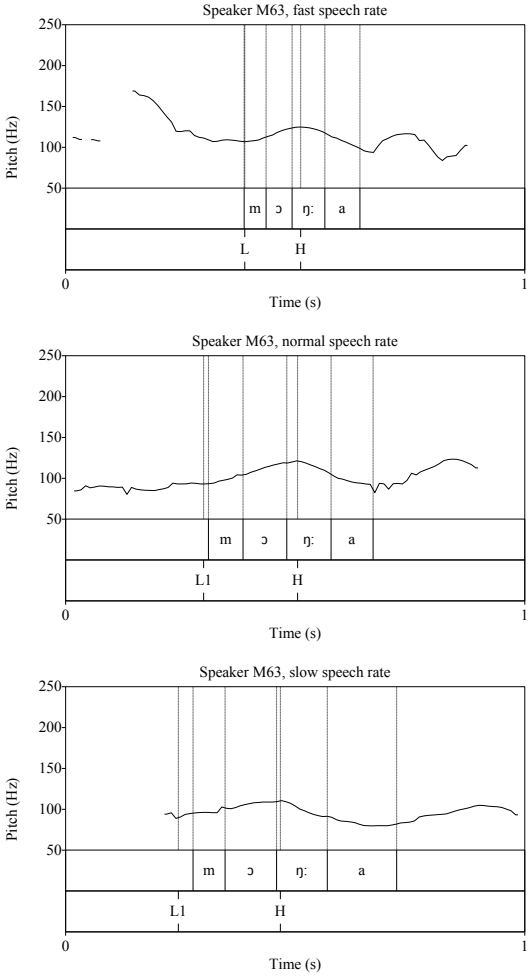

Figure 2: *The segmented target word [ˈmɔŋːa] in three different speech rates, spoken by male speaker M63. The low (L/L1) and the high target (H) of the tonal curve has been annotated.*

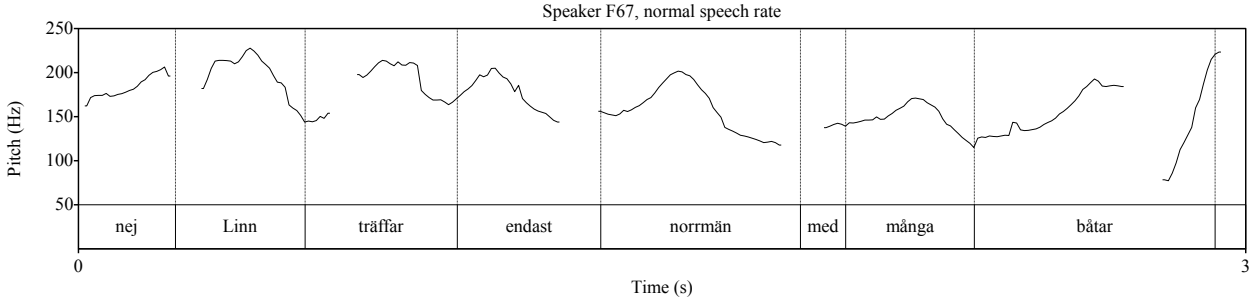

Figure 1: *One of the three target sentences in the material as spoken by female speaker F67 in normal speech rate. The sentence translated into English is: 'No, Linn only meets Norwegians with many boats'.*

3. Results

Average syllable duration shows a difference in speech rate between the recordings (Figure 3). An ANOVA confirmed that speech rate had a significant effect on syllable duration ($F = 66.490$, df 1, $p < .001$), concluding that the rate manipulation was successful. Since the segments are affected by speech rate, the temporal distance between the tonal targets L and H should also be affected by speech rate, if they are anchored with the segmental string. An ANOVA was run and showed a significant effect of speech rate on the temporal distance between L and H (henceforth, rise time) ($F=17.129$, df 1, $p = .006$) resulting in shorter rise times for faster speech.

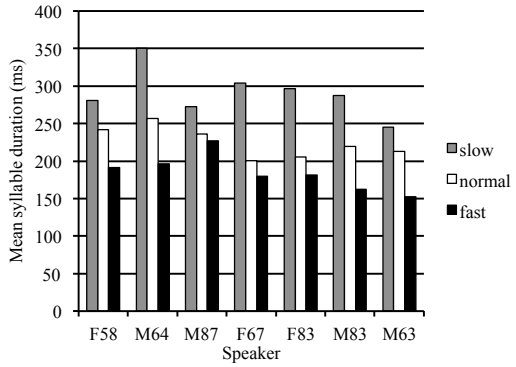

Figure 3: *Average syllable duration for each speaker in each speech rate.*

If anchoring of the tonal targets with specific points in the segmental string occurs this would necessitate a correlation between segment duration and distance between tonal targets. This was tested by means of a Correlations Pearsons (2-tailed) test. There appears to be a weak to moderate positive linear relationship ($R= 0.433$, $N= 74$), which indicates a correlation. However, it does not seem to be a convincingly strong correlation (Figure 4).

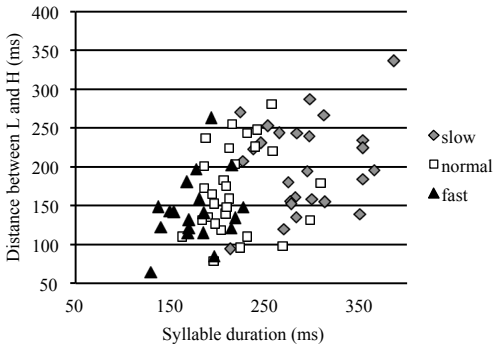

Figure 4: *Scatter plot of the relationship between syllable duration and the distance between tonal targets L and H.*

To test whether the weak to moderate relationship might indicate that either only one or neither of the targets is anchored, two new measures were calculated: the distance between L and syllable onset, and the distance between H and syllable offset, where anchoring is measured as distance in milliseconds. An ANOVA was first run with speaker as random sample. To account for missing data, an average value was first calculated for each speaker across the available items for each condition. The ANOVA showed no significant effect of speech rate on the distance between the tonal target L and syllable onset ($F =0.460$, df 1, $p = .523$). An ANOVA was also run on the distance between H and syllable offset, showing no significant effect of speech rate on anchoring of H ($F = .702$, df 1, $p = .434$). However, Figure 5 sends a different message and displays a large variance of anchoring of L between the speakers comprising alignments before as well as after syllable onset. The H-target also varies considerably in its alignment, but somewhat less than the L-target (see also Table 1). Notably, the H-target is consistently aligned before syllable offset, on average around 40 ms for both normal and fast speech (Table 1).

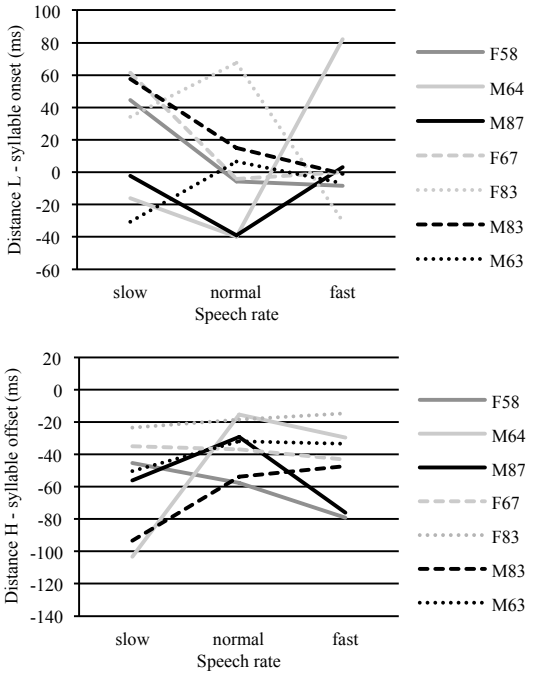

Figure 5: *Distance between tonal target and segment boundary, average value for each speaker. The first graph shows distance between L and syllable onset, the second between H and syllable offset. A negative number indicates that timing is before the boundary.*

Table 1: *Distance between tonal target and segment boundary (ms), average value for each speaker. Standard deviation in parentheses. A negative number indicates that the target is before the boundary. * Only one item in this condition.*

All	24 (51)	9 (54)	-6 (36)	-65 (37)	-38 (23)	-40 (27)

The anomaly of only one available item in some conditions for three of the speakers (M64, M87 and F83) can be seen in Table 1. In order to avoid a type II error, additional ANOVAs were made with target words as random sample.

The ANOVA with target word as sample showed that speech rate did in fact have a significant effect on the distance between L and syllable onset ($F = 14.095$, df 1, $p = .013$) suggesting that L does not seem to be constantly aligned at or close to the syllable onset. This conclusion is also supported by Figure 6, which, again, displays a large spectrum of alignments both before and after syllable onset. An ANOVA on the distance between H and syllable offset was also calculated which shows a low p-value; however not statistically significant ($F = 5.159$, df 1, $p = .072$). Speech rate appears to not affect the possible anchoring of H. Average value and standard deviations for each target word are shown in Table 2.

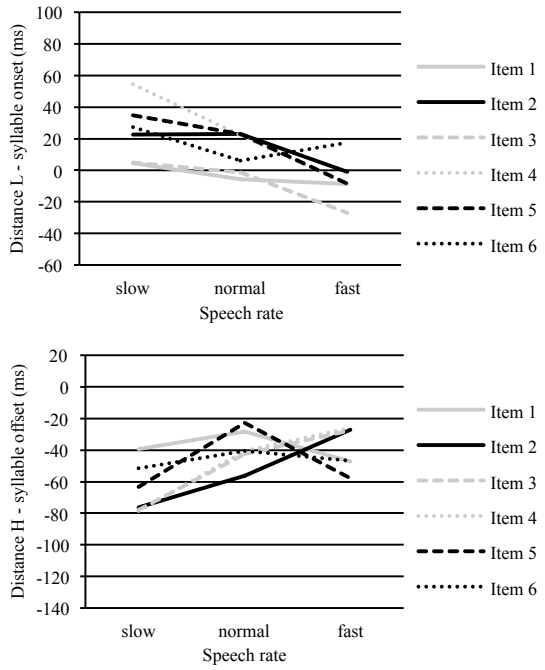

Figure 6: *Distance between tonal target and segment boundary, average value for each target word. The first graph shows distance between L and syllable onset, the second between H and offset. A negative number indicates that timing is before the boundary.*

Table 2: *Distance between tonal target and segment boundary (ms), average value for each target word. Standard deviation in parentheses. A negative number indicates that the target is before the boundary.*

	L - syllable onset			H - syllable offset

4. Discussion

This study seems to not support the anchoring of L in the L+H rise of South Swedish Accent II. The rise is surely an important feature of the word accent [10], but if the start of the rise is not constantly aligned it is possible that L is not a phonological event. The end of the rise, the timing of H, might be an important phonological feature. Independent of syllable duration H was aligned within the syllable, on average 40 ms before syllable offset in the case of normal and fast speech, which supports the Lund Model and the accent typology that incorporates the South Swedish dialect. The study would benefit from relative measures of syllable duration, not the least to further establish the location of H, but also to shed light on the variability of L which affected by speech rate occurs both before and after syllable onset (Figure 5 and 6). Future studies would also benefit from addressing the precision of tonal peak measures (a problem in many comparative studies [1]-[3], [5], [6]), and use alternative methodology, such as Tonal Center of Gravity (TCoG) [12].

The data displayed a great variability both between and within speakers. Ladd et al. [3] also observed a similar degree of variability. By excluding certain speakers that seemed to use a different strategy to define pitch accent, they were able to find support for segmental anchoring. It might be that constant alignment is a strategy only for some speakers or that the same speaker uses different strategies for alignment. The proposition by Niebuhr et al. [7] to include speaker strategy in studies on tonal alignment is thus a valid suggestion.

The auxiliary hypothesis that primary features of phonetic properties will try to be retained by speakers, while other features will be allowed to be modified by time pressure might be the case for the normal and the fast rate. The slow rate, however, seemed to divert from the others, which can be seen in the scatter plot with the slow rate being much more scattered than the normal or the fast rate (Figure 4). The anomalies found on slow speech rate have been reported in other studies as well, where difficulties with the slow speech rate seem to have brought forth additional prosodic features to enable the, perhaps, unnaturally slower speech [3]. Even though the results of the study confirmed that the manipulation of speech rate was successful, a future use of speech rate as an experimental tool needs to be further investigated.

The coincidence was pointed out that the rise of the pre-nuclear accent in intonation languages phonetically roughly matched the lexical Accent II in South Swedish. The results, however, did not confirm a phonological match. The start of a rising pre-nuclear accent in an intonation language needs to be anchored, but this does not seem to be the case for a South Swedish Accent II rise. Since evidence was found against L anchoring with syllable onset, the results do not support the revised Lund Model of a LH gesture. Further studies on the anchoring of the LHL tonal gesture in Swedish Accent II are suggested.

5. Acknowledgements

This paper is based on an unpublished master thesis. While working with an earlier version of the thesis I was supervised by professor Gösta Bruce and associate professor Hugo Quené. I am very grateful for having had their excellent supervision in the initial steps of the study. I also want to extend a big thank you to my supervisor Gilbert Ambrazaitis for his invaluable help, advices and enthusiasm.

Abstract

In this work we present a new version of our previously published Optimal Stylization (OpS) algorithm for pitch stylization. Here we give a better perceptual representation of the pitch curve for linguistics research. While the OpS algorithm produced good stylizations for naive listeners, when deployed in a prosodic analysis tool, we observed that, under specific conditions, important details were missed in the stylized curve to an expert's ear. Changes introduced in the dynamic tonal perception model to solve these problems resulted in a simpler and more robust model. We show how the new version of the OpS algorithm is able to recover these situations while not significantly altering the original OpS curves.

Index Terms: pitch stylization, tonal perception, prosody

1. Introduction

Prosodic research focuses on messages transmitted through the use of intonational strategies. While the $F0$ curve is indeed the main correlate of intonation, it does not represent what it is actually *heard* by the human ear. In [1, p. 25], it was stated that *No matter how systematically a phenomenon may be found to occur through a visual inspection of F0 curves, if it cannot be heard, it cannot play a part in communication*. This led to the definition of *stylization* as an approximation of the $F0$ curve by means of linear segments. In [1, p.42], this was defined as a sequence of segments that *[. . .] should eventually be auditorily indistinguishable from the resynthesized original and it must contain the smallest possible number of straight-line segments with which the desired perceptual equality can be achieved*.

Among the attempts to produce an account of the intonational account, the MOMEL algorithm [2] has been widely used in the literature. This algorithm does not produce a *proper* stylization as its goal is to produce a model of the macroprosodic component, which can be used together with the microprosodic component the algorithm produces to rebuild the original pitch curve. In this sense, a stylization should be intended as a lossy filter for microprosody while the output of the MOMEL algorithm does not discard the microprosodic component. Nevertheless, the macroprosodic profile obtained with MOMEL is usually considered as reference for stylization algorithms.

In [3], the concept of dynamic tones, or glissandos, was used in order to produce a stylization of the pitch curve. The Prosogram, a perceptually motivated representation of the pitch curve [4] is based on this algorithm. This representation includes a segmentation of the considered utterance into syllables to represent the pitch curve in terms of glissandos and static tones. In [5, 6], the concept of syllables was used again to position the linear segments used in the stylization. In [7], the pitch stylization problem was treated as an optimization problem for the first time by using a Dynamic Programming algorithm designed to optimize the position of a predefined number of segments estimated on the basis of the findings presented in [8]. As a quality measure, this algorithm used the statistical closeness between the stylized curve and the original one.

In [9], we presented the OpS framework along with an investigation of the possibility of using prominence information to reduce the number of points used to stylize non-prominent areas. The OpS algorithm uses a *divide et impera* strategy to balance a cost measure, based on the number of points used by the stylized curve, and a quality measure. In [9], we showed that statistical closeness does not necessarily reflect the results of the listening test so, in [10], we presented an updated version of the algorithm using a tonal perception model to compute the quality measure. While this model has the same basis of [3], it is dynamic in the sense that it uses the findings of [4] and the indications coming from the experiments with the OpS version using prominence annotation to avoid using rigid thresholds. Also, by retaining the generic OpS framework, it explicitly takes into account the cost of the curve during computation, closely following the definition of stylization.

In this paper, we summarize the parts of the OpS algorithm that have been modified to obtain the new version, we highlight the problems that the algorithm had in retaining certain classes of details that are important for linguistics research and we present the changes we introduced. Qualitative and quantitative tests performed on the same corpus we used for the objective tests in our previous works show that these changes do not alter the OpS curve on a large scale. By means of a case study, we show that the details we were interested in recovering are correctly represented by the new version of the algorithm.

2. The OpS algorithm

In [10], we presented a new version of the OpS algorithm substituting the original quality measure $q(S, \bar{S})$ with a new measure based on a tonal perception model, following the approach of [3]. This tonal perception model was dynamic in the sense that it did not use rigid thresholds to model the human ear's capabilities of perceiving dynamic tones (glissandos). This was achieved by considering the effect energy movements have on tonal perception (i.e. [11]) by taking as reference the Spectral Constraint Hypothesis (SCH) [12] and by relying on a continuous value to describe the *glissando likelihood* Γ_g of a pitch movement based on the findings of [4]. The reader is referred to [10] for details regarding the computation of the Γ_g value. For reasons of space, in this paper we summarize only the parts that we modified to obtain the new version of the algorithm.

First of all, we describe the segmentation strategy adopted during the first phase of the *divide et impera approach*. Given a generic pitch curve, the algorithm splitted this curve into two

subcurves sharing and an endpoint by choosing the first local maximum, if present, and choosing the midpoint otherwise. This is because, by considering them later during the backtracking phase, tonal peaks were implicitly considered more important than other points, as their removal influenced large portions of the final curve.

During the backtracking step of the *divide et impera* schema, the removal of the point shared by two adjacent subcurves $A = [a_1, \ldots, a_n]$ and $B = [b_1, \ldots, b_m]$, with $a_n = b_1$ was evaluated. The two possible mergings of the two subcurves were either the curve where the shared point was kept $S = [a_1, \ldots, a_n, b_2, \ldots, b_m]$ or the curve where it was not $\bar{S} = [a_1, \ldots, a_{n-1}, b_2, \ldots, b_m]$. The overall quality function $F(S)$, computed as the balance between perceptual equality and cost, was compared with $F(\bar{S})$. If $F(\bar{S})$ had a higher value than $F(S)$, the $\bar{S}$ curve was passed to the next backtracking step. For the sake of simplicity, in the following formulas we assume that the two curves being compared have the same number of points. Of course, when the removed point s_i is considered in the $\bar{S}$ curve, $\bar{s}_i$ corresponds to the value obtained by linearly interpolating s_{i-1} and s_{i+1} in t_{s_i}.

To compute the quality of the stylized curves, the algorithm considered the accumulated difference between the original curve and the proposed one in terms of glissando likelihood for each of the segments in the curve, evaluating the risk of introducing a glissando where a static tone was found and vice versa. The distance D between a generic segment $[s_i, s_{i+1}]$ and its stylized counterpart $[\bar{s}_i, \bar{s}_{i+1}]$ was computed as:

$$D([s_i, s_{i+1}], [\bar{s}_i, \bar{s}_{i+1}]) = \\ D_{acc}([s_i, s_{i+1}]) + \Gamma_g([s_i, s_{i+1}]) - \Gamma_g([\bar{s}_i, \bar{s}_{i+1}]) \quad (1)$$

The quality of the $\bar{S}$ curve with respect to the S curve was computed as the weighted mean glissando likelihood accumulated distance over the segments of the $\bar{S}$ curve. The weights were the time portions of the complete curve represented by each segment, thus obtaining:

$$q_g(S, \bar{S}) = \\ \sum_{i=1}^{n-1} \left((1 - |D([s_i, s_{i+1}], [\bar{s}_i, \bar{s}_{i+1}])|) \frac{t_{s_{i+1}} - t_{s_i}}{t_{s_n} - t_{s_1}} \right) \quad (2)$$

The model presented in [10] also takes into account a $q_d(S, \bar{S})$ measure related to differential glissando perception checking that a glissando, if present, is kept as it was. In this paper we concentrate on $q_g(S, \bar{S})$ as the changes we made to this function are simply replicated in $q_d(S, \bar{S})$.

Concerning the cost measure, in [9] it was computed as the ratio between the number of points used by the stylized curve and the number of points found in the original curve transformed with a sigmoid function. After introducing the dynamic tonal perception model, in [10] we reported a problem causing the quality measure to rapidly dominate the cost measure in long, continuous pitch curves and causing the insertion of more target points than necessary. In [10] we counterbalanced this effect by introducing an empirically determined α modifier to augment the weight of the cost factor depending on the length of the curve in the cost function. The cost function used by the OpS algorithm is:

$$c(S, \bar{S}) = 1 - \left(\frac{1}{1 + exp(\frac{-(x^\alpha - 0.5)}{0.1})} \right) \quad (3)$$

where x is the ratio between the number of points used by the stylized curve and the number of points used by the original one.

3. Observed problems

The results of the perceptual tests reported in [9, 10], in which naive listeners were recruited, indicated that the stylization proposals of the OpS algorithm performed, in terms of quality, in a similar way with respect to other approaches. The OpS algorithm had the advantage of being parameter independent and it was able to use less points by explicitly taking into account a cost measure during computation. In [13], we included the OpS algorithm in the Prosomarker tool: an instrument designed to give a perceptual account of the pitch curves and to describe the synchronization of the pitch targets with automatically detected segmental events (syllable boundaries and nuclei). While using this tool to describe simple intonation phenomena, we were able to trace a number of recurring situations in which the OpS algorithm was not able to capture specific classes of details from the curve that appeared to be critical to an expert linguist's ear.

1) In [10] we found that giving priority to local minima if no local maxima can be found in the curve during the splitting phase did not seem to introduce improvements. Not having this rule introduced the possibility that a local minimum was evaluated very early during backtracking. As we have seen, this implicitly assigns less importance to the point because the impact of its removal is evaluated on a limited portion of the curve. This was systematically noticed by the human experts evaluating the quality of the OpS curves while testing Prosomarker, as they were able to detect small discrepancies both in timing and in tonal level of lowering targets in the resynthesis with respect to the original utterance.

2) The quality measure dominating the cost one in long pitch segments was not completely addressed by the introduction of the α parameter. Continuous pitch segments, longer than the ones we tuned α on, were found in other corpora: in these segments the effect was strong enough to make the α weighting useless. The presence of the α parameter is also less motivated from a theoretical point of view than the rest of the model, thus making the framework less reliable than we intended.

3) When local maxima split the curve in two subcurves that are very unbalanced in length, the algorithm was unable to adequately protect the smaller part of the curve. The quality of the longer subcurve was considered more important than the quality of the shorter subcurve that, subsequently, was often overstylized. This was caused by the weighting of each segment dependently of the fraction of time it stylized.

4. The SOpS algorithm

We now present the updates to the OpS algorithm we introduced in order to address the problems we highlighted in the previous section. The final model we obtain is simplified with respect to the preceding version. For this reason, we will refer to the updated version of the OpS algorithm as the Simplified Optimal Stylization (SOpS) algorithm.

To address problem 1, we reintroduced the splitting rule giving priority to local minima if no local maxima can be found. By evaluating these points later during the backtracking phase, the SOpS algorithm is able to protect low targets better than the OpS algorithm. Problems 2 and 3 were both related to the measure we used to evaluate shared endpoints removal during backtracking. Specifically, having the whole subcurves influ-

ence the quality measure introduced the problems related to differences in the curves' length. However, the removal of the shared endpoint, while generically influencing the quality of the two curves' mergings, is more specifically related to the quality of the two neighboring *segments*. Back to the preceding example, given the A and B curves, the removal of the shared point $a_n = b_1$ only influences the quality of the $[a_{n-1}, a_n]$ and $[b_1, b_2]$ segments. Therefore, having the quality evaluation of the curves $[a_1, a_{n-1}]$ and $[b_2, b_m]$ contributing to the evaluation introduces an identical factor on both sides of the comparison operator. Eliminating this factor makes the algorithm take into account only the neighboring segments quality. By weighting equally these two segments, we also remove the effect of longer movements being considered more important than shorter ones. Equation 2 is reformulated as

$$q_g(S, \bar{S}) = \{2 - |D([s_{i-1}, s_i], [\bar{s}_{i-1}, \bar{s}_i])| - |D([s_i, s_{i+1}], [\bar{s}_i, \bar{s}_{i+1}])|\}/2 \quad (4)$$

Also, by considering local minima earlier in the splitting phase of the *divide et impera* schema, the *midpoint split* rule is applied to segments that are either quasi-linear or parabolic. In the first case, small differences are introduced by removing points while, in the second case, the *midpoint split* rule rapidly produces quasi-linear segments. This way, early evaluated points are more concerned with small details mainly depending on energy and pitch interactions, while lately evaluated points are more related with the description of larger prosodic events. Because of this distinction, it is not necessary to retain the fine details produced by the early backtracking steps up to the points controlling medium/long range pitch movements. Since the changes introduced by removing these points become very evident by delaying their evaluation to the latest steps of the backtracking process, the influence of the fine details on the decision process is not relevant. We therefore modified Equation 1 so that it does not keep track anymore of the preceding stylization steps obtaining the new formulation

$$D([s_i, s_{i+1}], [\bar{s}_i, \bar{s}_{i+1}]) = \Gamma_g([s_i, s_{i+1}]) - \Gamma_g([\bar{s}_i, \bar{s}_{i+1}]) \quad (5)$$

Concerning the cost measure, in [9] we used the sigmoid transformation of the ratio between the number of points used by the stylization and the number of points used by the original curve so that [9, p. 1994] values of the cost measure at one end of the scale would not have been very different. As the impact revealed itself to be negative with respect to the evaluation of the quality/cost balance, we now consider the untransformed ratio represented as x in Equation 3 as cost measure.

5. Test material

For the presented evaluations we employed the 382 files of the prominence annotated TIMIT subset used in [14] to test automatic methods for prominence detection. This dataset was chosen for the curves cost evaluation we presented in [9] because we needed a large set of prominence annotated speech samples to evaluate the impact of using prominence information in a pitch stylization task. The same dataset was used for the cost related tests in [10]. In this work, we use the same dataset for qualitative, other than cost, evaluation because our goal is to check that the new approach does not introduce detectable changes on a large scale as we are interested in recovering only the details the OpS algorithm was missing. The dataset consists of 382 files containing 20 minutes of read speech extracted from the TIMIT corpus.

6. Results

From the quantitative point of view, we considered the number of points used by the SOpS algorithm with respect to OpS. The SOpS algorithm, on the considered dataset, uses 3.46 points per second (Pps) while the OpS algorithm uses 3.59 Pps. Table 1 shows a summary of the cost test between OpS, SOpS and an older version of the OpS algorithm employing manual prominence annotation called OpSProm [9].

Table 1: Cost test results.

	OpS	SOpS	OpSProm
Points per second	3.59	3.46	3.47
Total points	4118	4007	4009

A paired t-test indicated that the difference in Pps between OpS and SOpS is not statistically significant ($p > 0.01$). However, close inspection of the pitch curves where the OpS algorithm introduced more points than necessary showed that the SOpS algorithm does not suffer from this problem. The amount of reduction observed (0.13 Pps) and the actual p-value (0.012) are coherent with the goal we had of reducing the number of points used only in specific areas. The performance of the SOpS algorithm in terms of Pps is much more similar to the one we obtained with the OpSProm algorithm. A paired t-test between the Pps measures obtained by SOpS and OpSProm confirms this ($p > 0.9$) with greater certainty with respect to the result we presented in [10], where we stated (p. 205) that the difference between OpS and OpSProm, while not significant ($p > 0.01$), was to be taken carefully as the actual p-value was 0.0142.

From the qualitative point of view, a Wilcoxon test on the differences between curves generated by the two algorithms showed that the location shift is not significant ($p > 0.4$). The size of the considered dataset makes it safe to assume that no significant differences can be found between the curves proposed by the two algorithms on a large scale. This result confirms that the modifications introduced by the SOpS algorithm do not alter the stylized curve up to a statistically detectable degree. Close inspection of the cases on which the new model is intended to perform better, however, show that the details the OpS algorithm was not able to retain are correctly modeled by the SOpS algorithm.

7. Case study

In Figure 1, we show the detail of a pitch contour, the stylization proposed by the OpS algorithm (dashed line) and and the alternative proposed by the SOpS algorithm (dotted line) along with the energy profile. While the two algorithms perform identically on the first movement, the final rise/fall sequence is described differently. Since the curve's portion after the peak is much shorter than the rest of the curve, protecting the final lowering movement was considered not valuable enough by the OpS algorithm. This decision is encouraged by the tonal perception model as the rising movement preceding the final fall is synchronized with a rising energy profile, thus lowering the modeled glissando perception capability. The influence of sections that do not depend by the point being evaluated also plays

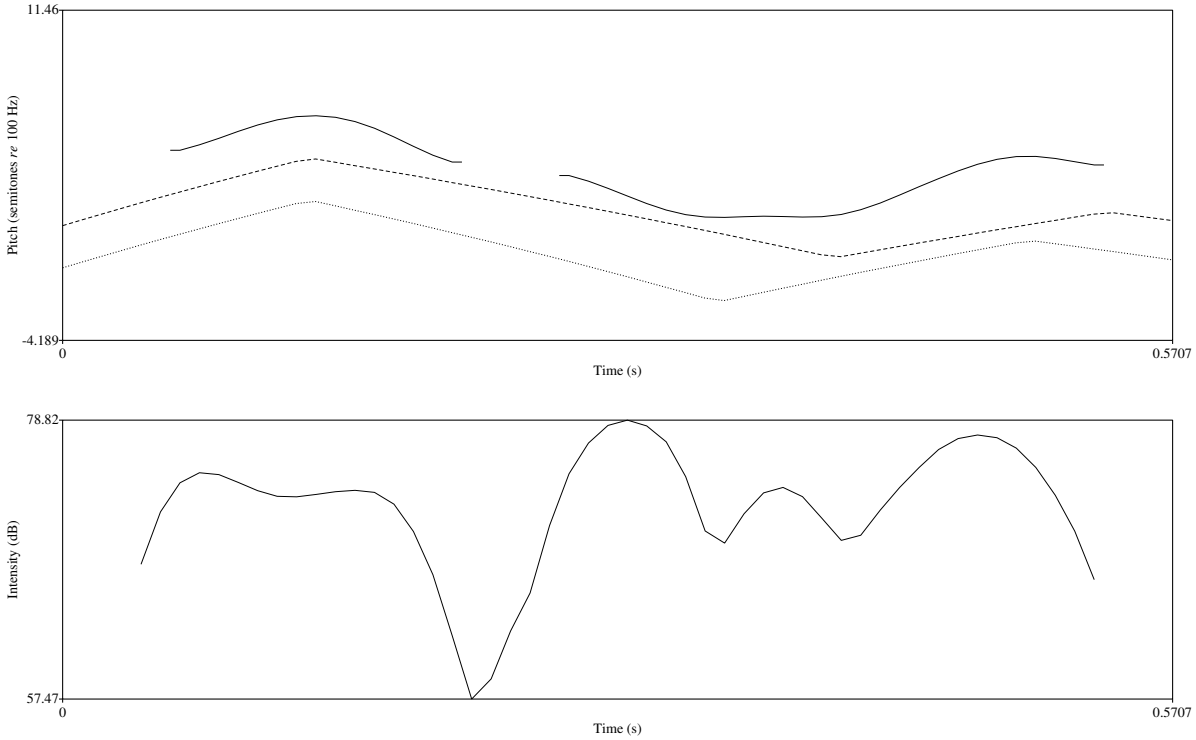

Figure 1: A pitch contour (solid line) along with the OpS stylization (dashed line) and the SOpS one (dotted line). The stylized curves are shifted by 2 Semitones each with respect to the original one for visualization purposes. Along with the pitch curve, the energy profile of the considered speech fragment is shown.

a role, as discussed before. The SOpS algorithm, by considering only the neighboring subcurves and by weighting them equally, is able to protect the final movement when evaluating the peak point, as expected because of the synchronized falling energy contour. The turning point before the rise is shifted 60ms earlier because of the segmentation strategy giving more importance to local minima. This improves the representation of the subcurve synchronized with the falling energy movement. The following pitch rise, synchronized with a rising energy contour, is more stylized than before, so no points are added. From perceptual inspection, this choice appears to improve the overall quality of the curve used in the example. The audio files of the original utterance from which the provided example is extracted are attached to this paper together with the resynthesis obtained with the OpS and SOpS curves. The magnitude of the changes the SOpS algorithm introduces with respect to the OpS curves are, in general, similar to the ones shown in the example. This explains why the similarity test based on statistical closeness is not able to detect a significant difference between the two algorithms. Being these changes important for an expert listener, however, we are in line with out observation that statistical closeness measures are not good estimators of a stylized curve's quality [9].

8. Conclusions and future work

We have presented the SOpS algorithm, an evolution of the OpS algorithm achieving better precision in stylizing specific details of the pitch curve that are important for an expert's ear. The SOpS algorithm is based on a simplified version of the dynamic tonal perception model used by the OpS algorithm. While the curves produced by the SOpS algorithms do not differ in a statistically relevant way from the original OpS curves in a qualitative and quantitative sense, we have shown that close inspection of the details we were interested in recovering are correctly represented by the SOpS stylization, thus obtaining a better representation of the *perceived* intonational profile that can be used in prosodic research. Concerning the number of control points used, we have shown that the new algorithm obtains results more similar to the ones we reported by using manual prominence annotations without altering the produced curves in a significant way. Therefore, the perceptual model behind the SOpS algorithm produces representations of the pitch curve that are both more precise and essential than the ones produced by its predecessor on fine intonational details. The simplified version of the dynamic tonal perception model will make it easier, in the future, to introduce the full range of changes indicated by the SCH, as we are currently considering energy only. The SOpS algorithm is implemented as a Python module of the Prosomarker tool, which is freely available for research purposes.

9. Acknowledgements

This work was supported by the European Community, within the FP7 SHERPA IP #600958 project. We would like to thank all the people who used the Prosomarker tool and gave us the necessary feedback to improve the OpS algorithm.

Interpersonal factors affecting tones of question-type utterances in Japanese

Abstract

The purpose of this paper is to clarify the interpersonal factors affecting phrase final tones of question-type utterances in daily conversations. We extracted question-type utterances ending with final particles from our Japanese dialogue speech database and classified them into two categories according to the degree of information request. Prosodic features were then analyzed by focusing on phrase final F0 movement and pitch reset. Analysis results indicated that F0 rising and falling degrees increase when the speaker expresses an attitude of intimacy to the dialogue partner, such as in conversations among family members and infant-directed speech. In addition, the presence of pitch reset in the phrase final was found to have functions of relieving the speaker's tension, when the dialogue partners have distant relationship.

Index Terms: question, intonation, interpersonal relationship

1. Introduction

In daily conversations, question is one of the most commonly-used speech acts. In general, a question is premised on the presence of an interlocutor. Therefore, it is a speech act peculiar of dialogues, being a key to understand the details in dialogue communication.

In general, it is important for raising the intonation of question-type utterances in Japanese. For example, it is stated that if the pitch of phrase final is lowered, it sounds like a cross-examination [1]. Therefore, an incorrect use of the phrase final intonation may cause misunderstandings in communication. Further, Japanese learners should acquire the phrase final intonation of questions [1].

There are many researches on prosodic analysis of questions in natural conversations. For example, in [2] the prosody of questions has been investigated in natural Swedish conversations, revealing that prosody differs according to the different types of questions. It was reported that yes-no questions generally have a falling intonation, whereas wh questions generally have a rising intonation in Swedish. In [3], terminal intonations of questions extracted from conversations between a doctor and a patient in Dutch have been examined. It was found that terminal F0 rises have higher values in the order of wh questions < yes/no-questions < declarative questions, in male speech. We also have investigated questioning prosody extracted from daily conversations in Japanese [4][5][6]. In our previous studies, we pointed out that the occurrence rates of non-rising tones increase in question types where the speaker assumes that the interlocutor does not necessarily hold the answer information.

These researches are mainly focused on the types of questions (e.g. yes-no questions, wh questions and so on). Although these approaches are effective to reveal prosodic variability of questions, one also should concern with another factor, namely interpersonal relationship between the dialogue partners. It is well-known that infant-directed speech (**IDS**) has some characteristic prosody relative to adult-directed speech (**ADS**) [7]. In [7], the prosodic modifications (such as higher mean-f0, f0-minimum and f0-maximum, greater f0-variability, shorter utterances and longer pauses) of IDS have been analyzed. In [8], it has been revealed that the voice quality parameter "NAQ" varies according to dialogue partner. As seen above, it is clear that the interpersonal relationships affect the speech prosody in various ways.

We have reported that phrase final tones of questions are varied according to the hierarchical relations or familiarity [4][5][6]. For example, if the interlocutor has higher status relative to speakers (e.g. senior staff), F0 of phrase final syllables are significantly lower than that of lower status (e.g. junior staff) or equal footings (e.g. colleague). These previous studies, however, were not conditioned about question types and phrase final part-of-speech information.

In this study, we aim to clarify the interpersonal factors which affect the prosodic modification of question-type utterances. Our previous research had made the result with combined all phrase finals, such as final particles, auxiliary verbs and without suffixes. Under that condition, it was unclear whether the difference in intonation was caused by morphological or interpersonal factors. Thus, in the present work, we constraint our analyses to questions ending with final particles.

2. Materials and methods

2.1. Speech data

We used a Japanese conversational speech database recorded in ATR/IRC labs, which was also employed in our previous studies [4][5][6]. The database has 69 dialogue sessions including 31 speakers (12 adult males, 15 adult females, 2 young child males and 2 young child females). "Young child" means pre-elementary school (age under 6) in this study. Each dialogue session has 10 to 15 minutes, face-to-face communication and no specific tasks (topic-free conversations). The total duration of speech data is about 900 minutes. Different types of interpersonal relationships between the dialogue partners are included, for example, mother/father-son/daughter, superior-subordinate, friends, first meets, and so on. Some speakers participated in multiple sessions talking with different interlocutors.

Simultaneous recordings of speech and EGG (electro-glottograph) signals are available in this database. Sampling rates are 16 kHz/16 bits. Audio data is recorded using directional microphone (Sanken CS-1). In part of the dialogue sessions, headset microphone data is also available.

2.2. Extraction of question-type utterances

The speech utterances in the database are segmented in phrase units based on pauses and clear pitch resets between phrases. 2~4 native Japanese speakers evaluated each utterance from the standpoint of turn-taking function (turn-keeping, turn-yielding, backchannel, and fillers). In the present work, we employed the turn-yielding utterances where 2 or

more annotator's judgments agreed. As a result, we got 4231 utterances from the database.

For each of the utterances, question types were annotated by 3 native speakers (research assistants). We used the same label set of question types used in our previous research [5][6]. The agreement rates (in terms of Kappa coefficients) among the question type labels by each pair of annotators were .77, .75 and .68. We use the utterances where 2 or more annotators agreed for the subsequent analysis.

We then separated these question types according to the degree of information request. The category of question types expressing higher degree of information request includes: *Yes-No questions* (n=1258), *Information request* (451), *Subjective feedback request* (317), *Repetition request* (39) and *Counter-questions* (16). The category of question types expressing lower degree of information request include: *Quiz-type questions* (n=8), *Agreement request* (979), *Open-type questions* (159), *Backchannel-type questions* (377), and *Self-questions* (161). We call the former category as "**HIR**: Higher degree of Information Request" and the latter category as "**LIR**: Lower degree of Information Request" hereafter. By the above procedure, we got 2081 utterance in HIR and 1684 utterance in LIR (total size is 3765).

2.3. Parameterization of phrase final tones

There are many acoustical candidates and categorizing method for phrase final tones. For example, the difference between the average pitch of the first half and the second half of the question is used in [1] for rough estimate of the rising or falling intonation. J_ToBI and X-JToBI are well-known prosodic labeling schemes [11][12]. The latter is particularly adjusted for spontaneous speech descriptions and used in the "*Corpus of Spontaneous Japanese*". In the present study, however, we employ a set of parameters proposed in [9][10] for description of phrase final tones, on the grounds that these parameters are based on human's perception. Five tone categories are used in the present work, namely Rise, Flat, Fall, Reset-Flat and Reset-Fall. Added to this, parameters can be automatically extracted by the procedures described below.

For phrase final duration, an automatic procedure was first realized, by using power and spectral change constraints [9]. And then the errors in the automatic segmentation were manually corrected. The newly segmented boundary intervals are used as segmental duration of the phrase finals.

For the pitch-related parameters, F0 values are first estimated based on a conventional method of picking peaks in the normalized autocorrelation function. F0 was extracted for both speech and EGG signals available in the database. However, the speech signals are used only when the EGG signals are not available in the database. For speech signal, the auto-correlation of the LPC inverse-filtered residue of the pre-emphasized signal was used, while for the EGG signal, the autocorrelation of a high-pass filtered signal with 70Hz cutting frequency (for removing DC and low frequency movements) was used. All estimated F0 values are then converted to a musical (log) scale.

The phrase final is split in two segments of equal length, and representative F0 values are extracted for each segment. Several candidates for the representative F0 values have been tested in [9]. Here, we use the ones that best matched with perceptual scores of the F0 movements. For the first segment, an average value is estimated using F0 values within the segment (*F0avg2a*). And for the second segment, a target value is estimated as the F0 value at the end of the segment of a first order regression line of F0 values within the segment (*F0tgt2b*). A variable called *F0move* is defined as the difference between *F0tgt2b* and *F0avg2a*, quantifying the amount and direction of F0 movement within the syllable.

F0move = F0tgt2b - F0avg2a

In this study, phrase finals are categorized as rise pitch movements when *F0move* > 1 semitone & duration > 100 ms, fall pitch movements when *F0move* < -1.3 semitone & duration > 100 ms, and flat pitch movements otherwise.

A parameter called *F0reset* is another important factor in categorizing the phrase final tones. This parameter indicates the presence or absence (or degree) of pitch reset between the phrase final and the syllable prior to the phrase final. The degree of pitch reset is defined as follows:

F0reset = F0avg2a - F0avg_p

F0avg_p is an average F0 value of the final portion of the syllable preceding the phrase final. *F0avg_p* is estimated from four reliable F0 values obtained by back-tracking and searching from the phrase final start point. A pitch reset is judged to be present when *F0reset* > 1 semitone.

The thresholds above were based on pitch movement perception experiments. From the utterances where agreement was obtained for the question type annotations, the ones where F0 could not be extracted and is unclear were removed from the analysis, resulting in a total of 2,226 utterances. We randomly picked 758 utterances for perception experiments. 3 annotators labeled each utterance according to the 5 tone categories (Rise, Fall, Flat, Reset-Fall and Reset-Flat). The agreement rates (in terms of weighted Kappa coefficients: Rise > Reset-Flat > Flat > Fall > Reset-Fall) among the tone category labels of the 3 annotators were 0.75, 0.61 and 0.57. The automatically classified tones under the above criteria were also checked for agreement with annotator's decision. The agreement rates (in terms of weighted Kappa coefficients) between above criteria and the 3 annotators were 0.68, 0.65 and 0.52.

Extracted phrase final tones according to the degree of information request, HIR and LIR, are shown in Table 1.

Table 1. Distribution of the phrase final tones classified according to degree of information request (HIR/LIR: Higher/Lower degree of Information Request). The numbers indicates the occurrences.

Tone	*HIR*	*LIR*	*Sum*
Rise	749 (62.8%)	319 (30.9%)	1068 (48.0 %)
Reset-Flat	88 (7.4%)	136 (13.2%)	224 (10.1 %)
Flat	25 (21.0%)	257 (24.9 %)	508 (22.8 %)
Fall	76 (6.4%)	152 (14.7 %)	228 (10.2 %)
Reset-Fall	29 (2.4%)	159 (16.4 %)	198 (8.9 %)
Sum	1193	1033	2226

2.4. Classification of phrase final morphemes

Linguistic information about the part-of-speech and morphemes appearing at phrase finals was taken into account when verifying the influence of tones. For example, the occurrence rate of rising tones at the last syllable of questions

was about 30 % in phrases ending with final particles, while it was over 60% in phrases not ending with final particles (e.g. nouns) [5].

For classification of phrase final morpheme and part-of-speech, we used the free part-of-speech and morphological analyzer software "MeCab" [13] (the dictionary used was UniDic [14]). Because of the spoken style of the utterances in the database, we checked and corrected the output from MeCab which mainly attempt to analyze written language. In this study, we selected the phrases ending with final particles.

Table 2 shows the distributions of the phrase final particles (top 3) according to the degree of information request, HIR and LIR. The total numbers of final particles were 391 in HIR and 660 in LIR.

Table 2. Distributions of the phrase final particles (top 3) according to the degree of information request (HIR and LIR). The number indicates the occurrences.

HIR		*LIR*	
/no (N)/	235 (60.1%)	/yone/	117 (17.7 %)
/ka/	115 (29.4%)	/ne/	110 (16.7 %)
/Qke/	14 (3.6%)	/na/	98 (14.8 %)

2.5. Criteria for analysis of interpersonal relationship

The aim of this section is to clarify if phrase final prosody could change according to the distance in the interpersonal relationship between the dialogue partners. For the subsequent analysis, we select the speakers according to the interpersonal relationship under the following criteria.

1. Speakers who have dialogue sessions with both young child and adult speakers.
2. Speakers who have dialogue sessions with his/her family member and others (only adult speakers).
3. Speakers who have dialogue sessions with acquaintances and with someone else for the first meeting (only adult speakers).

In case 1, we attempt to verify how *F0move* of phrase finals vary at questioning utterances of IDS and ADS in HIR and LIR. Under this condition, we got 5 speakers in HIR and 4 speakers in LIR. In cases 2 and 3, we attempt to verify how *F0move* or *F0reset* vary according to the degree of closeness (intimacy) in their interpersonal relationships. The purpose of case 2 is to verify whether the prosodic features of IDS appear in similar situations or not. Generally speaking, talking with a young child is a stress-free situation and the speaker's attitude tends to be friendly. This situation is thought to be similar to when talking with family members. Under this condition, we got 4 speakers in HIR and 5 speakers in LIR. The purpose of case 3 is to consider whether or not the speaker changes the prosody of questions when talking with a completely unknown person (for the first meeting). Under this condition, we got 7 speakers in HIR and LIR.

3. Analysis Results and Discussions

3.1. *F0move*: for young children or adults

Fig. 1 shows the average *F0move* in semitones when the interlocutor is young child or adult, in HIR and LIR conditions.

As **Fig. 1** indicates, when the interlocutor is a young child, *F0move* in the final particle is significantly higher than that of adult at HIR (Welch Two Sample t-test; t (48.1) = -2.8, p < .01). On the other hand, *F0move* for young child is significantly lower than that for adult at LIR (t (58.1) = 2.1, p < .05). No significant differences were found in *F0reset* in both conditions (HIR: *F0reset* for young child is -0.46, for adult is 0.98, t (37.9) = -0.4, *ns*; LIR: for young child is 1.97, for adult is 2.02, t (62.6) = 0.1, *ns*).

These results mean that the typical prosody to young child at HIR questions is exaggerated in rising tones. At LIR, on the other hand, we can notice that the falling tones are exaggerated for young child. The typical question prosody of LIR ending with final particles is a reset-flat (F0move > -1.3) when the interlocutor is an adult, while it becomes a reset-fall (F0move < -1.3) when it is a young child.

These results agree with a past study on Infant-directed speech (IDS), where it was mentioned that IDS has greater F0 variability than adult-directed speech (ADS) [7].

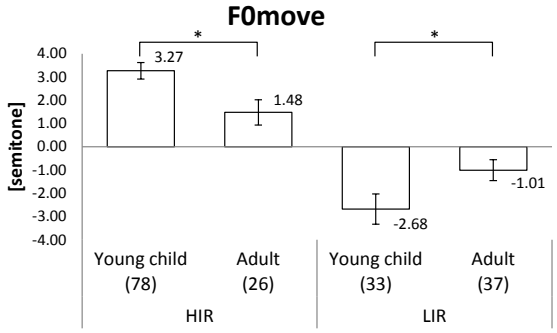

Fig. 1 Average *F0move* for young child/adult at HIR and LIR questions. The numbers in parenthesis indicate the numbers of occurrences.

3.2. *F0move*: for family members or others

Fig. 2 shows the average *F0move* in semitones when the interlocutor is family member or others, in HIR and LIR conditions.

As can be seen in **Fig. 2**, when the interlocutor is a family member, *F0move* of the final particle is significantly higher than that in others, at HIR (t (66.8) = 2.7, p < .05). On the other hand, *F0move* for family member is significantly lower than that for others at LIR (t (120.4) = 2.0, p < .05). *F0reset* is significantly different at LIR but not at HIR (HIR: *F0reset* for family member is -0.73, for others is 1.64, t (57.4) = -1.6, *ns*; LIR: for family member is 3.70, for others is 1.59, t (113.0) = 2.0, p < .05).

Fig. 2 indicates a similar tendency to **Fig. 1**. F0move is exaggerated for family members at HIR and LIR conditions. It is interesting to note that tone categories at both conditions for others are flat (i.e. -1.3 < *F0move* < 1). This result suggests that questions for others have the tendency to become a reset-flat tone. In other words, flattened F0 movements (i.e., repressed rising and falling degrees) in final particles appear in a relatively formal dialogue situation. In our previous study about questioning tones [4], it has been reported that if the interlocutor has higher status relative to the speaker (e.g. senior staff), *F0move* of phrase final syllables were significantly lower than that of lower status (e.g. junior staff)

or equal footings (e.g. colleague). And in [6], we showed that the occurrence rate of rise tone of question is lower when the speaker feels concern for the interlocutor (e.g. elderly) than that of "no concern" situation. These previous studies, however, were not conditioned on the part-of-speech of phrase finals. Generally speaking, speakers are required a formal speech style when talking with someone who has higher status or when feeling concern for the interlocutor. The results of the present work, where the part-of-speech of phrase finals is constrained to final particles, also support the results above.

It has been pointed out in [15] that a rising intonation at phrase finals in Japanese indicates a relatively heavy attitude of speakers. In other words, rising tone has a strong attitude of requesting an answer to the interlocutor. From this point of view, it seems reasonable to suppose that it is easier to speakers exposing their attitudes for family members. Consequently, the degree of *F0move* at HIR for family members becomes higher than that for others. In addition to the features of rising tones, the degree of falling can also be interpreted as showing strong attitudes at LIR condition (i.e. requesting agreement).

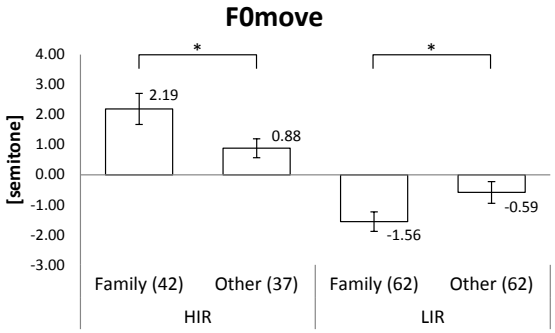

Fig. 2 Average *F0move* for family-member/others at HIR and LIR questions. The numbers in parenthesis indicate the numbers of occurrences.

3.3. *F0reset*: for acquaintances or first meets

Fig. 3 shows the average *F0reset* when the interlocutor is an acquaintance or a person of first meeting, in HIR and LIR conditions.

As **Fig. 3** indicates, when the interlocutor is a person of first meeting, *F0reset* is over 1 semitone (i.e. pitch reset is present) at both conditions (HIR and LIR). On the other hand, *F0reset* is lower than 1 semitone for acquaintance at both conditions. These differences are significant (HIR: t (91.5) = 2.1, $p < .05$; LIR: t (212.2) = 2.0, $p < .05$). In contrast, *F0move* didn't show significant differences in both conditions (HIR: *F0move* for acquaintance is 0.77, person of first meeting is 0.70, t (82.4) = -0.1, *ns*; LIR: for acquaintance it is -0.62, and for person of first meeting it is -1.23, t (213.1) = -1.7, *ns*).

As we mentioned in the previous section, speakers tend to be mindful of the questioning manner, according to the interpersonal relationship (to raise or drop in phrase final tone at HIR or LIR). Although significant differences did not appear, values of *F0move* are in the range of flat tones at HIR and LIR conditions (i.e. -1.3 < *F0move* < 1). It is thought that the effect of repressing the degree of rising or falling tones in relatively formal situations is reflected in this result.

In addition to this observation, **Fig. 3** showed another aspect of tone functions. Speakers clearly use pitch reset in questions at HIR and LIR conditions for completely unknown people (*F0reset* > 1). It has been described in [15] that pitch reset ("ukiagari-tyo" in their term) at phrase finals means speaker's light attitude. Although the participants of recordings can stop the dialogue at any time, they usually try to be friendly by continuing the conversation in smooth manner. Considering this situation and the description in [14], pitch reset at phrase final particles in question utterances can be interpreted as having functions of relieving the tension or showing a friendly attitude of the speaker.

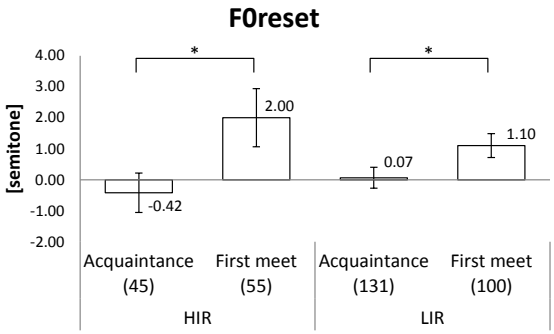

Fig. 3 Average *F0reset* for acquaintance/first meet at HIR and LIR questions. The numbers in parenthesis indicate the numbers of occurrences.

4. Conclusions

We conducted quantitative analysis on free conversational dialogue database, for clarifying the functions of phrase final tones in questions, from an interpersonal relationship viewpoint. Question-type utterances were classified into two categories on the basis of degree of information request (HIR and LIR). The analysis results indicated that:

1. The degree of F0 rising at HIR questions and the degree of F0 falling at LIR questions are exaggerated when talking with a young child, in comparison to when talking with an adult.
2. Similarly, the degree of F0 rising at HIR questions and the degree of F0 falling at LIR questions are exaggerated when talking with a family member, in comparison to when talking to others.
3. The degree of F0 reset at the phrase final syllable is higher when talking with a person of first meeting at both HIR and LIR questions, in comparison to when talking with an acquaintance.

It is inferred from these results that an increase of raising degree at HIR question and lowering degree at LIR question can be regarded as an attitude of intimacy to the interlocutor. In addition, the presence of pitch reset at the final particles can be interpreted as having functions of relieving the speaker's tension.

Prosodic correlates of perceived quality and fluency in simultaneous interpreting

George Christodoulides[1], *Cédric Lenglet*[2]

Abstract

This study explores the relationship between prosodic features specific to simultaneous interpreting and the listeners' perception of the fluency and accuracy of interpreting, as well as their comprehension of the source speech. Two groups of participants (47 subject experts and 40 non-experts) listened to a 20-minute lecture in German, along with its interpretation into French under two conditions (the actual interpretation, or a read-aloud rendition of the same text by the same interpreter) and answered comprehension and rating questions. The prosodic features of the two conditions were analysed, and differences regarding the temporal organisation of speech, disfluencies, pitch register and the interface between prosody and syntax emerged. Our results suggest that interpreting-specific prosodic features affect the perception of fluency, which in turn affects the perception of accuracy. However the impact on listeners who enjoy relevant contextual knowledge is less pronounced.

Index Terms: speech perception, quality of simultaneous interpreting, fluency

1. Introduction

Simultaneous conference interpreters facilitate multilingual communication in political, technical and other meetings. Typically, they work in soundproof booths, translating speech in real-time so that the participants can follow the debate in their language, without interruption. They are expected to "communicate the speaker's intended messages as *accurately, faithfully, and completely* as possible (…) and to *be clear and lively in [their] delivery*" [1, original emphasis]. Since prosody conveys important information in human communication (e.g. information status, focus, intent, emotion), the interpreter is expected to decode such information from the prosodic structure of the source language (SL) and encode it in parallel constructions in the target language (TL). This 'translation' of prosodic information, along with the linguistic information, from SL to TL inspired studies on the correspondence, or alignment, of prosodic patterns across languages (e.g. [2] where an algorithm is proposed to find equivalences between clusters of intonation patterns in a parallel bilingual corpus).

Beyond these conscious *choices* made by the interpreter, however, the prosodic features of SI are influenced by two *constraints*: the reformulation process of translation and the high cognitive load induced by the task itself [e.g. 3]. SI strategies such as stalling (i.e. waiting for enough input before producing a translation or committing to a syntactic structure) and anticipation (i.e. predicting part of the speaker's input) [4: 201] affect the temporal structure of interpreters' speech. Speech produced under high cognitive load presents specific characteristics, including a lower articulation rate, longer silent pauses, an increased number of filled pauses, corrections and restarts, as well as alterations in voice quality [5, 6, 7].

Surveys among users of simultaneous interpreting suggest that they consider accuracy (or fidelity) to be a crucial quality criterion, whereas prosodic features, such as intonation or accent, are not deemed paramount [8]. However, many users cannot assess the interpreters' accuracy because of their lack of knowledge of the source language. Instead, the users' perception of SI quality may depend on the prosodic features of the interpreters' speech, including intonation, hesitations and pauses. Moreover, the interpreters' liveliness appears to influence the listeners' understanding of the speech content [9, 10]. In other words, the core objective of SI, namely to "produce the same effect on [the listeners] as the original [speech] does on the speaker's audience" [10: 155], might depend not only on what the interpreters say, but also on *how* they say it.

The link between quality perception and prosody is all the more important in SI, as previous research indicates that SI has a distinctive prosodic profile. It results from the interplay of the choices and constraints outlined above, as a speaking style determined both by the situational context and by individual characteristics [c.f. 11, 12]. A particular prosodic profile for SI has been observed in studies for at least the following language combinations: Hebrew to/from English, with a large number of "low-rise non-final pitch movements" [13: 231]; English to German, with "long pauses [and a] high proportion of final pitch movements that indicate a continuation" [14: 72]; and English to French, with less numerous and longer silent pauses, and a narrower pitch range compared to the source speech [15].

Fluency has been regularly used as a quality criterion in expectation surveys on SI [8], although it is a polysemous concept. In ordinary language, fluency refers to general (often foreign) language proficiency, whereas a more technical definition associates fluency with speech flow and absence of disfluencies such as pauses, hesitations and repetitions [16: 537]. Experimental research has shown that these temporal features do not only influence the perception of the interpreter's fluency, but also that of its intonation [8: 67]. Listeners asked to rate "fluency" seem to blend temporal features with intonation (e.g. pitch variation). Consequently, it seems appropriate to merge these parameters in a perceptual study.

Does the particular prosody of SI have an impact on its perception? To date, most studies on prosody and quality in SI are based on carefully doctored speeches [8, 9]. Consequently, their findings cannot be linked directly to the perception of the *authentic* prosody of SI. Shlesinger [13] conducted a small-scale experiment on the impact of authentic SI prosody on 15 listeners' understanding of speech content, comparing excerpts of speeches produced under two different conditions: read aloud from a script and interpreted simultaneously. In a

listening test, the subjects' scores in the "read-aloud" condition were approximately twice as good. She concluded that SI intonation affected meaning and perception, but she argued that this effect would be counterbalanced in the case of authentic conference participants with the relevant contextual knowledge [13: 234]. Our experiment aims to answer the following research questions: Does simultaneous interpreting from German into French have particular prosodic features? If yes, do these features influence the listeners' objective and subjective understanding of the speech content, and their perception of the interpreter's fluency and accuracy?

2. Method

2.1. Perceptual Experiment

Our goal was to create a situation as close to authentic SI as possible. The original speech is an abridged presentation on investment strategy by a German fund manager; its duration is 20 minutes. German was selected as the source language in order to increase the likelihood that French-speaking listeners rely on the interpreter only. A professional conference interpreter (male, French native speaker, 6 years of experience) interpreted the German presentation into French in a state-of-the-art interpreting booth. The recording of this interpretation was transcribed; punctuation was added at syntactically-complete clause boundaries; discourse markers and interjections were included in the transcription (only filled pauses, e.g. 'euh', were omitted). The same interpreter read the transcript, after rehearsing it, and was recorded in a booth. We thus obtained two different prosodic profiles by the same speaker: under authentic SI conditions; and prepared reading, without the cognitive constraints of SI. The two versions were synchronized to the video of the original presentation using *Praat, Audacity* and *AviDemux*.

The experimental design is a conference simulation adapted from [9]. The subjects watch the video of the German presentation and listen to an interpretation into French. An interpreter pretends to work in a booth at the back of the room. This creates the impression of a live interpretation, whereas actually, the subjects are listening to one of the recordings, according to the experimental condition they were assigned to.

The subjects were 87 French-speaking university students: 47 students of economics and 40 translation students. Students in economics were chosen because of their specialized knowledge and their greater availability than professional economists. Translation students were chosen in order to control the influence of prior thematic knowledge. The subjects were matched for academic performance (based on grade records) to control memory and prior knowledge. The resulting pairs were randomly distributed between two experimental conditions: interpreted and read-aloud speech.

We use a listening comprehension test and an assessment questionnaire, which we both pretested extensively. The listening test consists of 3 multiple-choice and 4 half-open questions and assesses the comprehensibility of the speech with a listening score (interval scale). In the assessment questionnaire, the subjects are asked to rate on a 7-point ordinal scale how fluent the interpreter's delivery was (Fluency), how well they think they understood the lecture (Subjective Comprehension) and how accurately they reckon the interpreter rendered the speech (Accuracy).

2.2. Linguistic and Prosodic Analysis

The two recordings (SI and Read) were orthographically transcribed in Praat [17]. We obtained a phonetic transcription as well as an automatic segmentation of words, syllables, phones and pauses, automatically using EasyAlign [18]; the alignment was corrected manually. A 'delivery' tier was added to annotate articulation-related (schwa, creaky voice, liaison and elision) and paralinguistic phenomena (audible breath, noises). Part-of-speech tagging and multi-word unit detection were obtained automatically using DisMo [19] and subsequently verified manually. We applied an annotation scheme for disfluencies based on [20]: i) single-token disfluencies: filled pauses, hesitation-related lengthening, lexical false starts and intra-word pauses; ii) structured disfluencies: repetitions (of one or more words), deletions, substitutions, insertions, and complex combinations of the above.

To process our data we used *Praaline* [21], a toolkit that interfaces with *Praat* and runs a cascade of scripts and/or external analysis tools, each of which may add features to an annotation level (e.g. syllables, words etc.), stored in a relational database. We applied *Prosogram's* [22] two-step algorithm for pitch stylisation: for each syllable, vocalic nuclei are detected based on intensity and voicing, and then the f_0 curve on the nucleus is stylised into a static or dynamic tone, based on a perceptual glissando approach. Syllabic prominence was estimated with *ProsoProm* [23], *Analor* [24], and a manual perceptual annotation was also performed (cf. 2.3). Segmentation into accentual and intonational phrases was performed by an expert annotator (taking into account all prominence scores); furthermore, perceptually-motivated prosodic boundaries were calculated based on the approach proposed in [25]. Several aggregate measures were calculated using *ProsoReport* [12]. In order to study the interface between prosody and syntax, a three-level syntactic annotation was added. First, an annotation into minimal chunks based on the phrasal tag-set of the French Treebank [26] was added manually. We also applied the model for syntactic annotation into functional sequences and dependency clauses detailed in [27] and obtained segmentation into Basic Discourse Units whenever the major prosodic boundaries and the dependency clause boundaries coincide. In total, the two recordings are 42-minutes long (1256 seconds each), and contain 8760 syllables, 1335 silent pauses, and 6143 tokens (words).

2.3. Evaluation of automatic tools

As a corollary study, we evaluate the performance of the above-mentioned automatic tools. Results for prominence detection are shown in Table 2; in line with [28] there was a fair agreement between the human annotator and the tools, and between the tools themselves (consistently lower for the SI).

Table 1. *Evaluation of prominent syllable detection*

Both conditions	**ProsoProm vs. Analor**	**ProsoProm vs. Manual**	**Analor vs. Manual**
Precision	97.1%	81.9%	59.3%
Recall	39.9%	49.1%	86.4%
Correct	77.4%	84.4%	81.6%
F-measure	56.6%	61.4%	70.3%
Cohen's kappa	**0.447**	**0.524**	**0.576**
Interpreting κ	0.394	0.456	0.561
Reading κ	0.478	0.568	0.581

A comparison between the (manually corrected) segmentation into accentual and intonation phrases (AP/IPs), and the perceptually-motivated prosodic boundaries (PBs) proposed by [25] can be seen on Table 2. As expected, the perceptual PBs are coarser than the hierarchical segmentation into AP/IPs (which, for French, is based on the prominence of the last syllable of an each unit).

Table 2. *Comparison of prosodic boundary detection*

Sylls with PBs vs. IP/APs	IP boundary		AP boundary	
	Yes	No	Yes	No
No PB	427	**6773**	1262	**5938**
Minor PB	244	264	381	127
Intermediate PB	55	72	73	54
Major PB	**921**	1	**922**	0

The precision of the POS annotation (DisMo) was 96.3 %, while the syntactic annotation was performed manually.

3. Results

3.1. Global Prosodic Features

A selection of global prosodic features is shown in Table 3.

Table 3. *Global prosodic measures.*

Measure	SI	Read
Articulation ratio (%)	72.6	62.7
Articulation rate (syll/s)	4.91	5.27
Speech rate (syll/s)	3.59	3.33
Speech segments (runs)	493	858
… with average length (syll)	9.2	4.9
Var. coefficient of vowel duration	0.089	0.022
Var. coefficient of syllable duration	0.079	0.042
Median pitch (Hz)	127	152
Pitch range (semitones)	7.8	14.2
Pitch trajectory (semitones/s)	15.13	22.47

We note a higher **articulation rate** (syllables per second *excluding* pauses) under the Reading condition. The interpreter made more silent pauses in the Reading condition (cf. 3.2.); this is reflected in the lower articulation ratio, and the lower speech rate (sylls/s *including* pauses). Speech segments (continuous stretches of speech separated by silent pauses >250ms) are considerably more numerous and shorter under the Reading condition than in SI. These measures indicate that the interpreter **over-segmented** his speech in the Reading condition (short utterances and extensive use of pauses). The observed difference between the variance coefficients of vowel duration and of syllable duration indicate that under the SI condition, the interpreter accelerated and decelerated his articulation more frequently than under the Reading condition. Finally, **pitch range and pitch trajectory** are smaller under the SI condition, compared to Reading; this indicates that the latter was a livelier rendition of the text.

3.2. Silent Pauses and Disfluencies

A Mann-Whitney U test on average **silent pause length** indicates that it is longer under the SI condition ($p < 0.001$). We modelled silent pause length as a mixture of log-normal distributions, following the methodology in [29] and [30]:

$$f(x) = \sum_{i=1}^{N} \pi_i \Lambda_i(\mu_i, \sigma_i^2, x)$$

Three component distributions are identified (using a Bayesian Information Criterion), and their parameters estimated using the Expectation-Maximisation algorithm (Table 4, Figure 1). Cut-off values *t* (local maxima of the model's uncertainty function) are used as thresholds to categorise pauses as 'short', 'medium' or 'long' (instead of *ex-nihilo* fixed thresholds).

Table 4. *Log-normal mixture model of silent pause length (in ms), 1.3 < σ < 1.8, N = 3.*

Pause type	SI			Read		
	π	M	t	π	μ	t
Short	44%	195	283	39%	136	203
Medium	32%	568	1037	48%	581	602
Long	24%	1570		13%	1221	

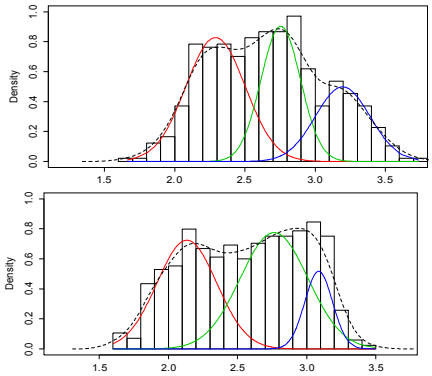

Figure 1. *Density plots of log (silent pause length) and component distributions (SI: top, Reading: bottom).*

Regarding **disfluencies**, under the SI condition the interpreter produced 272 filled pauses vs. only 8 under the Reading condition. Other types of disfluencies were almost inexistent in Reading. Under the SI condition false starts, repetitions and deletions (in order of frequency) were observed. In total, **9.8%** of the tokens were disfluent in SI, compared to **0.4%** in Reading.

3.3. Prosody-Syntax Interface

Basic Discourse Units (BDUs) in [27] are proposed as "the segments that speakers and listeners use to interpret the discourse they are engaged in". Based on the observation that listeners use both prosody and syntax as cues to information structure, BDUs are defined as segments that run between the points where major prosodic boundaries and dependency clause boundaries **coincide**. In a congruent BDU, one intonation unit (IU) contains one dependency unit (DU); in intonation-bound BDUs, one IU contains several DUs; in syntax-bound BDUs, one DU packs several IUs. Regulative BDUs contain only discourse markers or adjuncts. A mixed-boundary BDU contains more than one DU and more than one IU, and is the product of a lack of synchrony between prosodic and syntactic boundaries. Table 5 shows the distribution of BDUs of different types under the two conditions.

Table 5. *Number and average duration of BDUs per type and condition.*

Condition / BDU type	SI		Read	
	%	Avg dur (s)	%	Avg dur (s)
Congruent	21.3	2.57	20.2	2.04
Regulative	21.9	1.24	24.4	0.85
Intonation-bound	5.3	6.43	0.4	1.98
Syntax-bound	30.2	8.20	55.0	5.60
Mixed-boundary	21.3	11.79	0	

We observe that in the SI condition, there was frequently a **mismatch between prosodic and syntactic boundaries**. These are typically cases in which the interpreter constructs a phrase incrementally, pausing inside syntactic units. Figure 2 shows how the three different types of silent pauses are distributed between and within syntactic units (chunks and functional sequences) and BDUs.

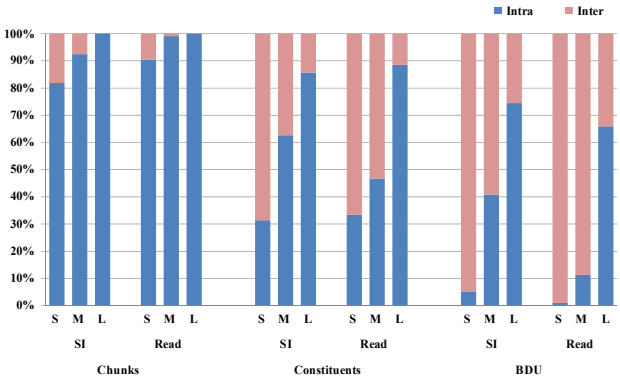

Figure 2. *Silent pauses of different types (S: short, M: medium, L: long), within (intra) and between (inter) syntactic units.*

We observe that in the SI condition, medium-length pauses *within* constituents and *within* BDUs occur more frequently than in the Reading condition (+15% and +30% respectively). This is in line with the high percentage of mixed-boundary BDUs observed. The high proportion of syntax-bound BDUs with a relatively short duration under the Reading condition is another indication of over-segmentation.

3.4. Perception of Quality and Fluency

The questionnaire data were coded and processed with *IBM SPSS Statistics*. Missing observations were excluded. The mean Listening Score, which measures Objective Comprehension (the sum of the correct answers in comprehension questions; max = 17), and the median Accuracy, Fluency and Subjective Comprehension ratings (1 = best), broken down by subject groups and experimental conditions are shown in Tables 6 and 7. Highest scores and best ratings are in boldface.

Table 6. *Mean Listening Score per group (17 = max)*

Group	SI	Read	Both
Translation students (TRAN)	8.47	**9.39**	8.94
Economics students (ECON)	7.95	**8.39**	8.18
Both groups	8.18	**8.83**	8.52

Table 7. *Median quality and subjective comprehension ratings per group (1 = best)*

Group	Rating	SI	Read	Both
TRAN	Accuracy	2	2	2
	Fluency	3	**2**	2
	Subjective Compr.	5	**4.5**	5
ECON	Accuracy	3	3	3
	Fluency	3	3	3
	Subjective Compr.	3	3	3
Both	Accuracy	2	2	2
	Fluency	3	**2**	3
	Subjective Compr.	4	4	4

The translation students' median ratings of fluency and subjective comprehension are better in the Reading condition. Across all groups, there is a moderate correlation between the experimental condition and the fluency ratings, which turns out to be significant in a Spearman correlation test (Translation: $r = -0.506$; $p = 0.001$; Economics: $r = -0.323$; $p = 0.027$; Translation + Economics: $r = -0.393$; $p < 0.001$; two-tailed). In other words, **the subjects who listened to the read-aloud speech tended to rate fluency better**.

Concerning the fluency ratings without regard to the experimental condition, there is a moderate and significant correlation between fluency ratings and subjective comprehension among the students of economics ($r = 0.480$; $p = 0.001$, two-tailed). There is a slightly stronger significant correlation between fluency and accuracy ratings across all groups (Translation: $r = 0.490$; $p = 0.002$; Economics: $r = 0.496$; $p = 0.001$; Translation + Economics: $r = 0.520$; $p < 0.001$; two-tailed).

4. Conclusions and Perspectives

In this paper we presented a perceptual study based on a conference simulation, striving to create a situation as close to authentic conditions as possible.

With respect to our first research question, our findings confirm previous studies regarding the **particular prosodic characteristics of SI**. In the SI condition, the interpreter produced long silent pauses, frequent filled pauses and several reformulation-related disfluencies. The articulation rate was more variable (i.e. more accelerations and decelerations), and the pitch range and trajectory were both narrower in SI, indicating that the same person rendered the text in a more lively fashion, when freed from the cognitive constraints of interpreting. The main effect of SI was observed in the prosody-syntax interface, with often mismatched prosodic and syntactic boundaries, and more intra-unit pauses. The combination of these prosodic features has had an effect on the perceived fluency rating. As previous research has shown that "some disfluencies may be considered felicitous by listeners" when used for communicative purposes [31], it will be interesting to explore the contribution of each prosodic factor in fluency ratings, in a future study.

With respect to our second research question, the results lend additional support to the claim that **the perception of the interpreters' accuracy is linked to that of their fluency**, thus confirming previous experimental findings [e.g. 8, 9]. The differences in listening scores (objective comprehension) between the experimental conditions are less pronounced among students of economics. This seems to support Shlesinger's claim that the prosody of interpreting has less impact on the listeners who enjoy relevant contextual knowledge. One explanation could be that the translation students processed the speech at a more superficial level and hence, were more affected by perturbations of the prosodic structure of the speech. The students of economics could use their prior knowledge to process the speech content at a deeper level and make inferences to compensate for disturbing prosodic variations. Admittedly, the higher mean listening score of translation students is unexpected. We hypothesize that these students benefited from their capacity to capture the gist of speeches in their notes thanks to an elaborate note-taking technique they develop in introductory courses to conference interpreting. In a future study, perceptual and prosodic data could be correlated to test the effect of each prosodic factor on perceived quality and fluency.

5. Acknowledgements

We would like to thank Prof. Liesbeth Degand (University of Louvain) for her help with the syntactic annotation; Dr. Mathieu Avanzi for the annotation of accentual and intonation units; our anonymous interpreter colleague who volunteered for the recordings; our subjects; and the teaching and technical staff at UMons, who made this experiment possible. The second author is supported by a UMons 100% research grant.

Abstract

This paper investigates rhythm speech metrics in Modern Standard Arabic. Recordings of native (L1) and non-native (L2) speakers were obtained from the West Point corpus. The experiment examined the rhythm metric properties of L2 speech using Pairwise Variability Indices and Interval Measures. The application of the Control/Compensation Index to the corpus is also described. Variations in rhythm metrics are detailed by focusing on between-speaker differences such as gender of speakers. L1 and L2 speakers (females and males) were compared through measurement of the duration of short and long vowels.

Index Terms: rhythm metrics, Control/Compensation Index, L2 speakers, gender of speakers, Modern Standard Arabic, English

1. Introduction

Recent studies have developed a battery of metrics to show rhythm differences and similarities between languages. These same metrics have also been used to study second language acquisition, by examining the impact of the first language (L1) on the rhythm of the second language (L2). A large number of studies have investigated the effect of L1 use on L2 production: Korean English [1]; Singapore English [2]; German L2 influenced by Chinese, English, French, Italian and Romanian L1 [3]; Norwegian as L2 [4]; English, Spanish, Dutch and French [5].

Rhythm refers to the temporal organization of speech. The rhythm models developed are based on the acoustic durations of vocalic and consonantal intervals in vocal signals. The most popular algorithms performed are: Interval Measures (IM) and Pairwise Variability Indices (PVI). The IM approach involves computing three separate measures from the segmentation of speech signals (global utterance) into vocalic (V) and consonantal (C) units (ΔV, ΔC and %V) [6]. The time-normalized metric measures (VarcoV/C) were introduced when it was observed that the consonantal interval measure is inversely proportional to speech rate [7]. The PVI algorithm differs from IM and VarcoV/C models in that it focuses on the temporal succession of the vocalic and consonantal intervals instead of the global utterance [8]. The model suggests that the rPVI should be used for the consonantal intervals, while the nPVI (normalized Pairwise Variability Index) should be used for the vocalic intervals, which are more prone to be affected by speech rate.

More recently, a new proposal of rhythm metrics has been put forward [9]. The model is inspired by previous studies on syllable compensation, which state that controlling languages (syllable-timed) show low levels of compensation at intra- and inter-syllabic levels in comparison to compensating languages (stressed-timed) that are thought to show higher levels of compensation. The rhythm metric suggested is the Compensation and Control Index (CCI) that may be used for computing the level of compression (lengthening or shortening) allowed in a language according to the context. In order to show the intra-syllabic comportment, the CCI takes into account all the segments composing each vocalic and consonantal interval. The formula used in CCI computation consists of a modification of the rPVI algorithm where each vocalic or consonantal interval is divided by the number of phonological segments that are included in this interval. A new version of the CCI formula has been developed [10], but for the purpose of this experiment, we used the original formula, shown below, where *m* stands for V or C intervals, *d* for duration, and *n* for number of segments within the relevant interval.

$$cci = \frac{100}{(m-1)} \sum_{k-1}^{m-1} \left| \frac{d_k}{n_k} - \frac{d_{k+1}}{n_{k+1}} \right|$$

The model aims to offer a better representation of the rhythmic tendencies of natural languages, suggesting that geminate consonants and long vowels separately count for two different segments. According to the model, the controlling languages should present similar tendencies of C and V local durational fluctuations scattered along the bisecting line. Conversely, compensating languages should fluctuate more in the V than in the C segments. They should be clustered under the bisector as shown in Figure 1 [10].

The experiment, described in this paper, focused on the rhythm properties of Arabic L2 speech by gauging the influence of L1 on L2 rhythm. A comparison of Arabic L2 with different languages is also given. The rhythm metrics that were examined include: three interval measures (%V, ΔV, and ΔC), two time-normalized indices (VarcoV, VarcoC), two pairwise variability indices (nPVI-V, rPVI-C), and two compensation and control indices (CCI-V, CCI-C).

The paper is organized as follows: Section 2 summarizes the main characteristics of the Arabic language. Section 3 gives an overview of the speech data and speakers used in the study. Section 4 describes the results and discussion about different rhythm experiments on Arabic L2. Section 5 concludes this work.

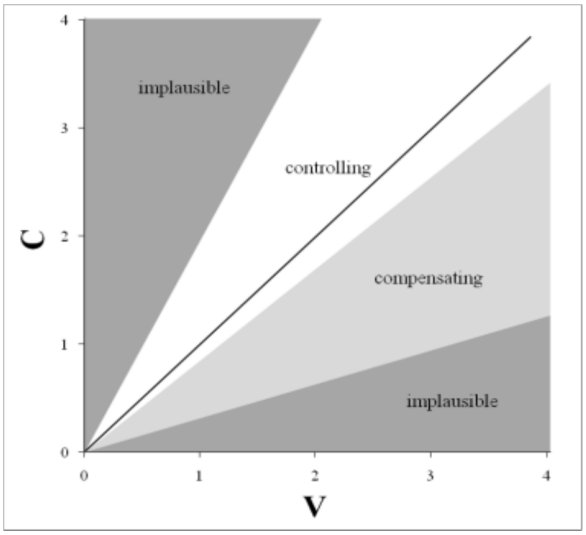

Figure 1: *Schematic representation of the major rhythmic types according to the CCI model [10].*

2. Modern Standard Arabic

Arabic is part of the Semitic language family, and spoken by more than 340 million speakers from the Middle East to North Africa. Modern Standard Arabic (MSA) is used in most written documents as well as in formal spoken interactions in all Arabic countries.

MSA uses a distinct phonological set that includes 28 consonants and six vowels: three short vowels /a/, /u/ and /i/ and three long vowels /a:/, /u:/ and /i:/, that are the counterparts of the short vowels. Regarding the number of vowels, Arabic is much less complex than English, which has twelve vowels. English and Arabic rely on different types of phonological contrasts in both vowels'quality and quantity [11].

There are two distinct consonant classes in MSA: pharyngeal and emphatic consonants. In addition to these, the language is characterized by two distinctive features that are fundamental in avoiding semantic ambiguity: long vowels and gemination. Gemination, or consonant elongation, occurs when a consonant is pronounced for a perceptibly longer period of time than a short consonant. All Arabic consonants may be geminated.

The Arabic language consists of two kinds of syllables: open syllables (CV and CV:) —and closed syllables (CVC, CV:C and CVCC). Arabic vowels never occur initially. Every vowel must be preceded by a consonant (which may include the glottal stop [ʔ]). All Arabic syllables must contain at least one vowel [12].

3. Corpus description and speakers

Speech material used for the study was taken from the West Point corpus, which was collected and processed by the Department of Foreign Languages at the United States Military Academy at West Point and the Center for Technology-Enhanced Language Learning (CTELL) (Linguistic Data Consortium (LDC) [13]). West Point speech files were recorded from 110 speakers. The corpus consists of collections of four main Arabic scripts including a total of 258 sentences. Script 1 is spoken by 75 L1 speakers of Arabic (41 males). Scripts 2–4 are read by 35 L2 speakers (25 males). The L2 speakers' recordings were captured at a sampling rate of 16 bit at 22.05 kHz. The recordings were collected at normal speech rate. The age of the speakers is not mentioned.

To reduce factors that can compromise the reliability of rhythm analysis, a large sample of speakers was used and the measurement effects across speech materials were controlled for. Speech material from 29 speakers reading either five sentences from scripts 1 or 2 was used. In total, 145 recordings were used in the analysis. Table 1 shows the number and gender of speakers in the sample.

Table 1. *Distribution of native and non-native speakers in Modern Standard Arabic (MSA) corpus.*

Native speakers (L1)		Non-native speakers (L2)	
male	female	male	Female
5	10	6	8
15		14	

To avoid variability due to the segmentation procedure, one researcher manually carried out all segmentations for the speech corpus. Recordings were analyzed using Praat software. All vowels and consonants were segmented by inspection of speech waveforms and wideband spectrograms by one researcher. Vowel and consonant durations were extracted using a customized script on the boundary label files. Rhythm metrics were computed for each sentence for each speaker.

4. Results & Discussion

4.1. IM & PVI metrics for L1 and L2 speakers

The first experiment studied rhythm metrics of L2 speakers in comparison to L1 speakers by computing different IM and PVI metrics. Table 2 reports the average values of each of the seven rhythm metrics applied to the data. Figure 2 reveals that all the vocalic metrics: vocalic interval measure, vocalic time-normalized interval, vocalic percentage, vocalic pairwise variability index (ΔV, VarcoV, %V and nPVI-V) are higher for L1 speakers in comparison to L2 rhythm values. As can be seen from the same plot, the consonantal interval measure and the consonantal pairwise variability index (ΔC and rPVI-C) for L1 speakers also present higher scores than L2 metric values. However, the VarcoC value for L2 speakers is close to the L1 measure.

Table 2. *Modern Standard Arabic (MSA) rhythm metrics (ms) for L1/L2 speakers.*

Metrics	L1 spk.	L2 spk.
%V	42.41	40.12
ΔV	49.42	45.58
ΔC	53.29	43.90
VarcoV	65.14	58.64
VarcoC	50.87	49.79
rPVI-C	74.84	68.71
nPVI-V	56.22	52.17

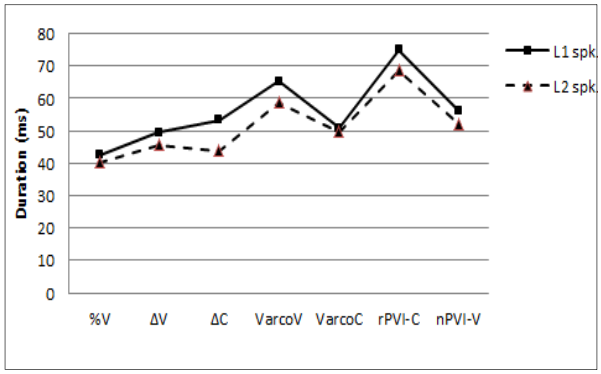

Figure 2: *Mean rhythm metrics of Modern Standard Arabic (MSA) L1 and L2.*

Statistical analysis (One-way ANOVA) shows significant effects between L1 and L2 rhythm values for three metrics: %V, ΔC and ΔV ($F(1.143)=13.17$, $p<0.001$; $F(1.143)=15.79$, $p<0.001$; $F(1.143)=8.71$, $p=.004$; 95% confidence intervals). These results show that L1 speakers present higher vocalic proportions compared to L2 speakers. This fluctuation in vocalic intervals suggests that non-native speakers reduce the vocalic intervals. Likewise, consonantal intervals of L2 speakers are less lengthened than their L1 counterparts. This finding suggests that the pronunciation of MSA consonants by non-native speakers decreases in duration compared to that of native speakers. Considering all the metrics employed, it seems that this reduction, especially in vocalic duration, helps L2 speakers to sustain syllable structures when producing MSA.

4.2. CCI metrics of L1 and L2

The CCI algorithm aims to describe the intra-syllabic behavior of languages. In the second experiment, CCI metrics were computed (vocalic/consonantal compensation and control Index; CCI-V and CCI-C) for each sentence of MSA produced by L1 and L2 speakers. Statistical analysis (One-way ANOVA) shows significant differences in CCI-C and CCI-V values between L1 and L2 rhythm ($F(1,143)=4.75$, $p=0.031$; $F(1,143)=29.78$, $p< 0.001$).

Regarding the CCI chart, the average values of each of CCI-C and CCI-V were computed for both native (L1) and non-native (L2) speakers. Comparison of the vocalic/ consonantal CCI metrics shows that L1 and L2 are separated by the bisector. As shown in Figure 3, L2 Arabic falls close to the bisecting line in the controlling area, whereas L1 Arabic is below the bisector in the compensating part.

Arabic is a stress-timed language, like English and German [14]. According to the CCI model, stress-timed languages should show higher levels of compensation between vowel and consonant segments, whereas controlling languages should present similar tendencies of C and V local durational fluctuations. However, the results reveal that Arabic L1 presents more compensating CCI while the opposite happens to Arabic L2 production, which appears to be more controlling then compensating. MSA L1 fluctuates more in the V than C segments compared to MSA L2, where the variation tendency is similar for vowels and consonants.

Some studies claim that rhythm metrics do not manage to clearly distinguish between L1 and L2 speakers [15]. However, the main findings of this experiment show that the deviation is noticeably observed in the case of Arabic L2 and L1 speakers when CCI metrics are used.

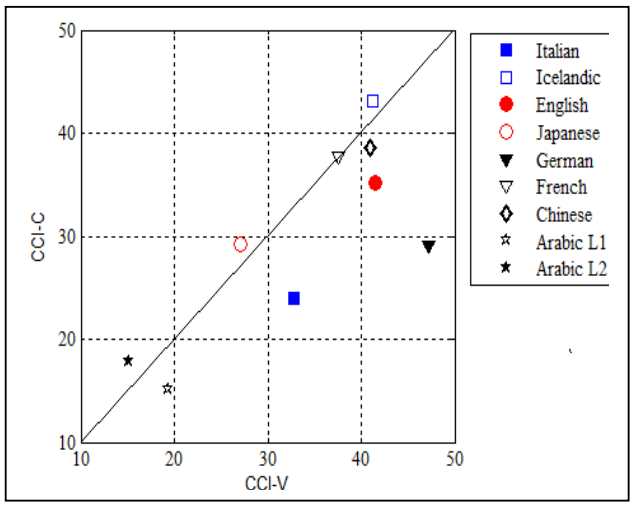

Figure 3: *MSA L1 and L2 among controlling and compensating languages.*

Figure 3 illustrates a comparison of Arabic L1 and L2 with a set of languages including English, French, Italian, Japanese, Chinese, Icelandic and German [16]. The graph shows that Arabic L2 falls in the controlling area, similar to French, which is considered one of the controlling languages. In contrast, Arabic L1 is grouped with the compensating languages, like English and German, which are clustered under the bisector. These results show that in the case of MSA, it is possible to distinguish L2 from L1, and Arabic L1 from other languages.

In this study, the L1 of non-native Arabic speakers was English. When L1 and L2 share the same rhythm typology, it may be difficult to distinguish between L1 and L2 speakers [15]. However, findings reported in Figure 2 show that distinction between L1 and L2 speakers is possible using rhythm metrics, even although Arabic and English are both stress-timed languages.

4.3. Vowel duration in L2

In light of the substantial differences between English and Arabic vowel systems (in terms of quantity) and IM, PVI, VarcoV/C and CCI–V findings, an investigation of the acoustic characteristics of MSA vowels produced by English speakers was conducted. The purpose was to show how durations fluctuate in the vocalic rhythm metric of L2 speakers. One-way ANOVA was conducted to test the effect of the origin of speakers on vowel duration values. The results show a highly significant effect ($F(1, 1347)=29.41$, $p<0.001$). Table 3 presents the comparison of the mean duration values in milliseconds of short (v) and long (V) vowels of L1 and L2 speakers.

Table 3. *Average durations of short (v) and long (V) MSA vowels by L1/L2 speakers (standard deviations are given in parentheses).*

	v (ms)	V (ms)	V/v
L1 spk.	86.62 (36.46)	170.29 (43.27)	1.97
L2 spk.	83.95 (36.41)	139.39 (43.45)	1.66

The results indicate that durations of L1/L2 short vowel values are close to each other. For long vowels, the data do not exhibit a unified pattern for both groups. L1 speakers have longer durations compared to L2 individuals. The results also show that the vowel length contrast (the ratio of long-to-short vowel durations) is greatest in the L1 group, while L2 speakers have a lower ratio. ANOVA was conducted to test the effect of vowel length (short/long) on L1/L2 speakers. The results show a significant effect of origin of speaker on vowel length [$F(1, 1345)=32.42$, $p<0.001$]. These findings suggest that the difference in duration of long vowels is mainly related to the L1 of speakers. The fluctuation observed in vocalic rhythm metric values of L2 compared with L1 speakers is due to the reduction of long vowels rather than short vowels. These results suggest that L2 speakers struggle to produce the long vowels as produced by L1 speakers.

To further examine between-speaker differences according to gender, a comparison of the mean duration of short/long vowels of female and male speakers for both L1 and L2 was performed. Results are summarized in Table 4.

Table 4. *Average durations of long and short MSA vowels by L1/L2 according to gender (standard deviations are given in parentheses).*

	v (ms)	V (ms)	VL1/VL2
L1 female	88.90 (36.99)	168.59 (45.05)	1.23
L2 female	88.09 (37.66)	136.58 (44.87)	
L1 male	82.19 (34.94)	174.10 (39.05)	1.22
L2 male	78.48 (34.02)	143.28 (44.87)	

The results show that L1 and L2 females have similar duration values for Arabic short vowels, while L1 males produce slightly longer durations than their L2 counterparts when producing short vowels. For long vowels, both L2 females and males show similarly reduced duration compared to the L1 females and males respectively (the ratio of VL1/VL2). Gender was the final independent variable tested in this experiment. Results of the ANOVA show a highly significant effect of gender on vowel length ($F(1, 1341)=8.51$, $p=0.004$). L2 speakers struggle to produce long vowels that are similar to those of L1 speakers in terms of quantity (duration), and this is true for females and males. This can be explained by the influence of the L1 of non-native speakers, in this case the phonetic system of English on that of the L2, Arabic. The L1 of non-native speakers influences the acquisition and subsequently the production of Arabic, the L2.

5. Conclusions

This study examined variation in rhythm of L2 speakers of MSA. Several experiments were conducted to show rhythm properties of Arabic L2 using IM and PVI algorithms. CCI models were also used to describe L2 production at the intra-syllabic level. The main results show that rhythm metrics of L2 speakers present many differences in terms of phoneme duration (vowels and consonants) compared to L1 speakers. To explain the fluctuation in vocalic rhythm metrics, a comparison of vowel duration (short/long) between L1 and L2 speakers was performed. The results show that the fluctuation in vocalic rhythm metrics is due to a reduction in duration of long vowels for both male and female L2 speakers.

Abstract

In this paper we present evidence that speech produced spontaneously in a conversation is considered more natural than read prompts. We also explore the relationship between participants' expectations of the speech style under evaluation and their actual ratings. In successive listening tests subjects rated the naturalness of either spontaneously produced, read aloud or written sentences, with instructions toward either conversational, reading or general naturalness. It was found that, when presented with spontaneous or read aloud speech, participants consistently rated spontaneous speech more natural - even when asked to rate naturalness in the reading case. Presented with only text, participants generally preferred transcriptions of spontaneous utterances, except when asked to evaluate naturalness in terms of reading aloud. This has implications for the application of MOS-scale naturalness ratings in Speech Synthesis, and potentially on the type of data suitable for use both in general TTS, dialogue systems and specifically in Conversational TTS, in which the goal is to reproduce speech as it is produced in a spontaneous conversational setting.

Index Terms: speech synthesis, evaluation, naturalness, MOS, spontaneous speech, read speech, TTS

1. Introduction

In speech synthesis research there are two generally used methods for evaluation, namely intelligibility and naturalness. Intelligibility is a metric which has robust measures such as semantically unpredictable sentences (SUS) [1] and synthesis systems perform well compared to natural sentences [2, 3]. Naturalness on the other hand is a less defined concept, although it is generally always used e.g. in the Blizzard challenges [2, 4, 5]. It is also used to evaluate prosody and is the focus of this paper.

Naturalness is normally evaluated as a Mean Opinion Score (MOS) where participants rate the quality of the synthetic speech on a 5-point scale ranging from 1-Very Unnatural to 5-Very Natural. The scale itself has not been much investigated, however the Blizzard 2008 [2] evaluation gave support to the scale being treated, by listeners, as an interval rather than ordinal scale by comparing it to scores obtained using an unnumbered slider. While systems tend to perform well on intelligibility they are generally lacking behind natural speech in terms of naturalness. One assumption made in several conversational speech synthesis studies is, that spontaneous conversational speech is more natural than read speech [6–8]. Thus, it is assumed, synthesis based on conversational speech will similarly increase the system's naturalness. However, it has not been shown that people actually find conversational speech more natural than read speech, and earlier studies using spontaneous recordings have not managed to increase the perceived naturalness of synthetic speech [6, 9]. People can distinguish the two modes of speech with high accuracy despite lexical equivalence [10], so it is likely that people will be able to pick up upon and judge according to this distinction when asked. This study attempts to test this by obtaining naturalness ratings of natural speech from the same speakers, of speech produced spontaneously in a conversation and when reading aloud. We hypothesise, as has been done before, that conversational speech is considered more natural.

It is also likely that 'naturalness' as a concept is underspecified. That is, we do not have an exact definition of what naturalness is. In fact differing studies give participants differing instructions. The Blizzard 2013 evaluation [11] instructs participants to give a score which "should reflect your opinion of how natural or unnatural the sentence sounded. You should not judge the grammar or content of the sentence, just how it sounds." In contrast [12] explains the meaning of naturalness as if it is "likely that a person would have said it this way?" (p.470). The two stand in contrast to each other, the one asking to disregard grammar and content, and the other to judge the 'way' it was said - including content and grammar. If listeners do find it to be underspecified then people's perceptions should be be influenced by their expectations of what naturalness means in any given context. We therefore attempt to influence the prior expectations of listeners by slight variations in instructions to bias them toward either conversational or read speech, and compare this to the general case with no further instructions.

Note that there are genuine worries about the ecological validity of MOS-scale naturalness tests of isolated sentences presented in very controlled noise environments. It is not the purpose of this paper to attempt to rectify these, but rather to explore current means and enable further detail in their application. Section 2 describes our first listening test, in Section 3 we attempt to separate audio and text and Section 4 discuss the overall implications, before concluding in Section 5.

2. Naturalness Ratings of Spontaneous and Read Speech

A simple way of testing if there is a preference for conversational over read utterances is to mimic the standard naturalness test setup. In such a procedure the common instruction is for the participant to listen to one sentence at a time, rating how natural they find the sentence. That is people are only told to rate what sounds 'natural' with no further qualification. If naturalness is an underspecified concept it should be possible to influences people's ratings by slightly changing the given instructions, and as we are concerned with the difference between conversational and read speech we attempt to influence people's perceptions in these directions. Instead of closely matching the content of these sentences by rating the same sentences either spoken in a conversation or read aloud (see Section 3), it was decided to ini-

Read	Spontaneous
Challenge and errors both go well.	It's kinda ridiculous, but it was funny at the time.

Table 1: Example sentences.

tially use sentences representative of the respective styles to see if a difference was to be found in a fairly unconstrained setting.

2.1. Data

Studio recordings of conversational and read-aloud data from two differing speakers, one male and one female, was used as the stimuli. For each speaker 30 conversational and 30 read sentences were selected. For the read sentences the female data included mainly read news text and the male data was the first 30 sentences of the Arctic prompts [13]. The conversational utterances were chosen from recordings of the speakers having an unscripted conversation with an experimenter. The sentences were chosen so as to be complete sentences with no initial or final disfluency, although disfluencies were allowed in the sentences. Where the read-prompts had a distinct third-person perspective most conversational sentences in the database were first person. To reduce this mismatch, conversational sentences were chosen to generally be about something rather than the speaker him/herself. Sentences in both conditions were also matched for length with the shortest being about 2s long and the longest about 6s. Table 1 provides a few example utterances and audio samples are available.[1]

2.2. Method

32 paid native speakers of English were recruited, mainly students at the University of Edinburgh. 11 participants rated general naturalness (GenNat), 10 conversational naturalness (ConvNat) and 11 participants reading naturalness (ReadNat). Participants were instructed to rate the sentences in the standard TTS paradigm and they were instructed to "Listen to each sentence and rate it according to how natural you find the sentence from a scale of 1 - Very Unnatural to 5 - Very Natural" in the GenNat case, in the ConvNat the sentence "if you were having a conversation" was added between "sentence" and "from"; in the ReadNat case "if somebody was reading aloud" was added in the same place. This difference in instruction was the only difference between conditions. Each participant rated all 120 sentences once, in a randomised order of presentation for each participant. Each participant also rated an additional 5 sentences as a trial run to get accustomed to the methodology. After the trial run participants were encouraged to ask clarifying questions before proceeding to the main part of the test. The test was performed in a soundproof room with the participants wearing good quality headphones. The test took about 15 minutes to complete. There were three groups of participants (GenNat, ConvNat and ReadNat) and two types of audio (conversational or read).

Table 2: Condition descriptives. The shown significances are between spontaneous and read sentences for each condition.

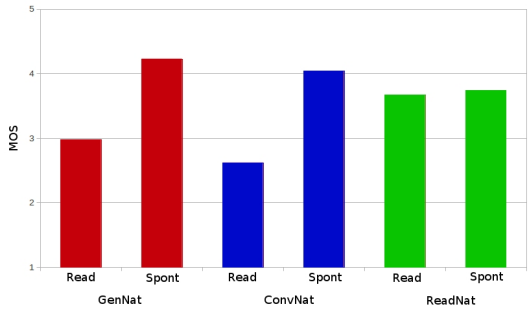

Figure 1: Overall ratings by category.

2.3. Results

As noted in Section 1 we have evidence that the 5-point MOS scale is used as an interval scale and not in an ordinal fashion, therefore we can meaningfully compare the means instead of the medians of the ratings [14]. No null responses were recorded and all ratings were used in the analysis. A significant difference was found between the read (M=2.98, SD=1.192) and conversation (M=4.23, SD=1.131) sentences in the GenNat group (t(1318)=19.644, p <0.001), this was also the case for ConvNat (Read: M=2.62, SD=1.291; Conv: M=4.04, SD=1.189; t(1198)=19.848, p <0.001) but not the ReadNat condition (Read: M=3.67, SD=1.182; Conv: M=3.74, SD=1.466; t(1318)=0.93, p=0.352). In other words, when asked to rate what they found natural with no further instruction, or instructions toward conversation, participants preferred the spontaneous utterances, however there was no preference when rating naturalness for reading aloud. See Table 2. Across instruction conditions one-way ANOVA's were run for each speech type. An effect for both read (F(2,1917)=122.285, p <0.001) and spontaneous utterances (F(2, 1917)=25.509, p <0.001) were found. Bonferroni correction showed all differences to be significant at the p <0.001 level for the read speech and for the spontaneous speech all differences were significant at the p <0.001 level except GenNat and ConvNat which was significant at p <0.05. Thus different instructions gave different ratings. It is possible that the findings are speaker specific or gender specific. Repeating the tests by speaker we find that the effects are slightly smaller for the male speaker and larger for the female, however both speakers exhibit the same tendencies with the same significant differences suggesting that, at least in this small sample, neither speaker or gender affects the results.

3. Separating Acoustics and Text

While we see a difference in a fairly unconstrained setting, it is clear that the content of the read and conversational sentences was quite different despite ensuring that each spontaneous utterance was "complete". It is therefore possible that the prefer-

p	p<0.001		p <0.0001		p <0.0001	

Table 4: Descriptives for the textual data. The significances are between spontaneous and read sentences for each condition.

ences found are not due to differences in articulation or speech mode - but rather due to differences in content. The opposite, however, is also possible, that is, the content has nothing to say and only the acoustic differences matter. In order to tear this apart further we need to isolate the two possibilities. This is possible in the following way, firstly in order to test whether it is purely the content of the utterance which affect people's perception, we can elicit ratings from people based on text only. That is by comparing normal written text - e.g. from newspapers or novels - with transcriptions of conversational speech we can avoid the acoustic component entirely and focus purely on the content. Secondly we can isolate the acoustic component by recording a speaker in a conversational setting and then, at a later time, ask the same speaker to re-read transcriptions of their own earlier utterances. The content of the utterances will be the same however the mode of speech will differ. In this way we can tear apart the effects of content and mode.

3.1. Data

One acoustic and one textual dataset was obtained. The acoustic data consisted of studio recordings of 50 sentences initially produced in a longer conversation by a female speaker with one of the experimenters. From this conversation 50 complete (as above) sentences were identified and transcribed. The speaker was then, a few days after the first recording, asked to re-read the sentences by having them given as prompts.[2] The textual data consisted of 120 sentences. Half were taken from transcriptions of spontaneous data and the other from written sources. The transcribed data was obtained 50/50 from two generally available corpora of spontaneous data (AMI [15] and Switchboard [16]). The written data contained 30 sentences from the Arctic [13] scripts and the last 30 sentences were from News data taken from prompts used in the Edinburgh Voicebank Project [17]. For both types, novels and news, names and quotes were avoided as none were included in the spontaneous and their length matched to the spontaneous in terms of numbers of words. The choice of using various sources for both written and spontaneous data, and the inclusion of disfluencies, was to enable analysis of the possibility of internal variation depending on the style of the textual data but this analysis is not presented here due to space constraints, however we note that it

[2]Samples are available at http://rasmus.dall.dk/SP2014Samples.zip

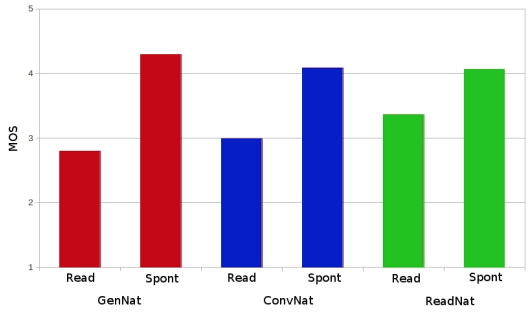

Figure 2: Naturalness ratings for the audio.

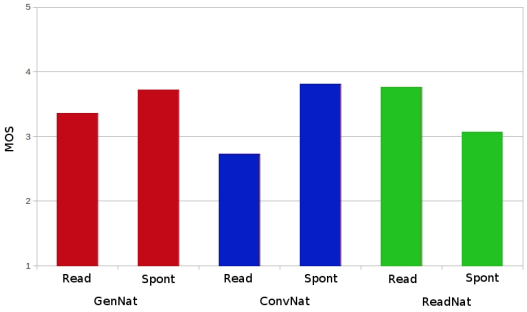

Figure 3: Naturalness ratings for the text.

does not significantly affect the presented results. An example sentence of each type can be found in Table 5.

3.2. Method

30 paid native speakers of English, mainly students at the University of Edinburgh, were recruited to take part. The general method was similar to the first experiment except as noted below. As before, each participant was assigned one of three groups - general naturalness (GenNat), conversational naturalness (ConvNat) or reading naturalness (ReadNat). The test had two sections. Section 1 consisted of the 50 audio samples and 4 test samples, two spontaneous and two read. Section 2 contained the 120 textual samples and 6 test samples, one of each text type. Except for test samples all presentation was randomised for each participant. In section 1 participants were asked to rate for naturalness according to their group as in experiment 1. In section 2 participants were asked to imagine that the sentence was either "spoken aloud" (GenNat), "said in a conversation" (ConvNat) or "read aloud" (ReadNat), and then judge how natural the sentence would be. In total the test took about 15 minutes to complete.

3.3. Audio Results

15 responses (1%) null responses were excluded. For the GenNat (t(492)=14.864, p <0.0001) and ConvNat (t(496)=10.837, p <0.0001) groups we see a repetition of the previous results with spontaneous speech being significantly preferred over read prompts (Table 3). Contrary to earlier we now have a significant difference for the ReadNat group (t(491)=6.888, p <0.0001) - that is *spontaneous* speech is significantly preferred over read speech (see Figure 2). Again one-way ANOVA's were run for each speech type across groups. Here we find that no difference exists for read speech (F(2, 746)=2.693, p=0.068) - ratings

Source	Example
AMI	Yeah, but you can appreciate the way they look.
SB	I do try and regulate how much exercise I get a week.
Arctic	Unconsciously, our yells and exclamations yielded to this rhythm.
News	The current deployment is designed as a deterrent.

Table 5: Example textual sentences. SB = Switchboard.

of reading naturalness did not change with instructions. However for the spontaneous speech a significant difference was found (F(2, 746)=12.197, p <0.0001) and Bonferroni correction showed the read group to be significantly (at p <0.01) different to the general and conversational group, no difference existed between those (p=0.154). In other words, instructions toward rating for reading naturalness changed peoples perception toward a higher preference for read speech.

3.4. Text Results

11 responses (0.5%) null responses were excluded. In both the GenNat (t(797)=3.877, p <0.001) and ConvNat (t(796)=12.207, p <0.0001) groups the transcribed text was significantly preferred. However, the ReadNat group significantly preferred the *written* text (t(790)=7.694, p <0.0001) (see Table 4). When imagining text spoken aloud or said in a conversation people find transcriptions of spontaneous speech over textual sources more natural - but when imagining it read aloud people found written text more natural. One-way ANOVA's support the conclusion that instructions affect peoples perceptions. For the transcriptions (F(2, 1196)=41.058, p <0.0001) Bonferroni correction showed the GenNat and ConvNat groups to differ significantly from the ReadNat group (both at p <0.0001) however not in between themselves (p=1). That is, only when rating for reading naturalness are peoples ratings affected by instructions for transcribed speech, and then towards being less natural (see Figure 3). In the written case there was also a significant effect (F(2, 1196)=58.978, p <0.0001) and with Bonferroni correction all differences were significant (p <0.001). So, when rating written text the instructions consistently affected peoples perceptions, people found written text the least natural when rating for ConvNat, more for GenNat and most natural for ReadNat (see Figure 3).

4. General Discussion

The perception of naturalness changes in the context in which it is rated, by simply adding "if you were having a conversation" or "if somebody was reading aloud" the ratings change. When no instructions were given as to what kind of naturalness to rate, participants find spontaneously produced utterances to be more natural - in line with the assumptions of earlier research. In experiment 1 the ReadNat group showed no preference for either mode of speech, when explicitly asked to rate according to naturalness when reading aloud, participants found spontaneously produced utterances *equally* natural. However, when tearing apart audio and text we see a general acoustic preference for spontaneous speech and a preference dependent on instructions for textual stimuli. Thus spontaneously produced utterances are *always* more natural acoustically than read speech - suggesting conversational speech to be the, generally speaking, most natural of the two modes of speech. If this is true it has consequences for how we should be doing speech synthesis. Assuming improved naturalness is the main current challenge in speech synthesis (in particular HMM-based) then it suggests that we should be utilising the preference for conversational speech by basing our models on such speech. This is particularly true if we wish to synthesise conversational speech, but even if we wish to make the most broadly applicable speech synthesis system we should not assume that read speech is a neutral middle ground, that may in fact be conversational speech. This is also supported by the contextual preference for transcribed speech over actual written sources.

From the second experiment, we can see that combining the general preference for spontaneous speech in the audio and the textual results, in which we see a preference for the written sources only for the ReadNat group, yields us the same picture as given in the first experiment. That is, we have successfully managed to tear apart the difference between the acoustics and the meaning content of the sentence by removing the variables in their respective tests. It is important to note that, for the textual case, we have focused on the spoken word, not the written, by instructing participants to rate it according to how natural it would be in various spoken scenarios and not how natural it would be focusing on it as text. In light of the clear effect of instructions on peoples ratings (more below) we would expect instructions geared toward *written* naturalness to yield a differing result. Both the first and the second tests support the hypothesis that naturalness as a metric can be easily influenced by experimental instructions, and that the influence is dependent on the type of data under consideration. This is likely due to the concept of naturalness in general being under-specified, and so by conditioning the experimental setting we can influence our participants toward various interpretations. Knowing this encourages both caution and enables more detail when evaluating synthetic speech. Caution because we must be diligent with the instructions we give participants so as not to bias them in an unwanted direction. More detail as we can condition the metric toward specific aspects of naturalness.

5. Conclusions and Further Work

We have shown that MOS-scale ratings can beneficially be employed to distinguish the conversationality of speech, in fact spontaneous conversational speech is found more natural by listeners than read prompts. We can affect peoples perception of naturalness by simple conditions in the instructions, enabling greater control over the testing scenario while also cautioning its use. Further work includes rigidly defining what is natural in the general case, but also attempting to utilise the apparent advantages of conversational speech. Our results suggests that read prompts may not be the neutral general speech as previously assumed and that this role is more likely attributable to spontaneous conversational speech. The gathering and use of such speech present many challenges which must be met before it is generally applicable, however we intend to attempt the use of such data by gathering an appropriate spontaneous corpora, but also by utilising existing data not recorded specifically for speech synthesis.

6. Acknowledgements

Thanks to Cereproc Ltd. for providing the female data for the first listening test. This work was funded by the JST CREST uDialogue project.

A Simplified Method of Learning Underlying Articulatory Pitch Target

Hao Liu, Yi Xu

Department of Speech, Hearing and Phonetic Sciences, University College London, UK

{h.liu.12, yi.xu}@ucl.ac.uk

Abstract

Previous research has shown that parameters of the quantitative Target Approximation model (qTA) proposed by Prom-on and Xu can be directly extracted from natural speech with high accuracy through analysis-by-synthesis implemented in PENTAtrainers. While this may raise the possibility that PENTAtrainers actually simulate natural acquisition of prosody production, it is questionable that the human brain actually replicates the full articulatory mechanics represented by qTA in order to learn and control prosody production. In this paper we explore if a much simpler function can be used to extract at least some of the qTA parameters. We first managed to reduce the number of qTA parameters from three to two by evaluating their relative sensitivity. We then tested a pursuit function that learns only pitch target height and slope. Using a corpus of Mandarin utterances varying in lexical tone and focus, we show that parameters learned by the pursuit function can be used in qTA synthesis to generate F0 contours closely resembling those generated with parameters learned with qTA-based analysis-by-synthesis, with the advantage of having a much simpler learning algorithm. These results suggest that it is possible to learn articulatory control parameters for prosody without fully replicating the mechanical process itself.

Index Terms: F0 contour modelling, target approximation, pursuit curve

1. Introduction

It has been recently demonstrated that F0 contours closely resembling those of natural speech can be generated by the PENTA model [1] with a small number of functionally specific pitch targets extracted directly from raw speech data [2, 3]. The F0 contour generation in those studies is done by the quantitative target approximation model (qTA), which simulates a third-order linear system [2]. Two automatic algorithms have been developed, as implemented in PENTAtrainer1 [4] and PENTAtrainer2 [5], to extract the parameters of qTA model from functionally annotated speech data using analysis-by-synthesis controlled by either exhaustive [4] or stochastic [5] optimizations. Such parameter extraction processes could be imagined as analogous to the natural speech acquisition process in which the child presumably learns to speak by discovering, also through analysis-by-synthesis [6], the articulatory control parameters needed to generate adult-like speech patterns. There are two potential problems with this analogy, however. The first is that the number of analysis-by-synthesis cycles is unrealistically large. The second problem is that the analogy assumes that either the child overtly imitates the same adult utterance over and over again, or develops a virtual replica of the qTA model in the brain for both learning and controlling the production of tone and intonation. With these problems in mind, in this paper we explore an alternative learning mechanism that a) uses a simplified model that approximates the core properties of qTA, and b) does not require analysis-by-synthesis searching process.

We will first try to reduce the model complexity from qTA by reducing the number of parameters from three to two by comparing the relative sensitivities of the three model parameters of qTA. We will then test a "pursuit" function [7], using a corpus of Mandarin utterances varying in lexical tone and focus, to show that the pursuit function can learn the two remaining target parameters directly, with the learned values very similar to those found by exhaustive analysis-by-synthesis as implemented in PENTAtrainer1.

2. Pitch modeling

2.1. Target Approximation model

The quantitative target approximation model (qTA) assumes that continuous surface F0 contours are the results of successive, yet non-overlapping underlying articulatory movements, each approaching an underlying target associated with a local host syllable. A target can be either static or dynamic (Figure 1), which can be represented by a simple linear equation:

$$x(t) = mt + b, \tag{1}$$

where b is target height, m is target slope and t is time relative to the onset of the host syllable.

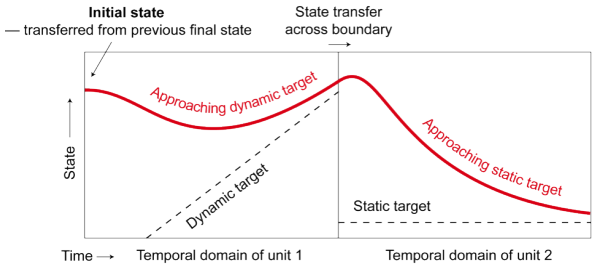

Figure 1: *Target approximation model.*

The qTA model is a third-order critically damped linear system as represented by the following equation

$$f_0(t) = x(t) + (c_1 + c_2 t + c_3 t^2)e^{-\lambda t}, \tag{2}$$

where $f_0(t)$ is the complete form of the fundamental frequency in semitones, $x(t)$ is the forced response and the polynomial and the exponential are the natural response [2]. λ is the rate of target approximation, i.e., how rapidly the target is approached. The transient coefficients c_1, c_2 and c_3 are jointly determined by the initial F0 dynamic state of the syllable, consisting of F0

level, velocity, and acceleration transferred from the offset of the preceding syllable:

$$c_1 = f_0(0) - b, \tag{3}$$

$$c_2 = f_0'(0) + c_1\lambda - m, \tag{4}$$

$$c_3 = (f_0''(0) + 2c_2\lambda - c_1\lambda^2)/2. \tag{5}$$

At the end of the syllable, the final F0 dynamic state is transferred to the next syllable to become its initial state, which results in a smooth and continuous F0 trajectory across the syllable boundary.

2.2. Control parameter sensitivity assessment

In order to find a simple model that can approximate the qTA model we examined the sensitivity of F0 contours generated by qTA to variations in the three pitch target parameters: m, b, λ.

A six syllable Mandarin phrase, /wó yǒu yí wèi yá yī/, was chosen and recorded by a male native speaker of Mandarin. PENTAtrainer1 [4] was used to find an optimal combination of m, b and λ. Then, three sets of F0 contours were generated by varying one parameter while holding the other two constant at their optimal values. The difference between the generated contour and the optimum contour was then analysed in terms of semitone shifts, as described in the paragraphs below.

Figure 2 displays the error vectors for which the target slope m and TA rate λ are set to be the same as the optimal values but target height b is given five different values. The graph is from the rising tone syllable /wó/. The pattern distributions of error vectors are very regular — all the curves gradually move away from x-axis at the same pace. The common starting point

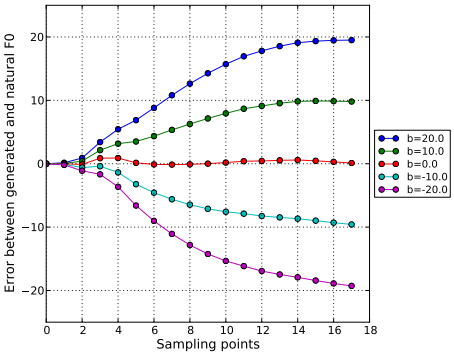

Figure 2: *Error vectors with varying b while m and λ are the same as the optimal values. Measured in semitone.*

is because qTA is a sequential model, and all variations in the current syllable step from the same offset value of the previous syllable. Because /wó/ is the first syllable of the chosen utterance, the starting point is always zero. When the values of b are equidistant from each other, the error vector curves exhibit an even distribution. Note that the middle curve represents the error vector resulting from subtracting the natural F0 contour of the syllable from the contour generated with the "optimal" parameters. The very small deviations from the x-axis indicates that the two contours are very similar to each other.

Figure 3 displays error vectors of contours that vary in m while b and λ are held constant at their optimal values. The fusiform shaped distribution here is due to the fact that in qTA b is defined as the ending point of a target. As a result, all

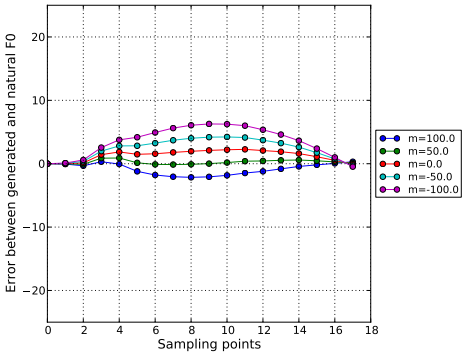

Figure 3: *Error vectors with varying m while b and λ are the same as the optimal. Measured in semitone.*

the generated contours have a fixed tail height by the end of the syllable, i.e., they shared the same offset. This means that, when b is held at its optimal value, the offset F0 of a syllable is virtually guaranteed to be near optimum.

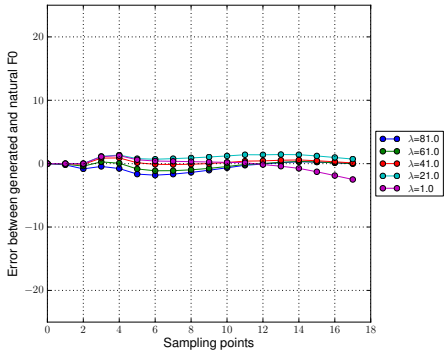

Figure 4: *Error vectors with varying λ while m and b are the same as the optimal. Measured in semitone.*

Figure 4 displays error vectors of cases where only λ is set to vary from the optimal value. The deviations are very small, indicating a much weaker effect than those of b and m. However, this does not mean that λ is unimportant in all cases. It has in fact been demonstrated that, when modelling data contain unstressed syllables and the neutral tone, the role of λ is crucial [3, 8].

The conclusion is that among the three qTA parameters, λ, i.e., target approximation rate, is less important than b, target height and m, target slope, at least for the present data set. It further suggests that a learning procedure that can find close-fitted target heights and target slopes may provide a good approximation to qTA, especially for data where λ does not have important functional significance.

2.3. Pursuit functions for pitch target estimation

The qTA model was designed to generate contours from underlying pitch targets. It is a third-order differential equation which contains non-linear elements. In this form it is not easy for learning, i.e., finding optimum underlying pitch targets from input signal. There is no analytical expression for the inverse of qTA, and so analysis-by-synthesis has to be used to estimate the model parameters from natural speech data. To make mathematical inversion possible, we investigated a method involving "pursuit" functions.

A pursuit curve is the path of an object that seeks to pursue another moving object. Consider a simple case of a hound chasing a fox, where the fox is moving at constant speed and constant direction. The pursuit curve is found under the assumption that the direction of the hound is always towards the current location of the fox, i.e. that the tangent of the pursuit curve at time t is directed towards the location of the hound at time t. Figure 5 shows an example pursuit curve.

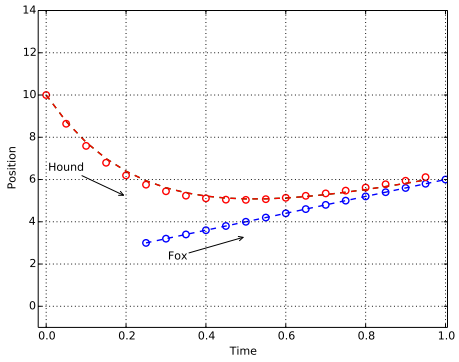

Figure 5: *A pursuit curve. Arrows indicate velocity directions.*

In the situation shown in Figure 5, where the pursued object is moving at constant velocity, the pursuit curve can be shown to have the form of an analytic equation

$$H(t) = F_0 + vt + (H_0 - F_0)e^{-t/l}, \quad (6)$$

where H_0, F_0, v, t, l denotes the initial position of the hound, initial position of the fox, velocity of the fox, time series and the "time lead" of the fox, respectively. We can interpret this as the pursuer attaining the location and velocity of the pursued according to some exponentially decreasing value of time. The rate of attainment is simply related to the time lead of the pursued.

If we use a pursuit curve to simulate the target approximation process, the linear path of the pursued becomes the underlying pitch target, the pursuit curve is the observed F0 contour, and the initial velocity of the pursuer becomes the initial conditions for the F0 at syllable onset.

As a simpler target estimation function, the pursuit function itself does not fit F0 contours as cleanly as qTA since it allows for instantaneous changes in velocity and acceleration at syllable boundaries. This can lead to rather unnatural looking F0 contours as the pursuer changes from one pursued target to another, as can be seen in Figure 6.

Since, however, we only want a simple way of deriving pitch targets represented by b and m from the input contours,

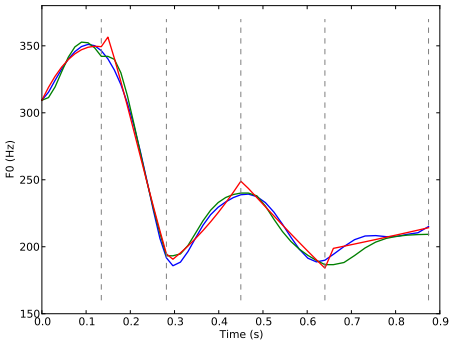

Figure 6: *Clear sharp turning points of pursuit curve at syllable boundaries. (Natural contour in blue, qTA fitted contour in green, pursuit curve in red.)*

these discontinuities may not be important. This is because, once the targets are learned, we will still use qTA to generate the contours from the targets, free of discontinuities at syllable boundaries.

In the next section we will compare the pursuit function with qTA-based analysis-by-synthesis in terms of quality of fit using a small corpus of utterances.

3. Pitch target learning

3.1. Data

480 utterances recorded from a female native Mandarin Chinese speaker were used to explore the fit of the target approximation model. This corpus was originally collected to examine the effects of lexical tones and focus on the formation and alignment of F0 contours [9]. The corpus consists of 24 sentences, each of them was said with four different focus locations and repeated five times. Every sentence consists of three Chinese words, the first and the third are bisyllabic and the second is monosyllabic. So there are five syllables in each sentence (Table 1). Further, the second, third and fourth syllables have varying lexical tones, which were the target syllables for the current experiment. The four focus conditions are: neutral focus (no focus), initial focus (on word 1), medial focus (on word 2) and final focus (on word 3). When a syllable is on-focus, its preceding syllable is pre-focus and its following syllable is post-focus.

Table 1: Tone patterns and corresponding sentences used as recording material. H, R, L, and F represent high, rising, low, and falling tones, respectively.

Word 1	Word 2	Word 3
HH māomī	H mō	HH māomī
HR māomí	R ná	LH mǎdāo
HL māomǐ	F mài	
HF māomì		

3.2. Method

The goal of the experiment was to learn the optimal pitch target slope and height, for each lexical tone in each focus con-

dition, using pitch targets learned by both qTA-based analysis-by-synthesis and the pursuit curve function. Results are then compared in terms of similarity of the discovered targets, overall quality of fit.

Both methods were implemented in Python. In the case of qTA, the exhaustive local search algorithm proposed by [2] was used, with rate of target approximation (λ) held constant at 41.0. The algorithm read the data and parameter constraints, and then iteratively tested all combinations of target values using a set of possible values for target height and target slope for each utterance separately. The parameters that showed the lowest sum square error between the generated and natural F0 contours for each utterance were chosen as the target. The optimal targets for each utterance were then averaged to derive different targets for each tone and focus condition.

For testing the pursuit function, the time lead of the pursued (l) was fixed at 0.075s. Like the qTA approximation rate parameter, the pursued time lead controls the rate at which approximation takes place and might be considered a characteristic of the speaker or speaking style [8, 10].

To fit the pursuit function, a linear least squares method was used over the whole data set. Each observed F0 measurement was expressed in terms of a number of coefficients applied to a vector of 32 unknowns, being the target height and slopes of the 4 tones in the 4 focus conditions. The least squares fit derives the values of the 32 unknowns that minimise the squared error of prediction of the data by the model.

3.3. Results and evaluation

The value of the pursuit function is that it provides a direct means to determine the optimal pitch targets from the measured F0. We would still like those targets to be compatible with qTA, since as mentioned above, the pursuit function has some intrinsic inadequacies for F0 contour generation.

Table 2: Learned functional pitch targets. For focus function, PRE, ON, and POS stand for pre-focus, on-focus, and post-focus regions, respectively.

Focus	Tone	Target slope (st/s)		Target height (st)	
		qTA	pursuit	qTA	pursuit
PRE	H	2.1	7.4	19.0	18.2
	R	30.7	17.7	11.6	12.9
	L	-16.4	-40.9	16.5	20.1
	F	-29.5	-27.3	21.5	21.6
ON	H	2.5	3.3	19.4	19.3
	R	28.7	12.5	10.8	13.0
	L	-79.1	-108.4	21.6	27.0
	F	-56.4	-43.2	28.3	27.1
POS	H	-11.6	-16.8	16.4	17.3
	R	11.9	-1.9	11.3	13.1
	L	-79.7	-119.0	20.4	27.3
	F	-36.8	-35.5	20.1	20.4

As shown in Table 2, the pitch target heights found using the pursuit function were very similar to those found using qTA. There are greater differences between the estimated pitch target slopes, but they are broadly of similar sign and size.

Figure 7 illustrates F0 contours generated from the qTA targets and pursuit targets shown in Table 2 for an utterance containing a "LHL" syllable sequence with focus on the second syllable. The generated contours for qTA and the pursuit function are similar to each other and to the measured F0.

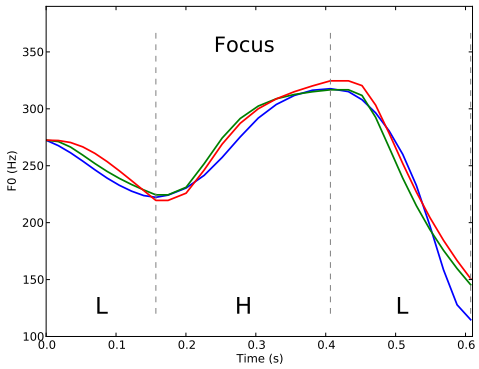

Figure 7: *Contour generated with pursuit targets is very close to the one with qTA targets. (Natural contour in blue, contour generated with qTA targets and pursuit targets are in green and red, respectively.)*

The quality of the targets obtained by the two methods was evaluated by measuring the root-mean-square error (RMSE) of prediction of the data set using the qTA model and the discovered targets. For the targets found by qTA-based exhaustive search, the RMSE of prediction is 1.83 semitones (Pearson $r = 0.8453$). For the targets found by the pursuit function, the RMSE is 1.81 semitones (Pearson $r = 0.8458$). Thus the new method of estimating underlying targets is as least as good as using the qTA model directly for inversion.

In terms of learning efficiency, although the linear least squares with pursuit function can get target parameters in a blink of time, we didn't expect it to be a replacement of simulated annealing as implememnted in PENTAtrainer2. Instead, we hope in future work, it is possible that further improvements can be made, perhaps by seeding the qTA model with pursuit function found targets and then applying some iterative hill-climbing method to find a local minimum error of prediction.

4. Conclusion

In this study, we have shown how a pursuit function can be used in place of the qTA function for the problem of finding underlying pitch targets from measured F0. From the results we can see that the pursuit function enabled a direct means of finding the pitch targets, and more importantly, that the learned targets could be reused by the qTA model for F0 contour production. This finding provides support for our hypothesis that without fully replicating the mechanical process itself, articulatory control parameters for prosody can be learned with simpler learning process which is more conceivably developed in motor control by the human brain.

5. Acknowledgments

We would like to thank Dr. Mark Huckvale (UCL) for originally suggesting the study. The content of the paper has been greatly improved by his helpful comments.

Abstract

The overarching goal of this paper is to advance on the understanding of how evidential meanings are expressed in natural languages. Specifically, we aimed to investigate what type of meaning was encoded in yes-no questions through the combination of the question particle (QP) *que* 'that' and the nuclear intonational pattern L+H* L% in Majorcan Catalan yes-no questions (i.e., *Que és un llibre?*$_{\text{L+H* L\%}}$ *'QP-It's a book?')*, and to understand any temporal information that might be encoded through this construction. Several complementary research methods were used to address our question: the Discourse Completion Task, an acceptability task and a multiple-choice questionnaire. The results show that three types of information are encoded in QP *que*_L+H* L% questions: sentence modality, inference based on direct evidence and immediacy of the evidence.

Index Terms: intonation, question particles, evidentiality, typology, Catalan.

1. Introduction

All languages have some way of marking information source, though different parts of the grammar may be recruited to do so depending on the language. Lexical means for specifying source of information are probably universal. For instance, the lexical item *es veu* is used in Catalan in (1) to indicate that the speaker does not have firsthand knowledge of the proposition ([1]). In Colombian Spanish, the combination of the verb 'say'[1] and the complementizer 'that' can have different functions such as a) reported speech, b) hearsay, c) labelling or d) dubitative ([4], [5]). This is also found in other Romance language such as Galician, Romanian, Sardinian or Sicilian ([6]).

(1) *S'han quedat sense llum a Girona.* ***Es veu*** *que hi ha nevat molt.*
'The power is out in Girona. There must have been a lot of snow.'

(2) *Y eso,* ***dizque*** *es peligroso, no?*
'And that's dangerous (reported), no?'

Some languages have true evidential systems, i.e., inflectional systems with morphemes that have source-marking at the core of their semantics and are obligatory. In other languages, evidentiality specifications are "scattered" throughout the grammar ([4]). While there is some work showing the relevance of prosodic or gestural cues in the expression of epistemicity, i.e., the degree of certainty about a proposition (see [7], [8], [9] for declaratives; [10] for both declaratives and interrogatives, and [11] for interrogatives), research examining prosodic marking of evidential strategies is still scarce. The only investigation we are aware of is [12], who showed that deaccenting is used in Japanese biased polar questions when the speaker expects a positive answer based on public evidence.

Majorcan Catalan is a variety of Catalan that is characterized by exhibiting several strategies for forming polar questions based on bias ([13], [14]). Speakers may choose from different pitch accents as in (3) or may head questions with question particles (QPs) such as *que* (complementizer 'that') or *o* (conjunction 'or'), see (4).

(3) *Teniu mandarines?*$_{\text{¡H+L* L\%}}$ 'Do you have tangerines?' vs *Que hi ha gana?*$_{\text{L+H* L\%}}$ 'Are you hungry?'

(4) *Que encara no ha vengut, s'electricista?* 'The electrician hasn't arrived yet?' vs *O no estàs bo?* 'Aren't you well?'

The main goal of this article is to assess the role intonation plays in encoding information source in questions headed by the QP *que* (i.e., in constructions of the type QP *que*_L+H* L%). If it is the case that information source is being encoded through the use of QP *que*_L+H* L%, we also asked what type of evidential information the speaker might be conveying. Since evidential markers may have temporal restrictions ([15]) we also sought to investigate whether, in cases where evidential information was encoded, temporal information might also be available to listeners. Some languages, such as Sherpa ([16], [17]), encode temporal information through the evidential marker. In the case of Sherpa, *immediate* evidence is encoded. We thus left this as an additional possibility, since often times questions are asked based on information that has just become available in the discourse ([18]).

We tested these questions performing different experiments: a) Experiment 1: the Discourse Completion Task ([19], [20], [21]), b) Experiment 2: the acceptability task and c) Experiment 3: the multiple-choice questionnaire.

2. Experiment 1: the Discourse Completion Task

2.1. Methodology

For this study the Discourse Completion Task involved the creation of a set of situations which contained two evidential conditions (inferred direct evidential and hearsay) plus a non-evidential situation (see examples (5), (6) and (7) respectively). The difference between the two conditions is

[1] The form *diz que* could be a shortened version of the plural form *dicen que* 'they say that' ([2]) which "began as the collocation of a verb introducing indirect speech and its complementizer, and developed into an evidential strategy" ([3]: 16).

that while in direct evidential contexts the speaker infers the proposition from direct evidence (s/he sees it directly), in hearsay contexts inference is based on hearsay or the report of the proposition by another individual. The situations provided in the DCT were read aloud by the first author of this paper to the participants. Then, the participants were asked to respond appropriately to them. The situations were expected to elicit two biased yes-no questions (in the case of the two evidential conditions) and a neutral polar question. The questionnaire was made up of 12 situations (3 conditions x 4 pragmatic contexts). Fifteen speakers (8 females, 7 males) participated in the experiment. The final database was comprised of 180 utterances. Data were coded in Praat ([22]) for the following: a) use of lexical markers (question particles such as *o* 'or', or *que*), b) use of syntactic markers (negative yes-no questions, split questions) and c) prosodic transcription using the latest version of the Cat_ToBI system ([23]). The annotations were collected automatically in .txt format through a Praat script and then transferred to an Excel and a SPSS file for subsequent statistical analysis.

(5) Non-evidential situation: 'You have a bit of a cough and suddenly, while you're talking to a neighbor, you feel a sore throat coming on. Ask her if she has a cough drop'.

(6) Hearsay situation: 'Your cousin visits you. While you are talking, she says that since she's stopped working, she has plenty of free time. You take this to mean that she retired, so you confirm with her'.

(7) Direct evidential situation: 'It's your birthday and your friend gives you a present. You ask him if it's a book, since the package has a book-like shape'.[2]

2.2. Results

Figure 1 shows the percentage of occurrence of the dependent variable COMBINATION OF LEXICAL/SYNTACTIC STRATEGIES AND INTONATION with three levels of lexical/syntactic strategies (no QP, QP and other) and four levels of intonational strategies (¡H+L* L%, H+L* L%, L+H* L% and other)[3] for each of the possible evidential conditions (neutral, hearsay or direct evidence). The results clearly show that whereas neutral and hearsay contexts elicit a high percentage of the ¡H+L* L% intonational pattern without any QP, direct evidential contexts elicit the production of the L+H* L% intonational pattern headed by a QP (*que* or *o*). A Friedman test revealed a significant effect of evidential condition (neutral, hearsay or direct evidence) on the intonation of the y/n questions ($\chi^2(2) = 28.203$, $p < .001$) as well as on the lexical/syntactic marking ($\chi^2(10) = 24.125$, $p < .001$).

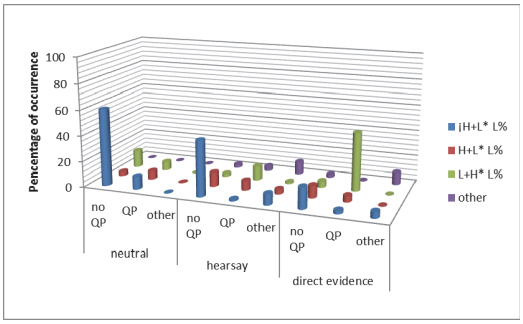

Figure 1: *Percentage of occurrence of the variable* COMBINATION OF LEXICAL/SYNTACTIC STRATEGIES AND INTONATION *for each of the possible pragmatic contexts (neutral, hearsay or direct evidence).*

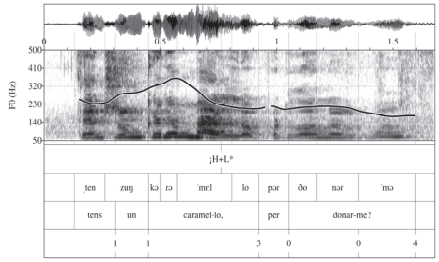

Figure 2: *Waveform and F0 contour of the y/n question Tens un caramel·lo, per donar-me? 'Do you have a candy to give me?' (the most common contour in the neutral pragmatic contexts).*

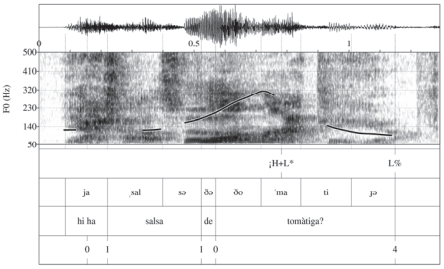

Figure 3: *Waveform and F0 contour of the y/n question Hi ha salsa de tomàtiga? 'There's tomato sauce?' (the most frequent pattern in the hearsay condition).*

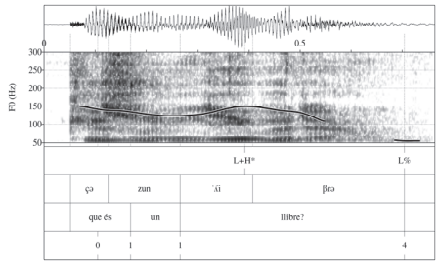

[2] All the biased situations used in the experiments had a positive bias, that is, they were situations designed to elicit an affirmative response.

[3] The ¡H+L* L% nuclear configuration is realized as a fall with a leading extra high tone aligned with the end of the preaccentual syllable. The H+L* L% pattern is identical to the previous configuration but with a just high leading tone. The L+H* L% pattern is characterized by a rising movement with the peak aligned with the end of the accented syllable followed by a falling final movement.

Figure 4: *Waveform and F0 contour of the y/n question Que és un llibre? 'QP-It's a book?' (preferred strategy for direct evidential contexts).*

3. Experiment 2: the Acceptability task

3.1. Methodology

Experiment 2 consists of an acceptability task, which allows us to evaluate the degree of perceived appropriateness of target intonational patterns (in this specific case, with the combination of lexical markers) to different pragmatic contexts. Six pragmatic contexts were created with two different evidential conditions (direct evidential for half of the contexts and hearsay for the other half, see (8) and (9) below). Then three different combinations of intonation and QP, which were understood to be semantically appropriate given the pragmatic contexts, were produced, as follows: a) no QP_¡H+L* L% intonational pattern; b) QP *que* _L+H* L% intonational pattern; and c) QP *que* _¡H+L* L% intonational pattern.[4] Thus, we had a total of 36 trials: 2 contexts (direct evidential and hearsay) x 3 combinations of QP and intonational conditions (no QP_ ¡H+L* L%, QP *que*_L+H* L% and QP *que* _¡H+L* L%) x 3 pragmatic contexts + 18 fillers.

Subjects were asked to rate the acceptability of the question produced in a specific context using a 7-point Likert scale (1=totally unacceptable, 7=acceptable). Forty-six Majorcan Catalan listeners (23 female and 23 female) participated in the experiment. The experiment was run by the Survey Gizmo software (online survey software – surveygizmo.com) and was approximately 10 min long.

(8) Hearsay situation: 'Maria arrives at the fruit store and hears the owners talking about how they have the shoes from the shop owner next door, who has recently retired and closed the shop.' Target question: 'Are you going to sell shoes?'

(9) Direct evidential situation: 'Maria arrives at the fruit store and sees that the owners are putting pairs of shoes on the shelves in the entrance.' Target question: 'Are you going to sell shoes?'

3.2. Results

Table 1 shows the mean of the ACCEPTABILITY RATINGS (dependent variable) and the standard deviation of the three possible combinations of QP and intonation (no QP_¡H+L* L%, QP_¡H+L* L% and QP_L+H* L%) for each of the possible evidential conditions (direct evidential and hearsay). As we can observe in Table 1, listeners rate the combination of QP *que* and the L+H* L% intonational pattern as the most natural when it is produced in a direct evidential context (mean of 5.41). However, the same pattern of intonation and QP shows a high rate of acceptability in the hearsay context (mean = 5.12). The results of two Friedman tests showed a statistically significant effect of the combination of QP + intonation on the acceptability mean in hearsay ($\chi^2(2) = 15.510$, $p < .001$) and in direct evidence context ($\chi^2(2) = 32.690$, $p < .001$). The Wilcoxon tests using a Bonferroni correction showed that the QP *que* L+H* L% pattern differs statistically from the rest in both the direct evidential and hearsay conditions ($p < .001$)

Table 1. *Acceptability mean and* ± standard deviation for each combination of QP + intonation and pragmatic context.

	Hearsay	Direct Evidence
no QP_¡H+L* L%	4.56 ±1.69	4.51 ±1.68
QP *que*_¡H+L* L%	4.27 ±1.68	4.34 ±1.95
QP *que*_ L+H* L%	5.12 ±1.73	5.41 ±1.73

4. Experiment 3: Multiple-choice questionnaire

4.1. Methodology

For the multiple-choice questionnaire we created three pragmatically neutral contexts and three different combinations of QP and intonational conditions. Each combination of QP and intonational conditions was inserted in each of the pragmatically neutral contexts. Therefore, we had a total of 14 trials: 3 pragmatically neutral contexts x 3 QP + intonational conditions (no QP_¡H+L* L%, QP *que*_L+H* L% and QP *que*_¡H+L* L%) + 7 fillers. The subjects were asked to answer 2 multiple-choice questions related to the information source and to the time at which the evidence was available. One example of the trials was as follows: —If Maria says 'You're going to sell shoes?' to the owners of the fruit store is because Maria: a) heard that they might sell shoes, b) saw that they might sell shoes, c) heard or saw that they might sell shoes (but I'm not sure), d) I don't know. —When did Maria hear or see it? a) Just now, b) A few hours ago, c) Yesterday, d) I don't know. The 'hearing' response was an intuitive response for the hearsay condition and the 'seeing' response for the direct evidential condition. Experimental presentation was done using the Survey Gizmo software (online survey software – surveygizmo.com) for the forty Majorcan Catalan listeners (25 females, 15 male) that participated in this task and lasted approximately 10 min.

4.2. Results

Figure 6 shows the count of the dependent variable SOURCE OF INFORMATION (four levels: auditory, visual, auditory or visual, DK) for the independent variable COMBINATION OF QP AND INTONATION (three levels: no QP_¡H+L* L%, QP *que*_¡H+L* L% and QP *que*_L+H* L%). The results show that the QP *que*_L+H* % condition elicits the highest rate of visual (54 out of 360 responses) and visual/auditory (48 out of 360) responses and no "I don't know" responses. By contrast, the QP *que*_¡H+L* L% condition elicits the highest rate of auditory responses (43 out of 360) and the second highest rate of visual/auditory responses (41 out of 360). The effect of the combination of QP and intonation was not statistically significant (Friedman test: $\chi^2(2) = 4.516$, $p > .05$). Wilcoxon tests were used to follow up on this finding and they demonstrated that the effect of the QP *que*_L+H* L% significantly differed from the effect of the ¡H+L* L% intonational pattern ($T = 1019.50$, $p < .05$, $r = -22.89$) on the count of the dependent variable SOURCE OF INFORMATION.

[4] The reason why we did not fully cross the lexical and intonational conditions is because the combination of the QP *que* and the L+H* L% pattern is ungrammatical. Thus, we prevented the listeners from rating the degree of acceptability of the target itself, rather than that of the target produced in a specific pragmatic context.

Figure 7 shows the count for the dependent variable TIME OF EVIDENCE (four levels: just now, a few hours ago, yesterday, DK) for the independent variable COMBINATION OF QP AND INTONATION (three levels: no QP_¡H+L* L%, QP *que*_¡H+L* L% and QP *que*_L+H* L%). As observed in the graph, the highest rate of 'right now' responses (70/360) were obtained for the condition QP *que*_L+H* L%. The Friedman analysis showed that the combination of lexical and intonational strategies had a statistically significant effect on the dependent variable TIME OF EVIDENCE (Friedman test: $\chi^2(2) = 13.225$, $p = .001$). The subsequent Wilcoxon tests revealed statistically significant differences between the combination of QP_L+H* L% and the rest of conditions ($p < .01$).

5. Discussion and conclusions

The aim of this study was to investigate what type of meaning was encoded through the combination of the QP *que* and the nuclear pattern L+H* L% in Majorcan Catalan y/n questions, and also to understand any related temporal information being conveyed through this construction. To this end, a set of three experimental tasks were carried out: a production experiment using the Discourse Completion Task methodology, a perception test (acceptability task) and another perception test based on a multiple-choice questionnaire. The results obtained from these different experimental approaches allow us to conclude that three types of information are encoded in QP *que*_L+H* L% questions. First, sentence modality, specifically interrogative modality, is encoded by the combination of the question particle and the rising-falling intonational pattern. Second, this particular construction informs us that the speaker has inferred the proposition through direct evidence (visual, in the specific case of this work) and now wants to ask for confirmation of this inference. Finally, listeners that hear the QP *que*_L+H* L% construction infer that the propositional content became available to the speaker just prior to the time of the utterance. Therefore, listeners are able to infer information about time reference directly through the QP *que*_L+H* L%. and do not need to rely on pragmatic context for this information. The construction we describe, then, also conveys immediate evidence like the Sherpa case mentioned above.

In this paper, only visual direct information was tested for direct evidential contexts. For instance, [15] showed that sentences with the particle *–te* in Korean signal sensory evidence, regardless of the tense that they occur with. We suspect that this is also the case for QP *que*_L+H* L% questions, in Majorcan Catalan. Unlike the *–te* particle, however, our data show a temporal restriction such that this construction can only be used just after the proposition was activated, and as a result listeners infer this temporal information when they hear the construction. Further research will be necessary to test whether the results obtained for the sense of sight are also applicable to other senses.

In sum, we conclude that the QP *que*_L+H* L% questions work as a construction, that is, a learned pairing of form and meaning ([24], [25]) which conveys sentence modality, source-marking and temporal information. In her paper on Korean evidentials, [15] notes the various strategies for encoding evidential information reported by [26] in his survey of 418 languages: verbal affix/clitic (131 languages) or particles (65 languages). [15] calls for research on languages that do not express evidentiality through distinct evidential morphemes, proposing that this will help us to understand how evidential meanings are expressed and how they make specific evidential distinctions. Our results show that without recruiting a specific part of the grammar (intonation), source-marking and temporal information are no longer available to the listener. Thus, we confirm that intonation is indeed a part of the grammar available for conveying evidential meaning, in this case working in tandem with the particle *que*. Our findings therefore have important typological implications for the study of evidential meaning.

6. Acknowledgments

A preliminary version of this paper was presented at the conference *Phonetics and Phonology in Iberia* (June 2013, Lisboa, Portugal) and the conference *Hispanic Linguistics Symposium* (October 2013, Ottawa, Canada). We are grateful to the participants at these conferences for their helpful comments and suggestions. We also thank all the subjects that participated in the different experiments. This research was funded by projects FFI2011-23829/FILO, BFU2012-31995 (awarded by the Spanish Ministry of Science and Innovation and the Spanish Ministry of Economy and Competitiveness) and 2009 SGR 701 (awarded by the Generalitat de Catalunya).

Abstract

It is very common for a language to have different dialects or accents. The different pronunciations of the same words is one of the reasons for the different accents, in the same language. Swiss French accents have similar pronunciation to standard French, but noticeable differences in prosody. In this paper we investigate the use of standard French synthetic acoustic parameters combined with Swiss French prosody in order to evaluate the importance of prosody in modelling Swiss French accents. We use speech synthesis techniques to produce standard French pronunciation with Swiss French duration and intonation. Subjective evaluation to rate the degree of Swiss accent was conducted and showed that prosody modification alone reduces perceived difference between original Swiss accented speech and standard French coupled with original duration and intonation by 29%.

Index Terms: French accents, Swiss prosody, duration, intonation, speech synthesis

1. Introduction

The perception of different regional accents in a language can result from several factors. In French, the accents can vary because of different factors according to the regions. Eventhough there are noticeable differences at the pronunciation level of some phones between "Français de Référence" (FR) defined by Morin [1] as standard and Canadian French (or Quebec French) [2], between FR and Swiss French the differences in prosody have an important role in accent discrimination.

In automatic speech recognition (ASR), regional or foreign accents and dialects of a language bring variations that decrease performance of systems. It was shown by Huang [3] that the two main sources of inter-speaker variation were gender and accent.

Kat [4] proposes two solutions to overcome the variability introduced by accent: using a wide training database which includes accented data, or building accent-specific systems which will be used according to the accent of the speech to be recognised. In the literature, there are many other attempts to tackle the accent issue (mainly for non-native accented speech) in ASR by using adaptation techniques [5, 6, 7]. More generally, ASR systems are often confronted with non-native accents, and need to counteract effects of accent component.

Conversely, in text-to-speech synthesis (TTS), producing accented speech is desirable for some applications like speech-to-speech translation (S2ST), foreign language learning and dialect synthesis. Synthesising accented speech is still a quite new and challenging area. In most cases, different accents are modelled separately using different training data. There is only limited recent work on regional accent adaptation in TTS. Astrinaki [8] proposed interpolation of TTS models using closest speakers to a chosen geographical position. In this way, the English voice has average characteristics of these speakers representing the specific regional accent. Another work by Gutierrez [9] consists of generating intermediary accent transformations between native and foreign speakers, to evaluate pronunciation of learners (computer assisted pronunciation training). This research topic can be seen as part of TTS for under-resourced languages and cross-lingual speaker adaptation for TTS.

In the SIWIS [1] project, we are aiming at personalised S2ST, i.e. being able to recognise, translate to another language and synthesise speech with an output voice sounding like the input speaker's. One of the goals is to improve prosody rendering in the TTS part of the system. The final goal is a system enabling communication between speakers of different languages. As people are generally more comfortable when speaking to someone with the same accent as theirs, synthesising speech with the same accent is more convenient for the user.

Considering the differences in prosody between French and Swiss French speakers, we believe that using robust acoustic French TTS models combined with Swiss French prosody models will allow us to synthesise Swiss accented speech. Adapting acoustic level features from a language to an accent can be done using standard speaker adaptation techniques [10, 11]. On the other hand, adapting prosody is a much more challenging issue.

In this paper, a preliminary step towards this idea is to investigate whether it is feasible to produce speech with Swiss accent using standard French acoustic models. In this direction an attempt is made to explore the importance of prosody in Swiss French accent by evaluating the degree of accent of partially synthetic speech. Our hypothesis is that using only Swiss prosody modification allows to identify Swiss accents, even with standard French pronunciation. For that we combine standard French synthetic speech and Swiss duration and intonation. Native French listeners evaluated the accent of the resulting speech.

The rest of the paper is organised as follows. We first give an overview of the differences in prosody between FR and Swiss French. Then, we describe how to exploit French TTS models to synthesise Swiss accented French. A description of the data we used is made. Experiments are detailled in the following section. Finally we conclude and propose future directions.

2. Swiss French accent

It is important to underline that the differences between FR and Swiss French are limited, since the speakers are geographically close and furthermore, linguistically, Romandie (the French

[1]Spoken Interaction with Interpretation in Switzerland, http://www.idiap.ch/project/siwis/front-page

speaking part of Switzerland) would not be distinguished from Eastern and Southeastern France according to Knecht [12].

Consequently, in this paper, the focus is only on the acoustic aspects and prosody of Swiss accent and not on lexical differences nor on the grammatical or semantic structure. It is difficult to define a description of Swiss accent in a global way, mainly because there are different granularities of accent distinction within Switzerland. Most of the French native Swiss people can distinguish the accents by canton (administrative Swiss regions). Moreover, within a canton, people are even able to distinguish accents among cities. We attempt to give a quick overview of the shared peculiarities in Swiss accents.

Some differences in pronunciation between Swiss and French speakers exist, but according to Swiss regions, these are not equally strong. Metral [13] gives more details on segmental aspects of Swiss accents.

There are some divergences – as often in the area of prosody – on the rhythm topic, i.e. Swiss speakers are known to speak slower than French. Miller [14] showed that on read speech samples, speaking rate was the same for French and Swiss (from Vaud canton) speakers, but the articulatory rate (excluding pauses) was slower for Swiss speakers. French speakers use more pauses, which decreases their speaking rate. Schwab [15] recently lead an empirical study to verify whether Swiss people indeed speak slower than French people or not. The findings showed that pause frequency and duration were not different among some French, Belgian and Swiss speakers. However, articulation rate was found to be slower for Swiss speakers.

Schwab [16] compared two Swiss regional accents with French accent, regarding penultimate accentuation, shows that Swiss speakers are more likely to accentuate penultimate syllables than French speakers. Variations were also observed among Swiss regions with different strategies in expressing prominence on these syllables.

Swiss speakers are often said to produce more variations in their intonation, however it is hard to study the phenomenon due to the variety of intonation patterns. By accentuating different syllables, they generate different intonation patterns that may sound more "lively" to French listeners.

3. Combining standard French average spectral parameters with Swiss French prosodic features

Our hypothesis is that Swiss prosody plays a major role in Swiss accent discrimination and hence that adding prosodic information will help perceiving the Swiss accent. If this is true, the degree of accent should get closer to the original Swiss accented speech when Swiss prosody is added to non accented speech.

Using analysis by synthesis, we can modify some parts of a speech signal without altering other parts. Based on this principle, we propose to generate synthetic spectrum using French TTS models (corresponding to vocal tract in the source-filter model) and combine it with original duration and intonation of Swiss French.

3.1. Acoustic and prosodic features

The acoustic features commonly used in HMM-based speech synthesis were used: mel cepstral coefficients plus energy coefficient, pitch and band aperiodicity and the first and second derivatives for each feature. The duration information was estimated with forced alignment based on these features and the existing model parameters.

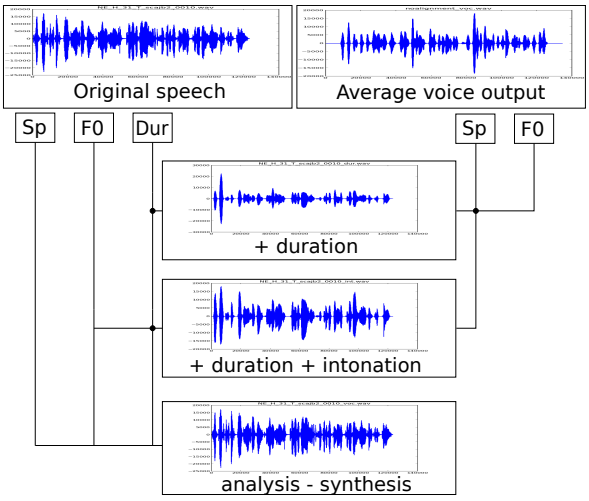

Figure 1: *Experimental setup. Features are Sp for spectrum, F0 for fundamental frequency, Dur for duration.*

3.2. Average French TTS models

We used statistical parametric speech synthesis models (hidden Markov models) to generate speech parameters that were used to "standardise" the pronunciation of all the speakers.

For that, we trained an average French HMM-based speech synthesis system using the HTS framework [17] and speaker adaptive training [18]. Average voice models are more robust than single speaker models and do not require extensive amounts of data from a single speaker.

Then, we could synthesise speech parameters and incorporate original duration and intonation information according to the prosodic features we wanted to evaluate using a vocoder.

3.3. Resynthesis

In parametric speech synthesis, the speech signal is represented by some parameters, spectrum and excitation in our case, and needs to be reconstructed to produce a waveform.

3.3.1. Vocoding

To homogenise the quality of the samples we want to produce, analysis synthesis was performed on the original waveforms, which consists of feature extraction and reconstructing the signal using a vocoder.

A completely synthetic waveform was also produced, using the French average models presented earlier. The parameters generated were finally put through the same vocoder.

3.3.2. Use of duration information

We used duration as a first prosodic feature to be added to the average synthetic speech. For that, we first extracted the duration information from the original waveforms using forced alignment: given the speech features and the corresponding transcription (full-context phonetic labels in our case), the Viterbi algorithm is used to estimate phone and state boundaries.

Using the state duration, a forced-aligned synthesis was performed, i.e. parameter generation given the known state sequence. The resulting speech was composed of synthetic parameters, but aligned in time with the original speech. The result was synthetic speech with original phoneme level duration.

3.3.3. Use of duration and intonation information

In this case, we also performed time alignment, and we replaced the synthetic intonation (log F_0) with the original one. After vocoding, the output was a speech signal composed of synthetic spectrum and aperiodicity coupled with original duration and intonation.

The reason for using both original intonation *and* duration is that it is not possible to use only original intonation, because the other parameters (spectral information) have to be aligned with the excitation part to reconstruct the speech signal.

Figure 1 gives an overview of the experimental setup described in this section.

4. Databases

The data used in this work comes from two databases: the BREF database [19] and a part of the PFC database [20] with additional content [21].

BREF is a French read-speech corpus designed for speech recognition model training and testing. The sentences to be read by the speakers were chosen from the French newspaper *Le Monde*. It consists of recordings from 120 selected speakers (55 males and 65 females), recorded in a sound-proof room. The complete database represents more than 100 hours of speech. The speech from 10 male speakers was used for this work.

The dataset taken from the PFC database consists of read speech by Swiss French speakers and French speakers from Paris. These data have been recorded in 5 cities: Paris (France) and 4 cities in 4 different Swiss cantons, i.e. Martigny (Valais), Nyon (Vaud), Neuchâtel (Neuchâtel), and Geneva (Geneva). For each location, 4 male and 4 female speakers born and raised in the city were recorded. In this work, 12 speakers were selected among the 20 male speakers available.

5. Experiments

The experiment conducted consisted of the generation of partially synthetic speech combined with Swiss French prosodic information, and was evaluated with a subjective listening test.

5.1. French TTS model

The TTS models were trained on a subset of the BREF database composed of 6857 sentences (about 12 hours of speech) from 10 male speakers. We used 39 mel cepstral coefficient with energy coefficient, log F_0, 21 band aperiodicities extracted every 5 milliseconds with STRAIGHT [22] and their first and second derivatives. 5 state left-to-right HSMMs were trained with full-context labels using version HTS 2.1 and speaker adaptive training [18].

5.2. Subjective evaluation

One common sentence was selected for the 10 Swiss and 2 French male speakers from our PFC dataset. Only male speakers were used to match with our existing TTS average French male models. This sentence was used in previous Swiss accent related studies evaluations [23, 24].

> *"La côte escarpée du mont St Pierre connaît des barrages chaque fois que les opposants de tous les bords manifestent leur colère."*

It was segmented manually and the orthographic transcriptions were corrected manually before full-context label creation (adding pauses and hesitations). Features were extracted from Swiss French data the same way as for training data. The trained TTS models were then used to estimate the duration of Swiss speech data.

A listening test was conducted in order to evaluate the degree of accent of the file generated as described in section 3.3. For this purpose, a webpage was built enabling subjects to listen to 1 completely synthetic file and 1 file with original duration, 1 file with original duration and intonation and 1 vocoded file for each of the 12 speakers, which sums up to 37 files in total. The vocoded version is perceptually very close to the original recorded speech as it is only analysis synthesis. It enables us to allow for the vocoder effect in the perception. For each file, the listeners had to give a degree of Swiss accent between 1 and 5, 1 being "no accent" and 5 "strong accent" (in the instructions, "no accent" was defined as *standard accent* and close to Paris accent). The test took approximately 10 minutes, and the listeners could listen to the files as many times as they wanted.

28 subjects did the test. Among them, there were 17 males and 11 females, 23 were French and 5 were Swiss (2 from Vaud, 1 from Valais, one from Neuchâtel and one from St Gallen). Their age was distributed in four age ranges (8 were 19-25 years old, 10 were 26-35, 7 were 36-55 and 3 were 56 - 75).

5.3. Results

5.3.1. Degree of accent

Figure 2 shows the mean and standard deviation of the three versions of the file for each speaker – the fourth version displayed in black, which is identical for each speaker, corresponds to the average voice output. The means and variances show that when adding intonation and duration the values get closer to the vocoded version than just adding duration, and modifying only duration gives closer values than the average voice output, as we expected. For the speakers with highest degree of accent (based on the vocoded version), $NE75$, $NY31$, $NY32$, $NY59$ and $NY70$ ($PA86$ has different behaviour), the means of the *intonation + duration* version is still much lower than the vocoded one. $PA86$ is a 86 year old Parisian and although he does not have a Swiss accent, his accent was perceived as strong. The average voice being based on French accent and pronunciation, he has the same pronunciation as the average voice. Adding the prosody resulted in a degree of accent close to the original, explained by both correct prosody and pronunciation.

These results are confirmed by a Wilcoxon signed rank test which was perform for each speaker among the four versions presented (3, plus the baseline average voice), as the data is ordinal [25]. In the case of average version against vocoded version, 9 out of the 12 speakers have significantly different scores; $GE24$, $GE27$ and $PA33$, corresponding to the least accented speakers, are not significantly different. In the case of the version with duration information against the vocoded version, 7 still have significantly different scores: $MA24$ and $NE31$ are not significantly different. Finally, when adding original intonation, the 5 speakers mentioned before as *very different* from the vocoded version are significantly different. $GE55$ and $PA86$ are not significantly different for these versions.

5.3.2. Prosody effect on accent perception

Table 1 shows the means of absolute differences between scores per speaker. For each speaker, a comparison was made between 2 versions of the file among the average voice output (ave), the version including duration (dur), the version including duration and intonation (int) and the vocoded version which is the reference (voc). In 8 cases out of 12, the combination of duration

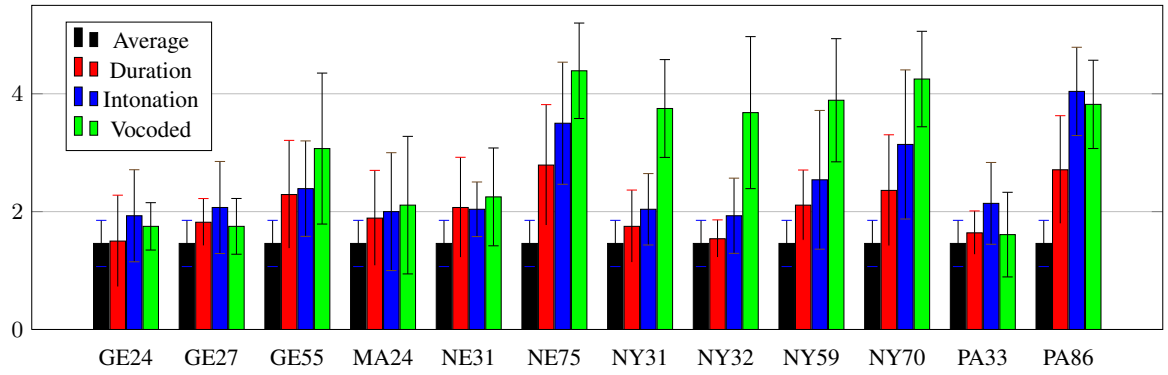

Figure 2: *Mean degree of accent for each version for the 12 speakers - Output of average TTS, with duration information, with duration and intonation, vocoded version*

Table 1: *Mean differences between configurations per speaker*

Speaker	$GE24$	$GE27$	$GE55$	$MA24$	$NE31$	$NE75$	$NY31$	$NY32$	$NY59$	$NY70$	$PA33$	$PA86$
ave_dur	1.04	0.82	0.96	0.96	0.96	0.86	0.89	0.96	0.93	0.79	1.29	0.64
ave_int	1.29	1.32	1.25	1.18	1.21	1.04	1.29	1.14	1.61	1.39	1.50	1.29
dur_int	0.61	0.79	1.07	1.14	0.75	0.68	0.61	0.96	0.89	1.11	1.00	0.93
ave_voc	1.68	1.93	1.54	1.25	1.57	1.54	1.75	1.89	1.60	1.60	2.21	1.79
dur_voc	**0.93**	1.54	**1.36**	1.64	**0.96**	1.04	**1.29**	1.57	1.39	1.39	1.64	1.57
int_voc	0.96	**1.25**	1.57	**1.07**	1.00	**1.00**	1.39	**1.46**	**1.21**	**1.14**	**1.21**	**1.21**

Table 2: *Mean differences between configurations*

	average	duration	intonation	vocoded
average	0	0.93	1.29	1.70
duration	X	0	0.88	1.36
intonation	X	X	0	1.21
vocoded	X	X	X	0

and intonation is closer to the vocoded version (values in bold). The 4 other cases give the advantage to the version including only duration information.

Table 2 gives the global absolute difference between each system. The last column gives the distance between the vocoded speech and the other versions. We can see that between the average voice output and the version with duration information we reduce the distance to the vocoded version by 20%, between the version with duration and the version including duration and intonation, the reduction is 11% and the overall improvement from average to duration and intonation version gives 29% improvement. A Wilcoxon signed rank test confirmed that the differences between score absolute differences were significant ($p - value < 0.01$ in the 3 cases).

It demonstrates that prosody plays an important role in Swiss accent perception. However, for the most accented speakers, prosody alone is not enough to obtain the same degree of accent. In these cases, adequate pronunciation is required to perceive the Swiss accent. This is backed up by the fact that accented Parisian speech can be produced with standard French pronunciation and specific prosody.

The low number of Swiss subjects did not allow us to evaluate the difference in accent perception between French and Swiss listeners, but the numbers showed similar trends for both groups.

6. Conclusions

In this paper we investigated the use of standard French pronunciation with Swiss prosody. This preliminary work was done with a view to adaptating French speech synthesis to Swiss accents. We hypothesised that Swiss accent was mainly characterised by its prosodic aspects. Analysis synthesis method and HMM-based speech synthesis were used to produce synthetic average French speech parameters which were then combined with natural speech prosodic features.

A subjective evaluation was conducted through a listening test to determine whether the degree of Swiss accent can be approached by modifying only the prosody of synthetic speech. The results showed that for 7 male speakers out of 12, using original duration and intonation with synthetic spectral parameters was not distinguished significantly from the original speech by the listeners. The difference of the scores between original speech and unaccented synthetic speech was significantly reduced by 20% by adding original duration and by 29% when adding original duration and intonation. This showed that prosody is important in the perception of Swiss accent. We also found that in the case of strong accents, prosody is not enough to model Swiss accent with standard French pronunciation. We did not use intensity information in this experiment, which would probably give further improvement.

Our future work will be to investigate the use of adaptation techniques for the pronunciation of the synthesis system to Swiss accents, and evaluate the impact of prosody in accent perception with Swiss pronunciation. The intonation contour could be investigated at a finer level to understand differences between regional accents. It would also be interesting to evaluate the accent identification rather than the degree of accent eventhough it is a difficult task for listeners.

Abstract

This paper introduces a hierarchical stress generation for expressive speech synthesis. In the previous study, we proposed a novel hierarchical Mandarin stress modeling method, and the text-based stress prediction experiments demonstrates a reliable stress assignment can be obtained from textual features. However, the stress model should be further verified to be an effective and efficient prosody model in a Text-to-Speech system. In this work, Fujisaki model known as an ideal global representation of prosody is adopted to construct the pitch contours. To illustrate the effect of stress model, the Fujisaki model parameters are automatically predicted by the textural feature with and without stress information. The synthetic speech sounds more natural than that without stress modeling. The RMSE of the pitch contour and the feature importance analysis also show stress information can improve the pitch modeling. This work offers a promising method to accurate pitch modeling for Mandarin expressive speech synthesis.

Index Terms: speech synthesis, Fujisaki model, stress, hierarchical modeling, pitch accent

1. Introduction

Expressive speech synthesis has gained a lot of attention recently because people are no longer satisfied with the flat synthetic speech in navigators, automatic call-center, and information broadcasting system etc. Therefore, the accurate modeling of prosody which can express the para-linguistic information, such as emotion, attitude, intentions, speaker characteristics and making the speech sound more vivid becomes particularly important. Stress is the perceptual prominence within words or utterances, and it constitutes the peaks and valleys of the pitch contours, which is an important factor of prosody.

Although previous work on stress realization which based on concatenation system [1, 2] can produce high quality speech, the expressiveness of the synthetic speech still relies on the audio corpus they used. Recently, HMM-based speech synthesis (HTS) draws growing attention for its flexibility in expressive speech synthesis. HTS-based stress generation can be categorized as direct modeling [3] and indirect modeling [4, 6], which mainly refers to prosodic parameter transformation.

The direct modeling is introducing the stress related question into the question set which is used in the HMM models clustering in HTS. However, the speech generated by this approach cannot convey stress clearly in HTS due to the weakness of emphasis/stress cues and statistical averaging effect of HTS [4]. Badino *et.al,* argue that more sophisticate context features should be designed to obtain a clear emphasis/prominence realization [5].

Regarding the indirect modeling, Yamafishi *et. al.*, [6] use speaking style interpolation and adaptation for HMM-based expressive speech synthesis. Maximum Likelihood linear Regression (MLLR) model is adopted in the style adaptation. Yu, *et.al.*, [4] utilize two-pass decision tree model and factorized decision tree model to extract word-level emphasis patterns from natural English speech, and then embed the emphasis model in the HTS framework. Although the speech generated by prosodic parameter transformation can convey stress effectively, it happened sometimes that a few syllables turned out too strong compared with the adjacent syllables, which makes the whole utterance sound unnatural. This indicates that the tradeoff between prominence and naturalness is hard to balance.

The ultimate goal of our work is synthesizing human-like expressive speech with stress. In the previous study, we proposed a novel hierarchical Mandarin stress modeling method [7]. The top level of this model emphasizes stressed syllables, while the bottom level focuses on unstressed syllables for the first time due to its importance in both naturalness and expressiveness of synthetic speech. The text-based stress prediction experiment demonstrates we can get a reliable stress assignment from textual features. However, the stress model should be further verified to be an effective and efficient prosody model in a Text-to-Speech system.

Therefore, generation process model of fundamental frequency contours known as Fujisaki model is adopted to generate pitch contours in this work. The reason of adopting Fujisaki model lies in two aspects. First, Fujisaki model is also a superpositional quantitative model for representing F0 contour of speech, which is perfect match the two-level hierarchical stress model we proposed, and thus we can directly control the hierarchical stress. Although some hierarchical pitch modeling methods [8-10] have already been proposed recently, the hierarchy is implicit modeled. Second, Fujisaki model is not only a parametric F0 contour stylization, but also has physiological and physical basis [11], and can well represent the long-term features than the commonly used frame-by-frame analysis method.

Some work on stress/prominence/focus realization has already been conducted with Fujisaki model. Kiriyama *et al.*, [12] and Chen *et. al.*, [13] implement a rule-base focus control with Fujisaki model. Ochi, *et.al.*,[14] also use Fujisaki model to control focus, but they predict the differences of the Fujisaki model commands between with and without focus utterances. The method is confirmed by the experiments. But, there are some constrains and limitations in the prosodic difference modeling.

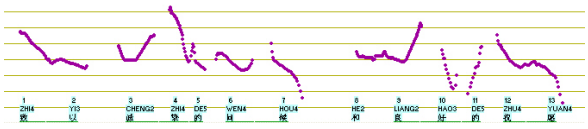
In this work, we want to testify whether the hierarchical stress model could improve the pitch modeling and how much improvement it will achieved. Therefore, we semi-automatically built a 500 sentence corpus with Fujisaki model parameters annotation as the first step. Then we constructed two Fujisaki model parameter prediction models using decision trees, among which, one utilizes the common features used in prosodic model parameter prediction, and the other introduces the stress information compared with the first model. Afterwards, the continuous pitch contours are generated by the two models. Listening test, objective experiment and features importance analysis are carried out. The results show stress model can improve the pitch modeling.

The rest of the paper is organized as follows. Section 2 introduces the hierarchical modeling method, including the hierarchical stress modeling and the superpositional modeling of F0 contour by Fujisaki model. Section 3 shows the details of text-based Fujisaki model parameter prediction with and without the hierarchical stress features. Experimental results and discussions are given in Section 4, and followed by the conclusion and future research in Section 5.

2. Hierarchical modeling

2.1. Hierarchical Mandarin stress model

Mandarin stress can be categorized as sentence stress and word stress from the range of their influence. Considering the importance of unstressed syllable in the naturalness and intelligibility of speech, a novel two-level Mandarin stress modeling method was proposed, in which, word level unstressed syllable investigation are emphasized for the first time, and in sentence level stressed syllables are studied as traditional methods do [7]. Fig. 1 shows a hierarchical stress assignment of a speech sample. First, the sentence stress is assigned onto words, and then each syllable's stress level is assigned within the word. The sentential stressed (denote as *3* in sentence stress) and unstressed syllable (denote as *1* in word stress) are the research focus of this model.



(a) Natural pitch contours

	zhi4yi3	cheng2zhi4de5	wen4hou4	he2	liang2hao3de5	zhu4yuan4
Sentence Stress	2	3	2	1	2	2
Word Stress	3 2	3 2 1	2 3	2	3 2 1	3 2

(b) Hierarchical stress assignment of speech sample (a)

Figure 1: Hierarchical Mandarin stress modeling.

2.2. Hierarchical pitch modeling with Fujisaki model

Fujisaki model is a command-response model that describe F0 contour as the superposition of the outputs of phrase and tone(/accent) commands [11].

Unlike most non-tone languages, which only have positive tone commands, Mandarin has both positive and negative tone commands. The tone command configuration for Mandarin can be found in [11]. The model (for tonal language) can be formulated by the following equations:

$$\begin{aligned}\ln F_0(t) = \ln F_b + \sum_{i=1}^{I} Ap_i Gp(t-T_{0i}) \\ + \sum_{j=1}^{J}\{A_{1j}[Ga(t-T_{1j}) - Ga(t-T_{2j})] \\ + A_{2j}[Ga(t-T_{2j}) - Ga(t-T_{3j})]\}\end{aligned} \quad (1)$$

$$Gp(t) = \begin{cases} \alpha^2 t \exp(-\alpha t), & for\ t \geq 0 \\ 0, & for\ t < 0 \end{cases} \quad (2)$$

$$Ga(t) = \begin{cases} \min[1-(1+\beta t)\exp(-\beta t), \gamma], & for\ t \geq 0 \\ 0, & for\ t < 0 \end{cases} \quad (3)$$

where F_b , $G_p(t)$ and $G_a(t)$ are base fundamental frequency level, phrase commands and tone commands respectively, the detailed symbolic representations can be found in [11].

2.3. Integrating the two hierarchical models

Figure 2 illustrates the integration and relationship between Fujisaki model and the hierarchical stress model. The sentence level stress is corresponding to the phrase command in Fujisaki model, and the word stress is corresponding to the tone command. Inspired by this relationship, we utilize the sentence stress information to improve the phrase command prediction, and the word stress feature is introduced in the tone command prediction. We expect that the Fujisaki model commands can be estimated more accurately through this manner. Then we can evaluate the prosody of the synthetic speech to verify the hierarchical stress generation method.

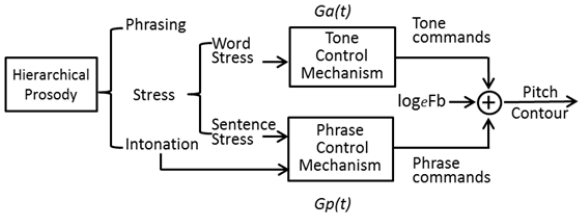


Figure 2: Integration and relationship between hierarchical stress model and Fujisaki model.

3. Fujisaki model parameter prediction

3.1. Corpus construction

In this work, we built a 500 sentences corpus, selected from the stress annotated corpus introduced in [7]. The Fujisaki model parameters are extracted automatically at first and then manually corrected. Fig. 3 is a sample of the Fujisaki model parameter labeling result through the FujiParaEditor [15].

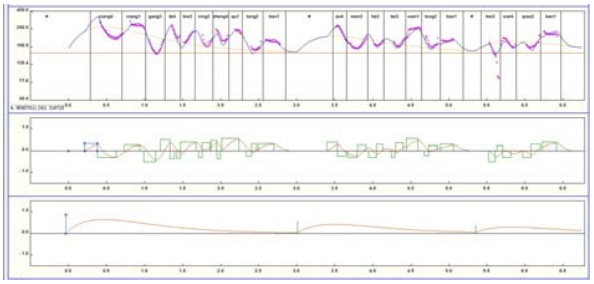

Figure 3: *Fujisaki model parameter annotation for Mandarin.*

The assignment of the phrase command usually coincides with the intonation phrase, but this is not a strict rule in the corpus labeling. The value of α, β, γ are the same as [11]. Ten percent of the data is reserved for testing.

3.2. Feature extraction

To verify the stress generation method, we designed two groups of textural features which are used in Fujisaki model parameter prediction. The first group includes the baseline features without stress information, and the second group includes the stress information as well as the baseline features. The sliding window is used for feature extraction in these two groups and the window size is five. For tone command prediction, the feature extraction unit is syllable, and for phrase command prediction, the unit is word.

As for the baseline feature set, different features are selected for the tone command and phrase command predictions. For the tone command prediction, the features are tone (indicate as *t*, hereinafter), syllable boundary (*bk*), the distance from the current syllable to the beginning/end of the sentence (*db/de*), the length of the word (*len*) to which the syllable belongs and its position in the word (*position*).

For the phrase command prediction, the long range context features are selected, namely, the Part-of-Speech of the word (*p*), the length of the word (*l*), the distance from the current word to the beginning/end of the sentence (*db/de*), the phrase length count by syllable and word respectively (*dis2sbsyl*, *dis2sbw*), and the index of the word in the intonation phrase to which it belongs (*posinphrase*).

In the second feature group, whether the syllable is unstressed or not is introduced in the tone command prediction and whether the word is sentential stressed is introduced into phrase command prediction. The windows for the stress related feature selection is also five. To verify the stress generation method, the hierarchical stress information is extracted from the annotated corpus rather than the automatic prediction from textual features.

3.3. Decision trees

According to Eq(1)-Eq(3), three parameters, with or without a phrase command, phrase command amplitude, and the command starting time, should be predicted from textual features. For tone command, five parameters, namely, two amplitudes and three timing values are selected as the targets. It should be noted that for tone 1, tone 3 and tone 5 syllables, one amplitude and one time value are set to zero. All the timing values are relative time, and are the offsets from the syllable(/word) starts time.

In the Fujisaki model parameters prediction, with or without a phrase command for each word is a binary classification problem, while the other commands, such as amplitude and command starting time, are continuous. J48 is adopted in the first task, and M5P is utilized for others which are both decision trees and implemented in Weka [16]. M5P combines a conventional decision tree with the possibility of linear regression functions at the nodes. In the preliminary experiments, we have tried several statistical models, M5P is slightly better than others in this study, such as C4.5 tree, J48 and linear regression.

4. Experiments and discussion

4.1. Pitch contours generation

The pitch contours are then generated by superimposing the phrase command and tone command responses. To simplify the work, the syllable duration and the base fundamental frequency level, F_b, are assumed to be the same with those in the training corpus. Then all the predicted time values can be converted to absolute values, and constitute a time sequence. Finally the synthetic speech can be generated by PSOLA algorithm which is implemented in Praat.

4.2. Experimental results

The average classification result for with or without a phrase command at a word's boundary is 73.69%. By introducing the hierarchical stress information, the average classification accuracy increases to 78.4%.

Table 1 shows the prediction results for the rest Fujisaki model parameters with continuous values, which only utilize the textual features. The first two rows are the results for phrase command predictions, including the phrase command amplitude A_{p1} and starting time T_0. The rest rows represent the tone commands prediction. It shows that the stress information can enhance the Fujisaki model parameter prediction, however, the improvement is small.

Table 1. *Text-based phrase command prediction using M5P decision tree.*

Model	Baseline (without stress)		With hierarchical stress feature	
	Corr.	RMSE	Corr.	RMSE
A_{p1}	0.85	0.18	0.85	0.17
T_0	0.81	106 ms	0.81	105 ms
A_{t1}	0.91	0.19	0.92	0.19
A_{t2}	0.94	0.11	0.94	0.11
T_1	0.58	43 ms	0.58	42 ms
T_2	0.80	34 ms	0.81	32 ms
T_3	0.57	54 ms	0.60	52 ms

Table 2. *Average RMSEs of utterance pitch contour predicted by models with stress and without stress.*

Experiment	RMSE (Hz)
without stress	46
with hierarchical stress	45

To further check the hierarchal stress generation, we align all the Fujisaki model parameters obtained by the automatic prediction, and combine the base frequency (F_b) to generate a continuous pitch contour. Table 2 shows the RMSEs between the natural speech and the F0 predicted by models with and without hierarchical stress. It also indicates that with stress information, pitch contour can be more accurately modeled. Fig. 4 shows pitch contours of two synthetic utterances generated by Fujisaki model. In this figure, the 8th syllable "*shang4*" is unstressed; the pitch is lower in the proposed pitch contours. On contrary, the 9th and 10th syllables"*fei1 chang2*" (In fact, they constitute a word, which means *very*.) are stressed, and "*fei1*" gets the final stress assignment through the

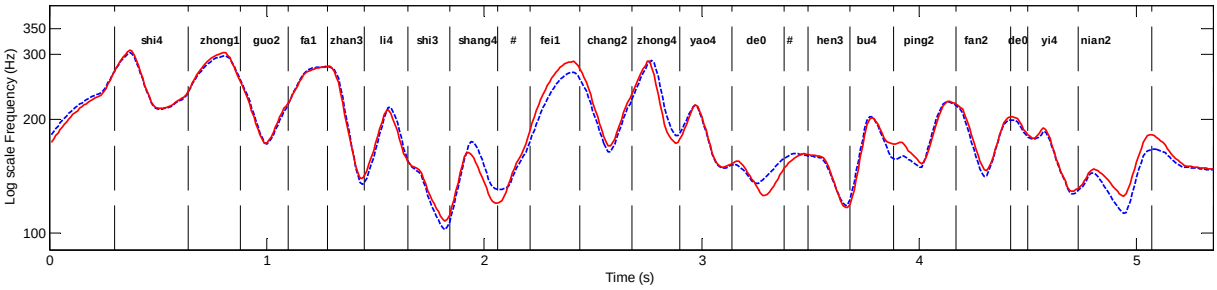

Figure 4: *Pitch contours generated by Fujisaki model with stress and without stress (line : with stress, dot: without stress).*

hierarchical mechanism, therefore, its pitch is higher in the proposed pitch contour. The informal listening test also shows the synthetic speech with stress model which using PSOLA algorithm sounds more natural. The over-salience syllables are hardly found in the synthetic speech. However, it should note that not all Mandarin tones are fully realized in connected speech, thus the variation of tone commands is complex and difficult to model using a decision tree which combines linear regression model in the nodes. Because of the tone command prediction error, some syllables sound unnatural, which makes the whole utterance sounds weird if there are too much tone command prediction errors. In such cases, the naturalness of the synthetic speech is worse than that generated by HTS. Nevertheless, the prominence and naturalness is well balanced in this method because the nature of command-response mechanism.

To evaluate the effect caused by hierarchical stress information in Fujisaki model parameter prediction, we also conducted a feature importance analysis by correlation feature selection [17]. Table 3 shows the feature selection results for each Fujisaki model parameter prediction. In this table, symbols, such as *p, l, t, bk,* represent the features introduced in Subsection 3.2. *s* represents the stress information. The number at the end of each feature denotes the offset in feature extraction. For example, *p_1* represents the Part-of-Speech of the previous word, and *s1* represents the stress information of the next syllable/word. Table 3 clearly illustrates stress information is indeed important in almost every parameter prediction.

Table 3. Feature importance in each Fujisaki model parameter prediction.(Y/N means with or without phrase command)

Prediction target	Feature importance (descending order)
Y/N	l_1, dis2sbw
A_{p1}	p_1, p0, l_2, l_1,dis2sbw,s_2,s_1,s0
T_0	p_2, p_1, p0, l_2, l_1, dis2sbw, s_2, s_1, s0
A_{t1}	t0, s0
A_{t2}	t0, bk0, db
T_1	t_2, t_1, t0, t1, bk2, bk0, s0
T_1	t0, s_1, s0, s1
T_3	bk2, s_2, s0

5. Conclusions

This paper introduces an attempt in Mandarin expressive speech synthesis by manipulating the stress generation with pitch contour generation process model (Fujisaki model). The Fujisaki model parameters are automatically predicted by the textural features with and without stress information. The hierarchical Mandarin stress modeling method is adopted to control phrase command and tone command correspondingly. And then the continuous pitch contours are generated and further evaluated. The experiments show hierarchical stress information can improve the pitch modeling both in global and local range. The advantage of the proposed method is it can make a good balance between prominence and naturalness compared with the previous direct and indirect stress/prominence modeling in HTS. This work offers a promising method to accurate pitch modeling for Mandarin expressive speech synthesis.

However, the accuracy of automatic Mandarin Fujisaki model parameter perdition needs further improvement, especially for the tone command. As reviewer suggests, a more comprehensive consideration of tones and how they interact with default focus, contrastive stress and different types/degree of stress in a sentence would be necessary. We believe that once this problem is solved, the MOS of synthetic speech can be greatly improved. Moreover the syllable duration variation in stress generation should be taken into consideration too. We will put more effort in these two fields in the future.

Too cautious to vary more? A comparison of pitch variation in native and non-native productions of French and German speakers

Frank Zimmerer, Jeanin Jügler, Bistra Andreeva, Bernd Möbius, Jürgen Trouvain

Department of Computational Linguistics and Phonetics, Saarland University, Germany
{zimmerer|juegler|andreeva|moebius|trouvain}@coli.uni-saarland.de

Abstract

This article presents preliminary results indicating that speakers have a different pitch range when they speak a foreign language compared to the pitch variation that occurs when they speak their native language. To this end, a learner corpus with French and German speakers was analyzed. Results suggest that speakers indeed produce a smaller pitch range in the respective L2. This is true for both groups of native speakers. A possible explanation for this finding is that speakers are less confident in their productions, therefore, they concentrate more on segments and words and subsequently refrain from realizing pitch range more native-like. For language teaching, the results suggest that learners should be trained extensively on the more pronounced use of pitch in the foreign language.

Index Terms: pitch variation, L1, L2, language learning

1. Introduction

When learning a foreign language, especially as adults, it is extremely hard to reach native-like skills in phonetics and phonology of this language. One of the reasons for this hardship is that the phonetic and phonological knowledge of the native language (L1) can interfere with the phonetic and phonological system of the foreign language (L2) (e.g., among many more, [6], [14], [18]). For instance, in German, voiceless plosives are produced with a long Voice Onset Time (VOT), whereas in French, VOT for voiceless plosives is rather short. When producing stops in L2, German speakers usually do not adapt their production, and their voiceless French stops do not sound like a native French production would.

However, apart from segmental differences that are hard to be learned perfectly, a foreign accent might also occur due to prosodic interference from the native language in L2 (e.g. [2], [26], [27]). Languages have been shown to differ with respect to the pitch range they use, their exact pitch contours and the exact placement of pitch changes (e.g. [3], [4], [5], [7], [10], [11], [13], [17], [19], [21], [22]). A study by Mennen and colleagues [22] suggests, for example, that there are differences both in level as well as range for English and German speakers in the respective L1. This finding is supported by data presented by Andreeva and colleagues [3] who found differences in level and range for Bulgarian, English, German, and Polish speakers. Keating and Kuo [17] found several differences between English and Mandarin speakers in pitch level and range, also depending, for instance, on the task the speakers were engaged in. Some of the differences that occur between languages can also be partly explained by (socio-) cultural factors (e.g. [17], [30]).

The difficulty to reach native-like performance in the prosodic realization of an L2 is arguably aggravated by the fact that when speaking a foreign language pitch variation is apparently compressed compared to the pitch range that is standard for native speakers (e.g. [9], [10], [16], [20], [29]), which can result in a foreign accent. Furthermore, the lack of correct pitch variation can lead to be perceived as speaking in a monotonous way (e.g. [15], [16]). One possible explanation for this compression is that L2 learners are less confident about speaking the foreign language, or that they focus on getting the segmental pronunciation and the placement of stress correctly before expanding the pitch range as native speakers do. For instance, Mennen [20] showed that Dutch (L1) speakers of Modern Greek failed to produce the same pitch range as native Greek speakers. Also, in a study investigating pitch range of Finnish (L1) speakers of Russian (L2), Ullakonoja [29] found smaller pitch ranges in the L2 production for these speakers compared to native Russian speakers. Furthermore, the results show that the pitch range was also different compared to the Finish L1 productions, and that extended stays in Russia led to a larger pitch range, implying the learnability of this intonation feature. Similarly, Busà and colleagues [10] found (non significant) long-term distributional (LTD) differences in the production of Italian speakers of English compared to native English productions. In a study of Arabic native speakers a comparison of their native productions with productions in English (L2) did not show a language effect [1]. In this study, however, the speaker group was quite advanced and living in the L2 environment. Thus, the results maybe due to the higher L2 proficiency level of the speakers.

Other studies have assumed a compressed pitch range *a priori*, and focused on the improvement of pitch range suggesting that the compression of pitch range can be overcome with enhanced training methods (e.g. [7], [15], [16]).

This short overview suggests a clear trend for a compressed pitch range in L2 speech production. Moreover, it seems that training helps to decrease the degree of pitch range compression. However, it is not clear whether the finding of reduced pitch range in the L2 is an universal tendency or whether pitch range compression is dependent on the language pair under investigation. This paper contributes to the research on L2 pitch range by investigating whether learners of French and German compress their pitch range when speaking their non-native language (German and French), compared to their L1 productions, to find out whether there is a general trend for pitch compression in L2 production, irrespective of L1. The construction of the corpus allows for a direct comparison for each speaker in each of the languages, because the same speakers were recorded in both languages (see also section 2.2).

A second question that will be touched upon is the extent to which language learners are able to learn to suppress pitch compression, that is, we investigate whether advanced learners compress pitch range less than beginners. The results reported in this paper are preliminary: the number of speakers (7 per native language) is rather small, the number of male and

female speakers is not evenly distributed across the two native languages and the number of advanced learners and beginners is also not equal. Even so, stable effects found in the present study will provide a strong motivation for an investigation based on a larger number of speakers.

2. Methods and materials

Different LTD measures have been used to quantify pitch range differences in the past (e.g. [15], [17], [22]). The quantifications that have been analyzed range from linguistically defined tonal structures to different measures of F_0 (e.g. in Hz or semitones) or a combination thereof. Furthermore, there is the overall level of pitch (usually calculated as mean value over time) and the range of variation within a given speech sample. In this paper we concentrate on the latter. It is outside the scope of this paper to discuss the (dis)advantages of one measure over another. We focus on the so-called Pitch Dynamism Quotient (PDQ), which allows for a normalized evaluation of pitch variation [15] (see also [25]) where it is called frequency modulation factor – and below, section 2.3.).

2.1. General corpus description

A bilingual learner corpus served as the basis for the analysis reported here. The corpus was created with French (L1) learners of German (L2) and German (L1) learners of French (L2) at the LORIA institute in Nancy, France and the institute of phonetics at Saarland University in Saarbrücken, Germany [28].

For the corpus, 7 speakers of each language were recorded. They were recorded both in the respective L2 and in their native language. This design allows for a within-subject comparison of the productions in the two languages. Furthermore, recording settings and the text data are comparable across the languages (as L1 or L2) and identical within a language (i.e. French texts read by both French and German participants and *vice versa*). Therefore, comparisons between individual speakers with different L1 can be drawn as well as differences between a group of speakers that differ with respect to what language they speak as native language. In each group (French and German native speakers) there were 5 beginners (A1-A2 level according to the Common European Framework of Reference for Languages: Learning, Teaching, Assessment (CEFR)). Additionally, 2 advanced learners (B2-C1 Level) of the respective language were recorded. In the group of French native speakers, 6 male speakers and 1 female speaker participated (15-22 years, M: 20.1 years, SD: 2.4 years), whereas for the German native speaker group, 5 female speakers and 2 male speakers were recorded (15-26 years old, M: 20.6 years, SD: 4.2 years). The 3 teenage speakers (all 15 years of age, all had completed the change of the voice, 1 French and 2 German highschool students) being part of the corpus were all male. The data of all 14 speakers were used for the analysis in this study.

Recordings were made in quiet office rooms with head-mounted microphones, which were amplified and digitized (16khz, 16 bit) in a M-AUDIO Fast Track USB device. Recordings were saved on Windows Laptop computers with a custom-made software that was developed at LORIA ("Corpusrecorder", [12]). Each sentence (and each story) was saved as a separate audiofile.

2.2. Text materials for the analysis

The corpus data analyzed for this paper consisted of read sentences and read short stories [28]. Both groups of speakers read a set of 25 sentences (*sentence-condition*) in their respective L2, before reading two short stories (an advertising text about ecological economic development and the story of the three little pigs), also in the respective L2 (*story-condition*). Then, the same tasks (reading a set of 25 sentences and a translated version of the two stories, slightly longer in the German than in French version) were recorded in the respective L1 of the participants. The sentences were different in the two languages, but similar in content and length. Due to a technical defect, only 24 sentences were recorded for 1 native speaker of French in the L2. Otherwise, all audiofiles could be used for further analysis.

2.3. Pitch analysis

Pitch measurements were done in three steps. First, F_0 was extracted automatically by means of the ESPS algorithm ("get_f0" [24]) from all files. For male speakers time steps of 0.01 seconds were used, whereas the computation of F_0 for female speakers was done in time steps of 0.005 seconds.

Then, manual correction was performed with PRAAT [8] to exclude cases of octave jumps, wrong measurements (e.g. when the algorithm found voicing in silent intervals or mistakes due to creaky voice, or other artifacts produced by the algorithm that were not based on changes in F_0, but possibly distorting the results). Other microprosodic variation (e.g. due to stop realization) was retained. In a final step, the first two F_0 values after an unvoiced segment and the last F_0 value before an unvoiced segment were excluded. This was done because the vocal folds need some time to achieve their intended vibration rate (i.e. start or stop of vibration) and this kind of irregular vibration could also exaggerate the F_0 variation. The resulting data was analyzed by means of the JMP software [23].

The number of female and male speakers differed strongly between the two groups of native speakers. This was one of the main reasons to investigate pitch variation with the PDQ as defined as the standard deviation divided by the F_0 mean [15]. This measure normalizes F_0 variation data and allowed us to concentrate on language differences while minimizing group differences at the same time. The lower the PDQ, the smaller is the variation.

Note, however, that due to the uneven distribution of male and female speakers across languages, comparisons between the native speaker groups (e.g. a claim like "French is generally more variable than German") cannot be made despite the use of PDQ (and thus, the normalization). First of all, the preliminary analysis of seven speakers per native language is not enough for general, far reaching claims concerning two languages. But more importantly, pitch *range* has been found to differ between male and female speakers (e.g. [25]). Therefore, possible differences in the results between the speakers of the two languages cannot be attributed with certainty to language differences, the source could as well be a gender difference. However, on a general level, differences between German and French pitch range may be expected on the basis of prior research (e.g. [5], [19]). Koreman and colleagues [19] presented evidence that both French and German speakers use F_0 to indicate accentuation, but they do so differently.

Therefore, what is possible, and this is done in this paper, is to investigate the pitch variation of the German group in the native and non-native language, as well as the same comparison for the French native speakers. The results will be reported in the next sections.

3. Results

Mean F_0 and the standard deviations were calculated for every audiofile (henceforth "item"). Subsequently, the PDQ was calculated for these items. These PDQ values were the basis for all subsequent analyses.

Overall mean PDQ for French speakers in their L1 is 0.134 when reading sentences, and 0.142 when reading the stories. In their L2, French speakers produce a mean PDQ of 0.119 for the sentences and 0.13 for the stories. German speakers have a mean PDQ in their L1 of 0.142 for the sentences and 0.146 for the stories. In their French productions, the mean PDQ drops to 0.118 for the sentences and 0.133 for the stories. Figure 1 depicts the overall mean PDQ results for the two speaker groups in the respective task languages.

Subsequently, the PDQ values were entered into a linear mixed model with *PDQ* as dependent factor, *speaker* and *item* as random factors and *native language* (French/German), *task language* (French/German), and *task* (sentence/story) as independent factors, as well as all their possible interactions.

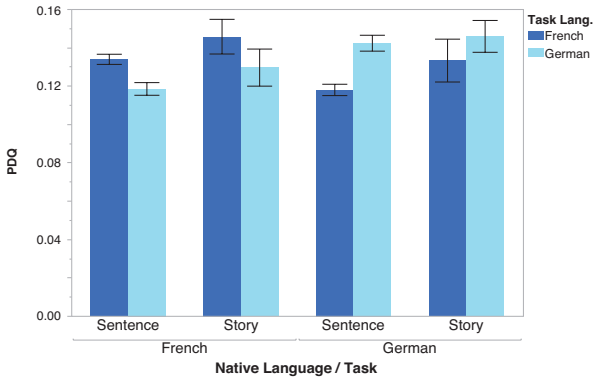

Figure 1: Mean PDQ for French and German speakers depending on task language and task.

The results of the statistical analysis indicate that there was a main effect of *task* ($F(1,735)=5.52$ $p<0.05$). Overall, speakers produced higher pitch variation when reading the stories compared to their sentence productions (mean PDQ for stories: 0.139; mean PDQ for sentences: 0.128). Also, the interaction of *native language* and *task language* was significant ($F(1,735)=14.85$, $p<0.0001$). A post-hoc planned comparison showed that for both language groups, the native productions were significantly higher in PDQ than the non-native productions (French L1: $t(2)=-2.51$, $p<0.05$; German L1: $t(2)=-2.94$, $p<0.01$).

No other factors or interactions reached significance. This first analysis suggests that irrespective of the L1, F_0 variation is compressed in L2 productions. Also, the F_0 range depends on the task in which participants were engaged. Reading stories leads to a greater variation in pitch than reading short sentences, irrespective of native language or task language.

A second model was calculated to tap into the effect of proficiency. To this end, the first model was extended by the factor *proficiency* (Beginner/Advanced) and all its interactions. The results indicate that proficiency level was not a significant factor, nor were any of its interactions. Again, *task* ($F(1,729)=5.66$, $p<0.05$) and the interaction of *native language* and *task language* ($F(1,729)=9.11$, $p<0.01$) were significant. Figure 2 shows the PDQ for the different fluency levels. As can be seen, the overall results remain very similar. However, for the French advanced learners of German, the *story condition* shows a small trend into a different direction. Here, the PDQ for the stories in German is slightly higher than the PDQ for the stories read in French. Note that there were only two advanced speakers in both native speaker groups that read the two stories.

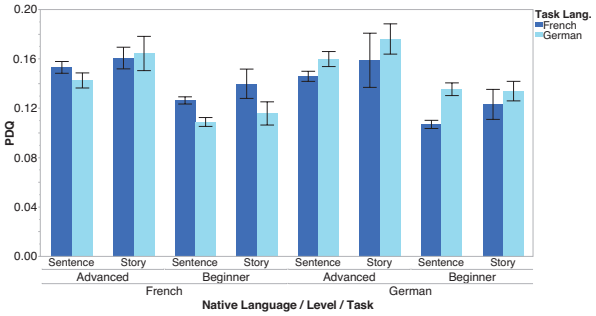

Figure 2: Mean PDQ for French and German speakers depending on task language, task and proficiency level of the learners.

Finally, we looked at individual speaker differences (Figure 3 for French native speakers and Figure 4 for German native speakers). The mean PDQ for French speakers speaking French shows a range from 0.102 to 0.162, whereas for the same speakers, the mean PDQ ranges in German from 0.078 to 0.171. For the German speakers, PDQ in German ranges from 0.083 to 0.194, whereas in the French production, the range lies between 0.069 and 0.164. This indicates that there is some individual variation, but that most speakers have a compressed F_0 in their L2 productions.

However, it becomes also apparent that three speakers show a somewhat different behavior. In the French group, there were two speakers (503 and 501) where the L1 productions showed a smaller PDQ than the L2 productions. One of them (503) is an advanced learner, the other a beginner (501). In the German group, one speaker (006) had almost identical PDQ values for L1 and L2 productions. This speaker was an advanced learner of French. Due to the small number of speakers overall, further interpretation of these results is not possible.

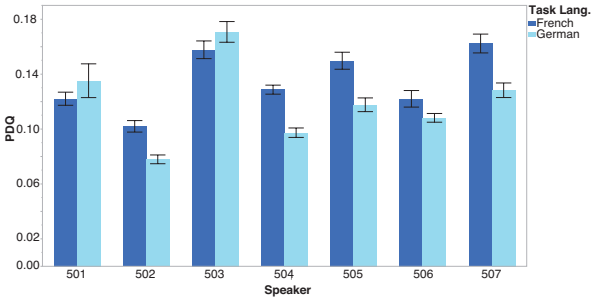

Figure 3: Mean PDQ of individual French speakers depending on task language. Speakers 503 and 505 are advanced learners.

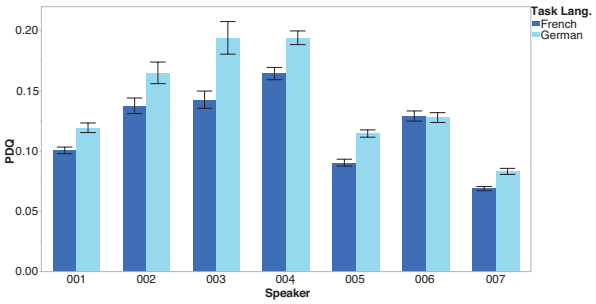

Figure 4: Mean PDQ of the individual German speakers depending on task language. Speakers 004 and 006 are advanced learners.

4. Discussion & conclusions

The first question this article was set out to investigate is whether there is a general trend that French learners of German and German learners of French compress their pitch range when speaking L2. The results indicate that the pitch range (measured in PDQ) is indeed smaller in the L2 for both language groups, that is, irrespective of the native language. This means that the actual pitch range that is produced by native speakers when they speak their native language is larger than the pitch range in their L2. This result is compatible with results presented by other researchers who also found a compressed pitch range in L2 productions (e.g. [9], [10], [20], [29]).

At this point, we cannot give clear answers to the question why this is the case. However, we can give a speculative explanation. This explanation would entail a factor of insecurity, because learners are not completely confident how and where exactly the correct F_0 targets have to be achieved. Furthermore, because they concentrate on other aspects, such as the correct pronunciation of segments, or the correct timing of stress, they could have a tendency to disregard the exact pitch range that is used by native speakers of a language. Future research needs to investigate the reasons for pitch range compression in more detail.

Furthermore, the results also replicate findings that there are differences in pitch range depending on the task (e.g. [1], [21]). In this study, speakers showed a higher PDQ in the story condition compared to the sentence condition. This finding is not surprising: the single sentences that were read by participants, occurred without any context and arguably do not have a communicative function. Therefore, contrastiveness or givenness, for instance, do not play a role in contrast to the story condition. Especially for the story of the three little pigs, a lively, narrative production is more likely than for single sentences.

As for the second question whether the L2 proficiency level of L2 has an influence on the pitch range compression, the results presented here are not conclusive. They do not exclude the possibility of an overall trend for advanced speakers to produce greater pitch variation in L2 compared to L1 and are closer to native speakers (as results by [29] would suggest). Of the three speakers that did not compress pitch range in the L2 production, two are advanced learners. However, such interpretations have to be made with caution, because there were only two advanced learners for each native speaker group. Additionally, there was also one French beginner with a higher PDQ in the non-native productions.

For language teaching, the results suggest that students should be made aware of the lack in pitch variation in order to sound more native-like. Results indicate that a special teaching of pitch variation indeed reduces the foreign accent (e.g. [7], [15], [16]). Pitch range differences that occur across languages otherwise might be aggravated (see also [4] for a cross-linguistic comparison of such differences).

As indicated in the introduction, the results reported here are preliminary. For instance, the two language groups differed with respect to the number of male and female speakers. Furthermore, there were only 2 advanced learners, compared to 5 beginners. More generally, the number of 7 speakers is not very high. However, despite the rather small and somewhat unbalanced number of speakers, we were able to obtain results that are promising for further research. The results reported in this article are in need of replication with larger speaker groups before far-reaching claims can be made. But the preliminary results are a starting point for further research, with a corpus that has more speakers. Such a corpus is planned to include many more speakers (see [28]) balanced for gender and proficiency level. Future research could also concentrate on the effect of different speaking styles on pitch range in a L2, such as reading alone, versus speaking in front of an audience, or engaging in conversations. In such scenarios, it would also be interesting to investigate whether convergence of pitch range can be observed, in that one speaker changes his or her behavior in response to an interlocutor.

Abstract

Generation process model of fundamental frequency (F_0) contours is ideal to represent global movements of F_0's keeping a clear relation with back-grounding linguistic information of utterances. Using the model, improvements of HMM-based speech synthesis are expected. A new method is developed to cope with erroneous F_0's of utterances included in HMM training corpus. F_0 extraction errors not only cause wrong F_0's, but also degrade segmental features of synthetic speech, since they affect the over-all accuracy of speech analysis. The method is to exclude speech segments from HMM training, where extracted F_0's are largely different from those generated by the generation process model. Experiments on speech synthesis showed a clear improvement in synthetic speech quality when phoneme-based exclusion is conducted with a properly selected threshold.

Index Terms: F_0 contour, generation process model, HMM-based speech synthesis, training segment selection

1. Introduction

HMM-based speech synthesis attains a special attention from researchers in speech communication field, since it can generate a good quality of speech from a rather limited size of speech corpus with flexible controls on voice qualities and utterance styles [1]. It can handle fundamental frequencies (F_0's) of speech in the same frame-by-frame manner with other acoustic features such as mel-cepstral coefficients. It is easy to prepare a training corps, since F_0 values can be directly used for HMM training without assuming any models of F_0 contours. However, this in turn causes demerits; it generally produces over-smoothed F_0 contours with occasional F_0 undulations not observable in human speech. Automatic extraction of F_0's occasionally outputs erroneous results; wrong F_0's and voiced/unvoiced decision errors. These errors not only degrade synthetic speech quality from prosodic feature aspect but also affect extraction of spectral envelope features, resulting in degradation also from segmental feature aspect.

The generation process model of F_0 contours (F_0 model) developed by Fujisaki and his co-workers can solve the problems of HMM-based speech synthesis [2]. The model represents a sentence F_0 contour in logarithmic scale as super-position of accent components on phrase components. These components are known to have clear correspondences with linguistic and para-/non- linguistic information, which is conveyed by prosody. Thus, using this model, a better control is possible in F_0 contour generation than the frame-by-frame control. Because of clear relationship between generated F_0 contours and linguistic and para-/non- linguistic information of utterances, manipulation of generated F_0 contours is possible, leading to a flexible control of prosody. We already have developed several methods, which use the F_0 model-generated F_0's in HMM-based speech synthesis, and showed their advantages in F_0 controls [3-7]. Recently, a method has been proposed, which uses F_0's approximated by the F_0 model instead of observed F_0's of training corpus for HMM training [8]. The method can partly solve the problem, which arises from F_0 extraction errors, but cannot avoid spectral envelope features affecting the synthetic speech quality.

In the current paper, the F_0 model is used in a different way to cope with the issue of erroneous F_0's; to exclude from HMM training samples which have large differences in F_0's from those approximated by the F_0 model. The performance of the method may rely on "how accurately the F_0 model parameters can be extracted from observed F_0 contours." For this purpose, the paper uses the method of automatic extraction of model parameters recently developed by the authors [8]. The method is motivated on how experts do when finding the F_0 model parameters, and utilizes linguistic information of utterances and our knowledge on Japanese prosody.

The rest of the paper is organized as follows: following to the explanation on the F_0 model, a new method of automatic extraction of F_0 model commands is briefly introduced in section 2. Section 3 shows the proposed method of datum selection for HMM training with the results of speech synthesis experiments. Some discussions on the method are given in Section 4. Section 5 concludes the paper.

2. Automatic extraction of F_0 model commands

2.1. F_0 model

Movements of F_0 along time axis are well represented by the F_0 model, which is a command-response model that describes F_0 contours in logarithmic scale as the superposition of phrase and accent components [3]. The *i*-th phrase component $G_{pi}(t)$ of the F_0 model is generated by a second-order, critically-damped linear filter in response to an impulse-like phrase command, while the *j*-th accent component $G_{aj}(t)$ is generated by another second-order, critically-damped linear filter in response to a stepwise accent command:

$$G_{pi}(t) = \begin{cases} \alpha_i^{\,2} t\, e^{-\alpha_i t} & t \geq 0 \\ 0 & t < 0 \end{cases}, \quad (1)$$

$$G_{aj}(t) = \begin{cases} \min\left[1 - (1+\beta_j\, t)\, e^{-\beta_j t}, \gamma\right] & t \geq 0 \\ 0 & t < 0 \end{cases}. \quad (2)$$

Based on the analysis of Japanese utterances, time constants α_i and β_j are known to be fixed to values around 3.0 s^{-1} and 20.0 s^{-1}, respectively. The parameter γ, which thresholds accent components, can also be set to a fixed value around 0.9. An F_0 contour is then given by the following equation (assuming natural logarithm):

$$\ln F_0(t) = \ln F_b + \sum_{i=1}^{I} A_{pi} G_{pi}(t - T_{0i}) + \sum_{j=1}^{J} A_{aj} \{ G_{aj}(t - T_{1j}) - G_{aj}(t - T_{2j}) \} , \quad (3)$$

where, F_b is the bias level, I is the number of phrase components, J is number of accent components, A_{pi} is the magnitude of the i^{th} phrase command, A_{aj} is the amplitude of the j^{th} accent command, T_{0i} is the time of the i^{th} phrase command, T_{1j} is the onset time of the j^{th} accent command, and T_{2j} is the reset time of the j^{th} accent command.

2.2. Method

When searching F_0 model parameters, time constants α_i and β_j, threshold γ, and bias level F_b are usually fixed and are put out of the search process. Therefore, the search is done for F_0 model parameters related to phrase and accent commands, and is called F_0 model command extraction. Several methods have already been developed for automatically extracting F_0 model commands from given F_0 contours. Their basic idea is: smoothing to avoid micro-prosodic and erroneous F_0 movements, interpolating to obtain continuous F_0 contours, and taking derivatives of F_0 contours to extract accent command locations and amplitudes [9, 10]. Phrase commands are extracted from the residual F_0 contours (F_0 contour minus extracted accent components) [9], or from low frequency components of F_0 contours (assuming F_0 contours as waveforms) [10-12]. Extracted phrase and accent commands are optimized by a successive process. These methods, however, are not robust for pitch extraction errors, and produce commands not corresponding to the linguistic information of the utterances to be analyzed. Although attempts have been conducted to reduce extraction errors by introducing constraints (on command locations) induced from the linguistic information, their performances are still not satisfactory [13].

Interpolation of F_0 contours has a drawback since it relies on F_0's around voiced/unvoiced boundaries, where F_0 extraction is not always precise. This situation leads to extraction of false commands. Micro-prosodic F_0 movements at voiced consonants may also degrade the command extraction performance, since they are not counted in the F_0 model. To avoid false extractions, a new method is developed which accounts F_0 contours only of vowel segments [8]. In turn, since no F_0 is available between vowels, it comes difficult to extract accent commands from F_0 contour derivatives. Therefore, the new method takes features of Japanese prosody into account. In Japanese, F_0's of a syllable take either High or Low values corresponding to accent types. The method extracts phrase commands first viewing "Low" parts, and then find accent command amplitudes from "High" parts. The method can extract minor phrase commands, which are difficult to be found from the residual F_0 contours. We can say that the new method is motivated from the human process of command extraction.

The method consists of three steps; pre-processing, parameter extraction, and optimization. As for accent phrase boundaries, and accent types, which are necessary for the following processes, those used in HMM-based speech synthesis are used; the method is in good match with HMM-based speech synthesis. Phoneme boundaries are detected by the forced alignment using Julius as the recognizer [14]. A significant improvement in extraction performance as compared to conventional methods is observed. Since it is developed taking Japanese prosody into account, further investigations are necessary to make it applicable to other languages. The detail of the method is given in [8].

3. Speech synthesis with selected training data

3.1. Selection of training data

Figure 1 shows an example of F_0's extracted by STRAIGHT [15], and their F_0 model approximation. Here, their absolute difference in (natural) logarithmic values in each frame is denoted as F_0 difference:

$$F_{0diff}(t) = \left| \ln F_{0obs}(t) - \ln F_{0\,model}(t) \right| . \quad (4)$$

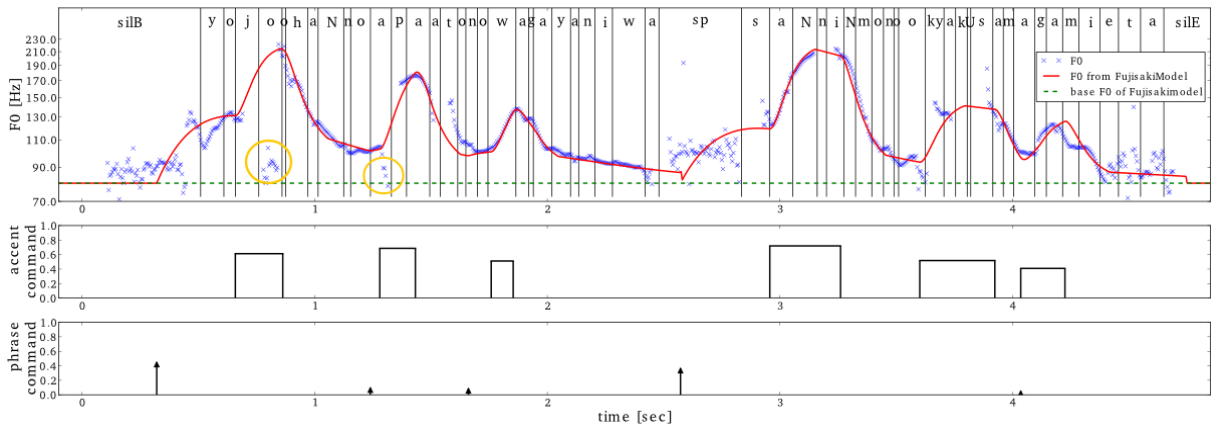

Figure 1: *An example for extracted F_0's (×) and their F_0 model approximation (in red solid line). F_0 model parameters (accent and phrase commands) are also shown. ("yojoohaNno apaatono wagayaniwa, saNniNmono okyakuga mieta": Three guests visited to my house, which was an apartment of only four and half "tatami" space.)*

$F_{0obs}(t)$ and $F_{0\,\mathrm{mod}\,el}(t)$ denote extracted F_0 and F_0 model F_0 at frame t, respectively. Half pitch extraction errors are observable around the second /o/. Also pitch extraction errors occur around the latter half of the second /a/. These segments may affect badly for the HMM training. It is possible to correct F_0's and to use them for HMM training, but the erroneous F_0's also cause errors in mel-cepstral coefficients (through STRAIGHT analysis). Here, speech segments with large F_0 differences are excluded from the data for HMM training. (Although F_0's are "wrongly" extracted at some speechless parts/pauses, they are ignored through F_0 model approximation and selection processes.) Two schemes are checked; one to exclude whole sentences which include many frames with large F_0 differences, and the other to exclude phoneme segments with large F_0 differences.

3.2. Experiments

Speech synthesis experiments are conducted using ATR continuous speech corpus of 503 sentences by male speaker MMI [16]. Out of 503 sentences, 450 sentences are used for HMM training, keeping 53 sentences for evaluation. Utterances for HMM training are analyzed using STRAIGHT with 5 msec frame shift. Fundamental frequencies are searched between 80 Hz to 250 Hz. Mel-cepstral coefficients and aperiodicity indices are calculated from analysis results by STRAIGHT using SPTK [17]. Feature parameters used for HMM training and speech synthesis processes have 138 dimensions: mel-frequency coefficients (0^{th}–39^{th}), aperiodicity indices (0-1 kHz, 1-2 kHz, 2-4 kHz, 4-6 kHz, 6-8 kHz), logarithmic F_0, and their Δ and Δ^2 features. Five-state left-to-right hidden semi-Markov model with single Gaussian distribution for each state, provided in HTS-2.1 [18], are used. A Gaussian distribution is represented by a diagonal conversion matrix. Decision tree-based context clustering is conducted with MDL stop criterion.

F_0 model parameters are extracted automatically from F_0 contours of training sentences using the method explained in section 2.2. Then, F_{0diff} is calculated for each voiced frame. When a frame has F_{0diff} larger than 1.0, and none of F_{0diff}'s of neighboring 10 frames (preceding 5 and following 5 frames) exceeds 1.0, F_0 model parameter extraction is re-conducted by neglecting the frame, and F_{0diff}'s are re-calculated.

As for sentence-based datum selection, utterances are excluded from HMM training, when they include "more than 2 frames with F_{0diff}'s larger than 1.0" or "more than 10 frames with F_{0diff}'s larger than 0.8." Forty three sentences are excluded from the 450 sentences by the process. These parameters for datum selection are determined through a preliminary experiment. Speech synthesis is conducted for two cases; one is when all 450 sentences are used for training (conventional method), and the other is when 43 sentences are excluded from the training (proposed method). Synthetic speeches obtained by these two methods are compared through a listening test with 3 scale scoring (1: better quality by the proposed method, 0: similar quality, -1: better quality by the conventional method). Two native speakers of Japanese conducted the listening test. Each speaker evaluated 10 sentences, which are selected randomly from 53 sentences for testing. The averaged result with 95 % confidence interval is 0.250 ± 1.337, indicating no significant difference between two methods.

Sentence-based datum selection may have a shortcoming that parts without F_0 extraction errors (and thus useful for HMM training) are thrown away together with other parts with erroneous F_0's. In order to cope with this situation, phoneme-based datum selection is conducted. Figure 2 shows the process. When second /a/, which is sand-witched by phonemes /r/ and /y/, includes a frame (frames) with large F_{0diff}, it is deleted from the training data. However, other phonemes in the same sentence without large F_{0diff}'s are left for HMM training. Three thresholds for "large F_{0diff}" are set so that 5 %, 10 % or 30 % of total voiced phoneme segments of the training corpus are excluded from the training. (No selection process is conducted for segments judged as voiceless.) Two versions of synthetic speeches, one by the conventional method and the other by the proposed method are compared through the listening test with 5 scale scores (+2: clearly better quality by the proposed method, +1: slightly better quality by the proposed method, 0: similar quality, -1: slightly better quality by the conventional method, -2: clearly better quality by the conventional method.). Nine native speakers evaluated the synthetic speeches by randomly selecting 20 sentences out of 53 sentences for testing in one turn. Every speaker conducted tree turns. The averaged results with 95 % confidence intervals are summarized in Table 1. Advantage of the proposed method over the conventional method is clear for the 5 % exclusion level.

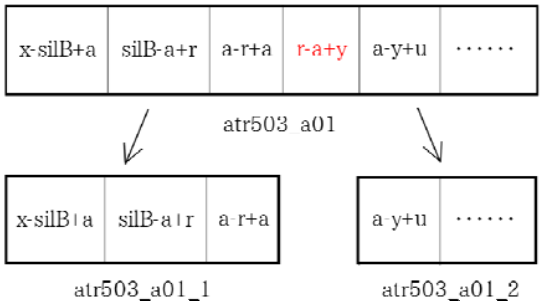

Figure 2: *Process of phoneme-based datum selection. Tri-phone HMM's, which are adopted for Japanese speech synthesis, are assumed. If tri-phone "r-a+y" has erroneous F_0's, it is excluded from the HMM training data.*

Table 1. *Scores of listening test with 95% confidence intervals for three levels of phoneme-based exclusion. Positive values indicate better quality by the proposed method.*

Level of exclusion	Score with 95 % confidence interval
5 %	0.300±0.148
10 %	0.139±0.147
30 %	-0.378±0.162

Figure 3 compares F_0 contours generated by the conventional method and the proposed method. Around sentence initial ("hyogeN"), a stable F_0 contour is obtained by the proposed method. F_0 contours around "nooryoku" and

"tsukeru" show better matches with accent types of the parts by the proposed method.

4. Discussion

Experiments are also conducted similarly to speech samples uttered by another speaker (female speaker FTY). Advantage of the proposed method, however, is not shown. The reason for the result will be due to the fact that F_{0diff}'s for FTY utterances are smaller than those for MMI. Selection of training data decreased the training datum size, and might affect negatively to the synthesized speech quality. Although, in the current experiments, the phoneme selection is conducted so that a fixed percentage of the training corpus remains, a scheme needs to be developed to use an absolute F_{0diff} threshold for selection. Also different thresholds can be used for different phonemes. A further study is necessary on the issue.

Reasons for large F_{0diff} can be divided into two cases; pitch extraction error and micro-prosody. Pitch extraction error can be further categorized several cases; double/half pitch errors which can be corrected through a post processing, pitch errors with large aperiodicity, and voiced/unvoiced decision errors. These errors should be treated differently. It should be noted that the method only counts voiced segments and no selection process works for voiceless frames. However, as is clear from Figure 1, F_0's are extracted for some unvoiced phonemes. When they have large F_{0diff}'s, they can be excluded from the HMM training. It is necessary to check how these exclusions affect the synthetic speech quality.

5. Conclusions

A method is developed to exclude speech segments from HMM training where their extracted F_0's are largely different from F_0's generated by the generation process model. Results on listening test for synthetic speech by the proposed method and the original HMM-based speech synthesis showed a clear improvement in synthetic speech quality when exclusion is done in phoneme-basis. Using F_0 values generated by the F_0 model without excluding segments with large F_{0diff} is another possible way to cope with erroneous F_0's [8]. A combined method is in our future research scope.

SVR vs MLP for Phone Duration Modelling in HMM-based Speech Synthesis

Alexandros Lazaridis, Pierre-Edouard Honnet, Philip N. Garner

Idiap Research Institute, Martigny, Switzerland

{alaza, pierre-edouard.honnet, phil.garner}@idiap.ch

Abstract

In this paper we investigate external phone duration models (PDMs) for improving the quality of synthetic speech in hidden Markov model (HMM)-based speech synthesis. Support Vector Regression (SVR) and Multilayer Perceptron (MLP) were used for this task. SVR and MLP PDMs were compared with the explicit duration modelling of hidden semi-Markov models (HSMMs). Experiments done on an American English database showed the SVR outperforming the MLP and HSMM duration modelling on objective and subjective evaluation. In the objective test, SVR managed to outperform MLP and HSMM models achieving 15.3% and 25.09% relative improvement in terms of root mean square error (RMSE) respectively. Moreover, in the subjective evaluation test, on synthesized speech, the SVR model was preferred over the MLP and HSMM models, achieving a preference score of 35.93% and 56.30%, respectively.

Index Terms: phone duration modelling, Support Vector Regression, Multilayer Perceptron, HSMM explicit duration modelling, HMM-based speech synthesis

1. Introduction

Prosody plays a very important role in verbal communication. Changing prosody can completely change the meaning of the message which is conveyed through speech [1]. There are three main aspects of prosody: duration, pitch and intensity [2]. Duration is a prosodic factor controlling the speaking rate, the rhythm of the speech [3]. Controlling this factor gives the ability to the speaker to emphasize more on some parts of a sentence and less on others, helping the listener to perceive the proper message. In the same way, duration and prosody in general, are essential factors in the field of speech synthesis.

Statistical parametric speech synthesis techniques, and hidden Markov models (HMMs) in particular, provide a framework for the task of speech synthesis, achieving on one hand high quality synthetic speech and on the other hand giving a high degree of flexibility in modelling and transforming various aspects of the speech, such as speaker identity, age, gender, emotions and prosody [4, 5, 6, 7]. Over the last years, many improvements have been introduced in HMM-based speech synthesis, one of them being the use of hidden semi-Markov models (HSMMs) [8]. The advantage of HSMMs is the explicit modelling of state duration using Gaussian distributions instead of the implicit modelling of HMMs by the transition probabilities of the states. In the training phase of HSMM-based speech synthesis, a decision tree is built according to some phonetic and linguistic features and a set of fixed binary (yes/no) questions controlling and even sometimes limiting [9, 10] the structure of the tree. The minimum description length (MDL) is used as a splitting and stopping criterion [11]. In the synthesis phase, the decision tree is traversed for each target unit until reaching a leaf node. The mean value of this leaf node is used as the predicted duration for the target unit. The drawback of this approach is that these trees cannot represent properly all the target units in speech synthesis [12].

To improve synthetic speech and alleviate monotonous prosody and specifically monotonous durations, a lot of research has been done over the last years. Various approaches and techniques, such as modelling duration combining models of multiple levels, e.g. state and phone levels [13], state, phone and syllable levels [14], using full covariance Gaussian distribution [15] or implementing Gamma distribution instead of Gaussian [16], have been introduced for this task. Furthermore, a lot of focus has been given on using external duration models, forcing their predicted durations on HMM-based speech synthesis [17, 18]. A variety of machine learning algorithms have been used for state, phone or syllable duration modelling, such as decision trees [19, 20], Bayesian Networks [21], Linear Regression [22], Instance-based learning [22], Support Vector Regression [23, 24], Multilayer Perceptron [25, 26], or even fusion of these algorithms [27, 28], to improve the accuracy.

The motivation behind this work is to investigate how Support Vector Regression (SVR) and Multilayer Perceptron (MLP) algorithms, which have been used successfully in various tasks, could improve, as external phone duration models, the prediction accuracy in order to improve the quality of synthesized speech. To our best knowledge, these two algorithms have never been compared in the same experimental conditions. We believe that the limitations caused by the use of HSMMs for the duration modelling, e.g. the use of a specific set of questions for the decision tree, or the difficulty of the decision trees to model complex context dependencies [9], could be overcome with the use of the external duration models. Furthermore, we consider that the ability of SVR in coping well with high-dimensional space in respect to the training data will result in a more robust duration model in comparison to a model build using the MLP. An American English male database is used (CMU-ARCTIC-RMS) for these experiments [29].

The rest of the paper is organized as follows. The HSMM explicit duration model and the two external phone duration modelling approaches, MLP, SVR are presented in Section 2 and 3 respectively. The experimental setup and results are presented in Section 4. In Section 5, the conclusions are given.

2. HSMM-based Duration Modelling

In HMM-based speech synthesis duration modelling is done at the state level, through the state sequence modelling. Consequently, the phone duration modelling is performed through the state modelling. The reasoning behind this approach is the fact that the state sequence modelling is not only responsible for the duration of the phones, but also is the basic structural element of the HMMs for spectrum and f0 modelling and generation.

In HMM-based speech synthesis duration modelling is done implicitly through the transition probabilities of the HMM

states i.e. an exponential distribution, making this structure unsuitable for modelling properly the timing in synthetic speech. The advantage of HSMMs in respect to HMMs, is the explicit modelling of state duration using Gaussian distributions instead of the implicit modelling by the transition probabilities of the states. Although the Gaussian distribution is clearly wrong (it implies negative durations are possible), it is a suitable approximation to the true distribution.

In the training phase, using the state durations and the phonetic and prosodic context-dependent features of the training data, a decision tree is built. This decision tree is constructed based on some predetermined binary questions concerning the content of the features (e.g. is the current syllable accented, is the previous phone fricative, etc.). For controlling the growth of the tree and the splitting of the nodes, the minimum description length (MDL) criterion is used [11]. Finally, the leaf nodes of the tree correspond to different clusters of the training data, sharing the same distributions (i.e. mean and variances). In the synthesis phase, according to the unseen data, the tree is traversed from the root node until a leaf node is reached. In this way, the Gaussian distributions of the leaf nodes are used to determine the duration of the synthesized speech.

Using HMMs/HSMMs for modelling duration in speech synthesis leads to some drawbacks. First, it is inefficient to express complex context dependencies such as XOR, parity or multiplex problems by decision trees [9]. In order to be able to cope with such cases, decision trees must become very large. Furthermore, the mean values of the Gaussian distributions of the leaf nodes are inadequate, due to over-generalization, to deal properly, in respect to duration modelling, with all the cases of the unseen data during the synthesis phase.

For overcoming these problems and improving the duration modelling accuracy, two external models are implemented and evaluated in this work, using the SVR and MLP algorithms.

3. External Phone Duration Modelling

In this section the two external phone duration models, the MLP and SVR, are described. When an external phone duration model is used in HMM-based speech synthesis, the predicted duration of the phone during the synthesis phase, has to be forced upon the HMMs [30]. Consequently the HMMs for each phone, having the predefined phone duration, are used only to distribute the predicted phone duration to the states.

3.1. Multilayer Perceptron

The Multilayer Perceptron is a feed-forward neural network having one or more hidden layers between the input and output layers [31]. Having a feed-forward architecture means that the connections between all the units and layers follow only one direction, from input units to the output units. Apart from the input units, each unit is modelled using a non-linear activation function. Furthermore, each unit of a layer is connected with a specific weight to every unit of the next layer. Consequently, the input layer is connected to the output layer through a weighted linear combination of non-linear functions. In this way the input data are transformed into another space, where can be linearly separable. In our experiments the MLP was implemented using one hidden layer.

3.2. Support Vector Regression

A Support Vector Machine (SVM) constructs a hyperplane in a high-dimensional space, which can be used for classification (SVM) and regression (SVR) tasks [32]. The basic idea governing the SVR is the production of a model that can be expressed through support vectors which define the hyperplane. A linear regression function is used to approximate the training instances by minimising the prediction error. A parameter ε defines a tube around the regression function. In this tube the errors are ignored. The parameter ε controls how closely the function will fit the training data. The parameter C is the penalty for exceeding the allowed deviation defined by ε. The larger the C, the closer the linear regression function can fit the data [33].

For our experiments the support vector regression (SVR) model [34], which employs the sequential minimal optimization (SMO) algorithm for training a support vector classifier [32], was used. Many kernel functions have been used in SVR such as the polynomial, the radial basis function (RBF) and the Gaussian functions [35], etc. In this paper, after some preliminary experiments, the RBF kernel was selected [35].

4. Experiments

As mention earlier, there are two hypotheses we are interested in verifying with the following experiments. Firstly, whether external models could build more robust phone duration models than the explicit modelling of HSMMs. Secondly, whether the SVR model, since SVMs cope in a better way with the high-dimensionality of the feature space than MLP, would outperform the MLP external PDM.

4.1. Experimental Setup

In this section the database along with the feature set used in the experiments are presented. Furthermore, the setup of the HSMM explicit duration model and the external SVR and MLP phone duration models are described. The same HSMM framework, used for the explicit duration modelling, was also used for the HMM-based speech synthesis models used for synthesizing speech (using the predicted by each model durations) for the subjective evaluation test. The implementation of the external SVR and MLP PDMs was done with the WEKA software [36].

4.1.1. Database and Feature Set

For the experiments, the RMS voice of the CMU-ARCTIC database was used [29] which is a database of standard size for speaker-dependent HMM-based speech synthesis. The RMS voice is an American English male containing 1132 sentences of reading style speech. The data were divided into three sets, a training set containing 900 sentences for training the three models, a development set of 100 sentences for fine tuning the external phone duration models and a test set of 132 sentences for evaluating the three models with objective and subjective evaluation tests. Throughout the entire database, all starting and ending silences in each sentence were removed. Only the internal silences (silences between words in each sentence - phone "pau") were kept and modelled as the rest of the phones. This concluded to a phone set of 41 phones.

Concerning the features used for training the HSMM system, a standard in HMM-based speech synthesis set of features was used, composed of phonetic and prosodic features such as phone identity, identity of the two previous and next phones, number of syllables in a word, accented/stressed syllable, etc., concluding to a 53 feature set. For the external phone duration models, the same feature set was used expanded with some additional articulatory features. These articulatory features correspond to information such as the category of the phone (e.g. vowel, approximant, nasal, etc.), vowel length (e.g. short, long, etc.), height (e.g. high, middle, low), frontness (e.g. front, mid-

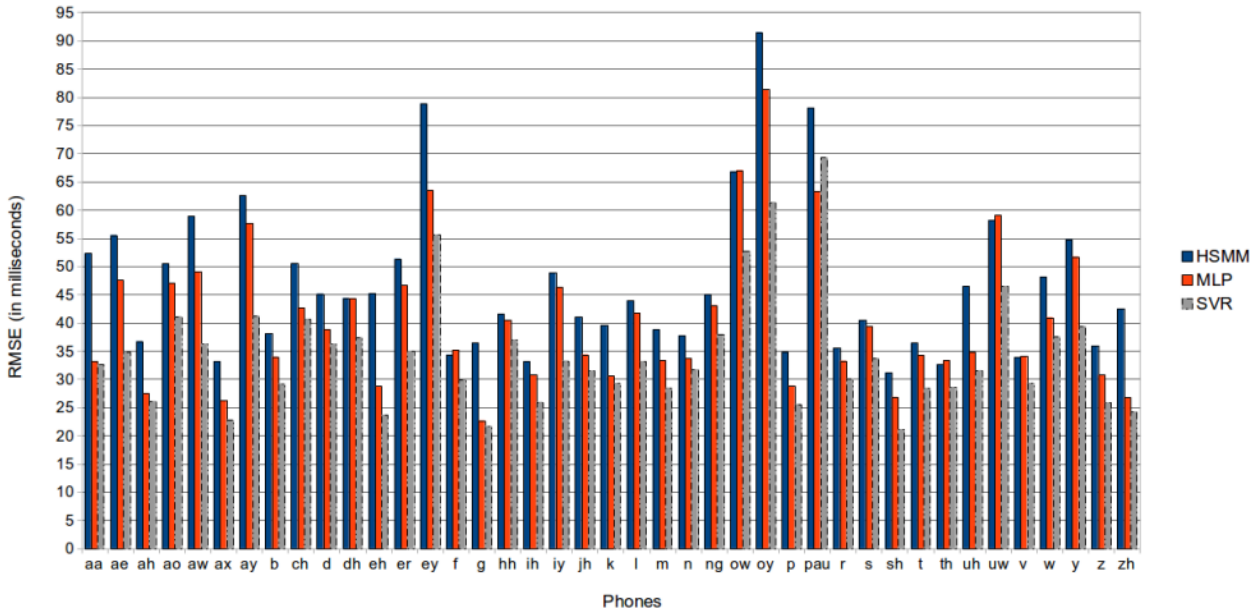

Figure 1: *This figure shows the RMSE for the three PDMs (HSMM, MLP and SVR) per phone*

dle, back), place of articulation (e.g. labial, alveolar, palatal, etc.), etc. The Relief [37] feature selection algorithm was used in some preliminary experiments for selecting among 37 binary articulatory features and their temporal (one previous and one following phones) information, the most appropriate ones. The final feature set consisted of 100 features.

4.1.2. HSMM model

For the implementation of the HSMM model, the version 2.2 of the HTS toolkit [38] was used. The speech data which were used had 16kHz sampling frequency. Five-state, left-to-right, no-skip HSMMs were used. The speech parameters which were used for training the HSMMs were 24th order mel-cepstral coefficients [39], log-f0 and 21-band aperiodicities [38], along with their delta and delta-delta features, extracted every 5 milliseconds (ms). The number of the used questions and the number of the leaf nodes of the decision tree were 304 and 547 respectively. STRAIGHT [40] was used for the analysis and synthesis phase of the HSMM-based speech synthesis.

4.1.3. MLP model

For the MLP model, a backpropagation based approach was used. The 100 input units (features) were converted to 570 units since all the nominal (categorical) features were converted to binary ones - an attribute with k nominal values is transformed into k binary attributes. The MLP model consisted of the input layer with 570 units, a hidden layer (H) with 10 units and an output layer with one unit (phone duration). The learning rate (L) of MLP, to ensure that the weights converge to a response fast enough without producing oscillations [41], was set equal to 0.05. The momentum term (M), which determines the degree to which each weight change will depend on the previous weight change, was set equal to 0.05. The epoch of the MLP (N), which determines the maximum number of iterations in which the full training set is presented in the model, was set equal to 500. These values were selected after a grid search (H={5:1:90}, L={0.01, 0.05, 0.1, 0.2, 0.3, 0.5, 1.0, 1.5, 2.0}, M={0.01, 0.05, 0.1, 0.2, 0.3, 0.5, 1.0, 1.5, 2.0}, N={50, 500, 1000, 5000, 10000, 50000}) of the model on the development set in respect to the RMSE of the model.

4.1.4. SVR model

For training the SVR model, as in the case of MLP, 570 binary features were used. In our experiments the RBF kernel was used as mapping function for the SVR. The ε and C parameters, where $\varepsilon \geq 0$ is the maximum deviation allowed during training and $C > 0$ is the penalty parameter for exceeding the allowed deviation, were set equal to 0.005 and 0.5 respectively. The gamma (G) parameter of the RBF function, determining the RBF width, was set equal to 0.05. These values were selected after a grid search fine tuning (ε={0.001, 0.003, 0.005}, C={0.5, 1.0, 1.5, 10, 100}, G={0.01, 0.03, 0.05}) of the model on the development set in respect to the RMSE of the model.

4.2. Experimental Results

For the evaluation of the models both objective and subjective tests were done for evaluating the accuracy of the models and the overall quality of the synthesized speech respectively.

4.2.1. Objective Evaluation

In the objective evaluation, the root mean square error (RMSE) in terms of milliseconds (ms) between the predicted and the reference (the original phone boundaries of the database) phone durations was used. To determine the phone duration prediction in ms using the HSMM model, the sum of frames of each of the five states on each phone was calculated and multiplied by the frame shift of the model. In Table 1, the overall performance accuracy of the three models (HSMM, MLP, SVR) on the development and test sets is presented. The MLP and the SVR models managed to outperform the HSMM one with a relative improvement in terms of RMSE of 11.56% and 25.09%

Table 1: *This table reports the accuracy in terms of RMSE (ms) for the three PDMs for the developement and test sets.*

Set	Phones	HSMM	MLP	SVR
Dev	All	43.89	37.11	**33.07**
Test	All	43.97	38.89	**32.94**
Test	Vowels	48.96	42.13	**33.95**
Test	Cons	39.91	36.31	**31.87**

Table 2: *This table shows the subjective evaluation (ABX test) for the three pairs (HSMM vs MLP, HSMM vs SVR and MLP vs SVR).*

ABX test	***HSMM vs MLP***			***HSMM vs SVR***			***MLP vs SVR***		
Set	**HSMM**	**Eq.**	**MLP**	**HSMM**	**Eq.**	**SVR**	**MLP**	**Eq.**	**SVR**
Set1	26.43%	28.57%	45.00%	15.00%	26.43%	58.57%	16.43%	51.43%	32.14%
Set2	24.62%	32.31%	43.08%	11.54%	34.62%	53.85%	18.46%	41.54%	40.00%
Both	25.56%	30.37%	44.07%	13.33%	30.37%	56.30%	17.41%	46.67%	35.93%

respectively, verifying our first hypothesis, i.e. these external models are able to build more robust models than the HSMM explicit duration modelling. Furthermore, the SVR model in comparison to the MLP model achieved a relative improvement of 15.3%, showing the superiority of the SVR over the MLP model, verifying our second hypothesis, i.e. the SVR could model better the phone durations in comparison to MLP. As it was expected, the SVR model managed to cope in a better way with the high-dimensionality of the feature space in comparison to the MLP model.

Moreover, as it was expected, since the development and test sets are not involved in the training procedure of the HSMM model, the RMSE for these sets are almost identical. In the case of the MLP model on the test set, a 4.79% relative decrease in terms of RMSE in respect to the development set (used for the fine tuning of the model) is achieved, showing some degree of overfitting of the model to the development set. On the other hand, in the case of the SVR model, even though the model is fine tuned using the development set, the RMSE for the development and test sets are almost identical, showing an additional advantage of the SVR over the MLP, i.e. the ability of SVR to make robust model without overfitting to the development set.

In Table 1, the overall accuracy in terms of RMSE on the test set separately for vowels and consonants is presented. It can be seen that these results follow the overall results described above. For all models, the RMSE calculated on the vowels is higher than the one on the consonants, which can be attributed to the fact that the mean of the standard deviation of the vowels (on the reference-original durations of the phones) is significantly higher than the respective one for the consonants.

In Figure 1, the RMSE in milliseconds for each phone for the three models on the test set is presented. It is shown that the SVR model managed to outperform the MLP and the HSMM models for all phones apart from the silence ("pau"), where MLP model achieved the best performance followed by the SVR model. The biggest difference between the SVR and the HSMM models is shown in phone "ey", where SVR model achieved a 37.74% relative improvement over the HSMM model in terms of RMSE. On the other hand the smallest difference for the respective models is shown in phone "hh", where SVR model achieved a 10.9% relative improvement over the HSMM model in terms of RMSE. In the comparison between SVR and MLP models, the biggest difference is shown in phone "ay", where SVR model achieved a 28.36% relative improvement over the MLP model in terms of RMSE. The smallest difference is shown in phone "aa", where SVR model achieved a 1.64% relative improvement over the MLP model in terms of RMSE. Comparing the MLP and HSMM models, it can be noticed that in several cases (e.g. "f", "th", "uw" phones), the MLP model was outperformed by the HSMM model. On the other hand the biggest difference for the respective models is shown in phone "g", where MLP model achieved a 37.76% relative improvement over the HSMM model in terms of RMSE.

4.2.2. Subjective Evaluation

In order to investigate whether the objective performance among the three models is reflected to the overall quality of the synthesized speech, a subjective evaluation test was done. Using the HSMM-based speech synthesis framework described earlier, the phone durations predicted by the SVR and MLP models were forced on the speech synthesis system, in order to synthesize speech using the predicted durations and determining internally the state sequence of the model.

The subjective evaluation was composed by three ABX tests, comparing each of the model to the other two. Two sets of ten sentences where randomly chosen from the test set and were evaluated by 14 and 13 subjects respectively. For every sentence, the subjects were presented with three pairs of samples (HSMM vs MLP, HSMM vs SVR and MLP vs SVR) in random order, without any knowledge about the three systems and a reference sample. In each case the subjects had to choose between the two samples of the pair in terms of sounding closer to the reference one (synthesized with forced alignment using the reference durations) or they could choose "equal" if they had no preference over them.

In Table 2, the results of the ABX tests are presented. As can be seen the SVR model was preferred over the MLP and HSMM models with a score of 35.93% over 17.41% and 56.30% over 13.33% respectively. Furthermore, the MLP model was preferred over the HSMM model with a score of 44.07% over 25.56%. These results follow the trend of the objective evaluation, showing that the SVR managed to build a robust model capable of outperforming the explicit HSMM model and moreover the other external model using MLP, in the overall quality of the synthesized speech.

5. Conclusions

In this paper we compared the HSMM-based explicit duration modelling with two external phone duration models using Support Vector Regression (SVR) and Multilayer Perceptron (MLP). The goal was to investigate whether and in which degree the external duration models outperform the HSMM model and if this is perceived in a subjective evaluation test on the quality of the synthesized speech. The experiments were done on an American English male speaker database. In both objective and subjective tests, it was shown clearly that the external duration models are more appropriate in the task of phone duration modelling in comparison to the explicit duration modelling of HSMMs, verifying our initial hypothesis.

Additionally, between the two external models, the SVR one outperformed the MLP model verifying our second hypothesis that the SVR would managed to tackle this task more efficiently. In the objective test, SVR model managed to outperform the MLP and HSMM ones showing a relative improvement in terms of root mean square error of 15.3% and 25.09% respectively. Finally, the subjective evaluation test showed that the superiority of the SVR model over the MLP and HSMM models is reflected also on the quality of synthetic speech, achieving a preference score of 35.93% and 56.30% over them, respectively. As future work it would be interesting to investigate how these three models perform using larger databases.

Abstract

Three independently motivated types of information are usually assumed to influence prosodic boundary placement and to play a role in their relative strength: the morpho-syntactic structure, the information structure and the metrical complexity. The phonetic realization associated with the different boundary types (in particular IP and ip) is also assumed to vary.

Based on data of clitic left-dislocations in French, we argue here that differences in the relative strength of the prosodic boundary occurring at the end of the dislocated XP (i.e. an intermediate (ip) or an intonational phrase (IP) boundary) cannot be derived in a straightforward manner from these three types of information. In a production experiment, where the syntactic and information structure were controlled, while the metrical complexity was varied, the analysis of the data achieved with a semi-automatic tool, ANALOR, showed that the strength of the boundary occurring at the right edge of the dislocated object NP displayed a high degree of variability. In addition, the results indicate a lack of correlation between metrical complexity and boundary strength. The results lead us to argue that a sort of phonological neutralization occurs in certain textual contexts. This neutralization does not allow for distinguishing between intermediate and intonational phrase boundaries in all cases.

Index Terms: prosodic phrasing in French, boundary strength, phonetic realization, clitic left-dislocation (CLLD)

1. Introduction

In most studies dedicated to prosodic phrasing and intonation, an utterance is considered to be segmented into hierarchically organized prosodic constituents (see, among others, [1], [2], [3], [4] und [5]). Three independently motivated types of information are usually assumed to influence prosodic boundary placement and to play a role in the evaluation of the relative strength of the boundary:

- The morpho-syntactic structure, as prosodic phrase boundaries align to designated edges of various syntactic phrases (right or left edge of heads of maximal projections, etc.). See [5], [6], [7] and [8], in which syntax-prosody mapping is expressed in terms of alignment constraints, as well as [3], [4] and [10] for different ways of describing prosody-syntax mapping.
- The information structure, as the topic or the informational focus of an utterance may call for the realization of specific prosodic boundary. See, for instance, the various constraints that account for the alignment of the prosodic phrases to the topic (as in [8],) or focus constituent (as in [11], [12], [13] and [14]).
- The metrical structure, since the size or the metrical structure of a syntactic unit, may influence prosodic phrase placement. In French, for instance, it has been shown that the size of the accentual phrase (or prosodic word) is usually limited to six or seven syllables (see, among others, [7], [15] and [16]). As for Spanish, Catalan and Portuguese, [17] showed that a constituent length of five syllables has an important effect on prosodic phrasing, in contrast to syntactic branchingness.

Even if these various types of information may influence boundary placement, we argue here that they cannot always account for the relative strength of the boundary. A sort of neutralization occurs in some contexts and prevents one from distinguishing between differences in boundary strength, in particular the difference between ip and IP boundaries (see [18] and [19] for a description of these two distinct prosodic constituents in French).

Our proposal is based on the investigation of the prosodic phrasing of clitic left-dislocations (CLLDs) in French, while using a semi-automatic procedure to assign boundary strength. CLLD is an optimal phenomenon for several reasons. First, in terms of syntactic structure, the canonical word order is changed according to the dislocation of a constituent. This yields a specific prosodic pattern, in which the right edge of the dislocated XP is aligned with a prosodic phrase boundary: many (prosodic and syntactic) studies claim that the CLLD constituent is typically demarcated by an IP boundary (e.g. [10], [20]), and some others show that the right edge of CLLDs coincide with either an IP boundary, or an ip boundary (see [8], [13], or [21]). Note however that some studies argued that CLLDs may be prosodically unmarked, or aligned with a lower level boundary such as prosodic word or accentual phrase (see [22] and [23]). Second, with respect to the information structural status, the CLLD constituent is usually considered to be a topic and to be given (in a general sense; see, among others, [23] for a discussion of the interpretative function of CLLD). Third, in the context of metrical structure, the branchingness or the size of the CLLD constituent can vary. We apply this option in the present study. [23] showed that the length of the dislocated XP may play a role in the strength of the prosodic boundary occurring at its right edge (IP, ip, or no real marking which leads to phrase the dislocated XP with the subsequent sentence material). Catalan CLLDs, in contrast, do not show any restructuring effects, according to [8].

Thus, by using CLLD structures, we control for the syntactic structure and the information packaging of the sentence (neither changes), while modifying the metrical structure (expressed in terms of branchingness or length). If a one-to-one correlation exists between the syntax of CLLD and its prosody, no variation in boundary strength (ip or IP) should occur. The same holds for the information status: since the interpretation of the CLLD constituent remains the same, the boundary strength should not differ. In addition, if metrical weight plays a role, boundary strength should be clearly correlated with the (non-) branchingness of the dislocation.

The results, however, show that there is great variation in both boundary strength and phonetic realization in each condition.

The paper is organized as follows. In section 2, the major theoretical issues concerning the representation of prosodic structure and the definition of prosodic phrases in French are given. Section 3 presents the methodology and the corpus used to carry out this research. In section 4, we give a description of the results obtained by analyzing prosodic phrasing in our data. Section 5 consists of a discussion of our findings and presents some perspectives for future research.

2. Background and problematic

In the last few decades, many theoretical studies in prosody have been dedicated to prosodic structure and its organization. Focus has been given to two different issues: the internal organization of the prosodic hierarchy and the criteria involved in the definition of the different prosodic units.

2.1 Prosodic hierarchy and levels of structuring

In most prosodic descriptions, an utterance is considered to be segmented into units that are hierarchically organized. The number of levels above the word level is usually assumed to be either two (e.g. the accentual phrase and the intonational phrase or the phonological/intermediate phrase and the intonational phrase as in [4] and [25]) or three (the accentual phrase, the intermediate phrase and the Intonational Phrase, see, [18] and [26] for French).

Even in studies that are not overtly based in the metrical-autosegmental framework, two or three distinct levels of phrasing above the word level are usually assumed for French (see, among others, [23] and [27]). It is worth mentioning that two authors working on French intonation argue for a different approach: Mertens proposes only a single unit called the *groupe intonatif* ([9], [10]), while Martin proposes that the number of levels of phrasing critically depends on the morpho-syntactic structure of the sentence, [16], [28], [29].

The proposal made here is done within the metrical-autosegmental framework (see [1] and [2]) and relies on the idea that three levels of phrasing are distinguished in French (e.g. the AP, the ip and the IP as in [18], and [26]). We will show, however, that the distinction between ip and IP phrases may be neutralized in some contexts.

2.2 Criteria for the definition of the prosodic constituents

Among the works focusing on the definition of different types of prosodic phrases, a distinction can be made between roughly two categories of work:

- In some works, realizational differences in the prosodic events occurring at phrase boundaries are crucial in distinguishing boundary strength (e.g. [18], [19]). In a certain sense, phonetic and phonological criteria are thus given priority compared to syntax-prosody mapping in the definition of the prosodic phrases.
- In others studies, the definition of prosodic phrases is considered to be constrained by the mapping between the morpho-syntactic, the informational and the metrical structure (see [4], [5], [6] and [8]).

As far as we are concerned, the difference between these two approaches should be limited to a unique perspective: one would hope that both approaches will lead to the same results.

In this work, we assume that differences in boundary strength (here: ip vs. IP) are associated with various prosodic realizations, but we also assume that some categorical differences exist between the different levels of phrasing which can be accounted for by the linguistic criteria explaining boundary placement. Our aim here is thus to determine which criteria come into play in the placement of the two prosodic phrase boundary. This will be done by calculating boundary strength through an automatic procedure in comparable structures.

3. Methodology

To carry out this research, data were gathered by means of a production test. The obtained utterances were then analyzed by using a semi-automatic procedure. The data collection protocol and the analysis procedure are explained in the next sub-sections.

3.1 Corpus and data collection protocol

The experiment was conducted in Paris (France). Ten native speakers of Standard French were recorded. For the present study, six speakers were analyzed, ranging in age from 22 to 29. All subjects were post-graduate students and remained naive as to the purpose of our investigation. The data were recorded as WAV files (16bits, 44.1 kHz) with the Roland UA-55 Quad Capture USB audio interface and the AKG C520 headworn condenser microphone. The speakers were asked to read sentences, for which a context was given.

The utterances to be produced were designed to contain clitic left-dislocations and consisted of simple assertions and questions as shown in (1). While the left-dislocated constituent in the assertions consisted of either one (1a) or two (or three) lexical words (1b), in the questions it consisted of only one lexical word (1c). In order to guarantee the givenness of the left-dislocated constituent (in bold in (1)) and the newness of the core clause, each utterance was preceded by a corresponding context, in which the dislocated element was mentioned, as exemplified in (2) for (1a,b) and in (3) for (1c); cf. the underlined element. The corresponding contexts allow for the classification of the left-dislocated elements as *active topics*, since the latter are active in the speaker's mind and are textually given, i.e. they have just been mentioned in the discourse.

(1a) **La bouteille** Jean-Marie l'a donnée au voisin.
'The bottle, Jean-Marie gave it to the neighbor.'

(1b) **La bouteille de Bordeaux** J.-M. l'a donnée au voisin.
'The bottle from Bordeaux, J.-M. gave it to the neighbor.'

(1c) **Et ce roman** tu l'as déjà lu ?
'And this novel, did you already read it?'

(2) Que s'est-il passé avec <u>la bouteille de Bordeaux</u>? Elle est où?
'What happened to the bottle from Bordeaux? Where is it?'

(3) Je t'ai apporté <u>un roman policier</u>. Je l'ai mis sur la table.
'I brought you a detective novel. I put it on the table.'

In our data, the left-dislocated element was always chosen as to fulfill the function of the object, there being an ongoing discussion of whether sentence-initial subjects in French are actually clear instances of left-dislocation (see [22], and [31]).

There were a total of 144 target sentences (four sentences of type (1a), five sentences of type (1b), three sentences of type (1c), multiplied by two repetitions and six speakers). Additional filler clauses were added.

The subjects were recorded in a quiet room at the Linguistics Department of the University of Paris 7. The stimuli were presented in a pseudo-randomized order on sheets of paper with roughly six target and filler sentences per page. The subjects were told to read the stimuli out loud at a normal rate of speech. Since no sentence-internal punctuation was used, the subjects were told to first read the sentences silently before uttering them aloud. Each recording started with a short practice session.

3.2 Prosodic analysis of the utterances

The data were analyzed in three steps. First, the data were transcribed by the two authors using *praat* [32]. Second, the utterances were automatically segmented into phones, syllables, and graphemic words by means of the speech processing script *EasyAlign* [33]. The obtained segmentations were controlled and corrected when necessary by the authors. Third, the strength of the prosodic breaks associated with the right edge of the dislocated elements was determined by means of the semi-automatic annotation software ANALOR (see [23], [34] and [35] for more details). The software automatically measures the four acoustic parameters (i) relative syllable duration, (ii) relative F0 average, (iii) slope contour amplitude, and (iv) presence of an adjacent silent pause, detects the prominent syllables, and assigns a degree of prominence to each syllable, be it prominent or not. The degree of prominence is calculated on the basis of the parameters that are considered as fundamental for marking prominence in French (see, among others, [23], [34] and [35]). ANALOR's calculations of the degree of prominence rely on two elementary principles, the *quantity principle* and the *compensation principle* (see [22]). The first states that the larger the number of acoustic parameters involved in the detection of a prominence, the stronger the prominence is perceived. The second balances the parameters with one another: if one parameter shows a high prominence score and the other a low one, they are perceived as presenting a medium score together. The results of the calculation are presented in grades ranging from 0 (no prominence) to 10 (high prominence). Since accentuation plays a crucial function in the demarcation of the prosodic units in French (see, among other,[9], [25], [26] and [36]) , we have inferred the boundary strength from the degree of prominence assigned to the last metrical syllable of each word: the higher the degree of prominence, the stronger the break.

Thanks to the software, the detection of the level of prominence for each syllable is robust and we could thus avoid the variation which typically occurs between experts in manual prosodic annotation (see, for instance, [1], p. 288ff). Since accentuation and phrasing are closely related in French (see [9], [23], [25] and [36] among others), we associate the degree of prominence with specific prosodic constituents:

- Level > 2 and < 3 = AP boundary
- Level 3 and 4 = ip boundary
- Level 5 and higher = IP boundary

In describing the results in the next section, we rely mostly on the prominence levels. It is only in section 5 that the association between degree of prominence and prosodic constituents (or boundary strength) will be discussed in greater detail.

4. Results

The results indicate that there is generally a prosodic boundary at the right edge of the left dislocated constituent, and its strength forms a gradient ranging from 2 (as > 2) to 9. In addition, this boundary corresponds to an ip or higher boundary in more than 97% of the cases in assertions. In questions, the prosodic boundary is weaker in more than 15% of the cases. In 16,7 % of the cases, it corresponds to an AP boundary.

Table 1 gives the scores of the boundaries at the right edge of the dislocated constituents as detected by ANALOR. Column 1 represents pattern (1a), column 2 (1b), and column 3 (1c). The bars at the top of the table illustrate the percentages given in the table for each score (from 2+ to 9; scores 1 and 10 are not attested in our data).

Table 1. *Prominence of final syllable in CLLD constituent (ANALOR degrees).*

	Decl. 1w	Decl. 2w	Interr. 1w
9	0	1,7	2,7
8	0	5	0
7	39,6	46,7	16,7
6	14,6	5	5,6
5	6,2	3,3	13,9
4	27,1	30	19,4
3	10,4	8,3	25
2	2,1	0	16,7

4.1 Dislocated constituent as a single word in assertions

The most prominent score in the assertive sentences with one lexical word (Decl. 1w) was 7 (39.6%; 19 out of 48 instances). The second highest score for this condition is 4, with 27.1% (13/48). In addition, scores 3, 5, and 6 were also attested more than one time (score 3: 10.4% = 5/48; score 5: 6.2% = 3/48; score 6: 14.6% = 7/48). Score between 2 and 3 is attested only once (2.1%). The percentages of scores ranging from 4 to 7 add up to 87.5% (42/48). Scores 8 and 9 are not attested.

According to these results, IP boundaries occur at the right edge of dislocated object NP in more than 60% of cases, while ip boundaries occur in only 37.5 %. The AP boundary is observed only in 2.1% of the cases.

4.2 Dislocated constituents with two words in assertive sentences

As for the condition with two lexical words (Decl. 2w), all scores between 3 and 9 were attested. Score 7 was by far the most prominent one with a percentage of 46.7 (28/60), followed by score 4 with 30% (18/60). All other scores fell below 10%. In condition 2w, the percentages of scores ranging from 4 to 7 add up to 85% (51/60). In contrast to condition 1w, condition 2w had instances of scores 8 and 9, but no instance of score inferior to 3. Together with the very high percentage for score 7, the data show that the prosodic boundaries in condition 2w are generally slightly stronger than in 1w.

Despite this picture, IP and ip boundaries occur similarly frequently in both conditions. Note that some speakers even realize a stronger boundary in 1w condition than in 2w condition.

4.3 Questions

Table 1 shows that score 3 was most prominent with 25% (9/36); followed by score 4 with 19.4% (7/36), and score between 2 and 3 with 16.7% (6 cases out of36). These three scores add up to a total of 61.1% (22/36). This shows that the general degree of CLLD boundary strength is much lower in questions than in assertions - even though there were six instances of score 7 (16.7%) and 5 instances of score 5 (13.9%).

The interpretation of the results in terms of boundary level shows that an AP boundary occurs in 16.7 % of the cases, while an ip boundary occurs in 44.4 % and an IP in 38.9% of the cases. In comparison to assertive sentences, non-IP boundaries (i.e. AP or ip boundaries) are found to be more frequent in questions.

5. Discussion

Up to now, the results were mostly presented by relying on the ANALOR scores of prominence. In this section, we would like to highlight the interpretation of these scores in terms of prosodic constituents and prosodic structure: accentual phrase (AP), intermediate phrase (ip), and Intonational Phrase (IP).

Before running the experiment, the authors agreed to assign all scores between 2 and 3 to the AP, the scores between 3 and 4 to the ip level, and the scores equal and higher than 5 to the IP level. [22] and [23] made slightly different choices in assigning scores between 2 to 3 (2<score<3) to the AP level, score 3 to the ip level, and everything equal and greater than 4 to the IP level. Despite the difference in the affiliation of score 4, this score always signals that a clitic-left dislocation in French is not obligatorily followed by an IP boundary, but rather can be realized on either the ip or the IP level. Similarly, the prominence of the ultimate syllable in the dislocated constituent is subject to strong variation.

According to the two classifications, our results show that it is only in questions that the CLLD constituent needs not to be prosodically separated from the following sentence by an ip or an IP boundary. In assertions, the CLLD constituent is almost always separated from the sentence by an ip or an IP boundary (just one case of an AP boundary was observed in all the data). The impossibility of having an AP is even clearer with branching CLLD constituents, as these never group with the subsequent material in our data. Interestingly, the boundary at the right edge of the dislocation is the strongest boundary one can find sentence internally: (i) it is the strongest one within the dislocated XP (in case the XP consists of at least two distinct prosodic units, and (ii) it is also the strongest one with respect to the following sentence internal boundaries. This means, independently of the CLLD boundary being an ip or an IP boundary, it is always the strongest sentence-internal boundary. Only the sentence-final boundary might be stronger. The first point is not really surprising and confirmed what was said by [10], [15] and [16] among others. As for the second point, it shows that no restructuring with subsequent elements is possible in French, even when the boundary strength is not very important. To sum up, it is possible to say that a phrase boundary is always realized at the right edge of the CLLD in assertive sentences. The results show however that the mapping between syntax/information structure and prosody is not invariant with respect to the boundary strength, since it is either an ip or an IP boundary. In addition, the great variation in prominence and boundary strength in conditions 1w and 2w clearly indicates a lack of correlation between metrical complexity and phonetic realization of the boundary.

As for the behavior of CLLD in questions, we think that the sentence type may play a role: all questions were declarative questions, which end with a rising tonal contour. So, in order to distinguish this contour from the rising contour occurring after the CLLD, the speaker may realize a weaker sentence-internal rising contour, or even a falling one. These realizations confirm the proposal made in [16], [28] and [29]. They are also in accordance with more recent studies ([37], [38]) which show that global intonational patterns may be more important than the exact strength of a boundary as the "impact of prosodic boundaries depends on the other prosodic choices a speaker has made" ([38], p. 244). In the cases where a non-rising contour has been observed at the right edge of the dislocated XP, the assigned degree of prominence may result from the form of the contour. The calculation, as currently made has a tendency to underweight falling contours. Since such cases are not very frequent, they cannot invalidate the conclusions made here.

6. Conclusion and Perspectives

The analysis of our data shows that the choice between the different boundary levels cannot be systematically explained on the basis of the three criteria usually claimed to account for prosodic phrasing, i.e. syntactic and information structure, and metrical complexity. There is great variation in the realization of boundary strength. To our mind, this could be attributed to a sort of neutralization: in some contexts, the distinction between ip and IP boundaries is not really relevant, since the sentence as a whole does not request to distinguish three levels of prosodic structuring. In order to be the strongest sentence-internal break, the prosodic break occurring at the end of the dislocated XP could be an ip or and IP boundary.

Further research is necessary to understand the exact motivation behind this neutralization. One could for instance take into account CLLDs in embedded clauses in order to address some of the issues. In addition, a more comprehensive study of the phrasing in questions has to be achieved in order to see what motivates the occurrence of AP boundary in this context: is it due to tonal and realizational constraints, or to the expression of some difference in speaker 's attitude.

Abstract

This paper describes a modeling technique of Thai tones for HMM-based speech synthesis. Tones are important prosodic features for tonal languages including Thai because the phonetically same words but with different tones give different meanings. Although there have been several approaches to improving tone correctness of synthetic speech by considering tone types, another significant factor, stress, was not used explicitly for prosody modeling. We incorporate stress/unstress information into the framework of the HMM-based speech synthesis. Objective and subjective evaluation results show that the use of stress information improves the performance in Thai tone modeling.

Index Terms: HMM-based speech synthesis, tone correctness, stress, context clustering

1. Introduction

In the speech synthesis of tonal languages including Chinese, Vietnamese, and Thai, tone correctness of the synthetic speech is a crucial point, because different tones give different meanings even if the phonetic information of words is the same. In this context, various techniques have been examined to improve tone correctness for Thai speech synthesis. A tone-separated tree structure was introduced for HMM-based Thai speech synthesis to reduce the tone-dependent effects in the context clustering process [1]. Moreover, to capture a variety of shapes of fundamental frequency (F0) contours effectively, phrase-intonation and tone-geometrical features derived from Fujisaki-model were used as the contexts in the HMM-based speech synthesis [2]. Another approach to modeling tone in Thai is the use of Tilt model [3]. The Tilt model was extended for modeling F0 contours in tonal languages and the modified Tilt model for Thai is called T-Tilt model [4]. To enhance T-Tilt model, an optimized T-Tilt model by expanding the Tilt curve over the whole syllable was also proposed [5]. If tone information is determined from transcriptions of speech data in the modeling, the quality of synthetic tones much depends on the accuracy of tone labeling. For this problem, a tone modeling technique using a quantized F0 context was proposed to reduce the tone distortion caused by inconsistent tonal labeling, in which quantized F0 symbols were utilized as the context for constructing the decision trees [6].

Although, these techniques improve the naturalness and tone intelligibility of synthetic speech, tone correctness is not perfect and the tones of some syllables in continuous synthetic speech are perceived to be obviously incorrect and unnatural. To alleviate this problem, we focus on one of other factors, which affects prosodic features and has not been considered explicitly as a context in the conventional HMM-based Thai speech synthesis. In [7], it is reported that stressed syllables have largely different characteristics from unstressed ones. Stressed syllables have typical F0 contours and long durations. In contrast, unstressed syllables are diverse. For example, the effect of speaking rate on the F0 contours of unstressed syllables is more extensive, both in terms of height and slope, than that of stressed syllables [8]. As described in [9], coarticulation and intonation affect tonal assimilation and declination. The coarticulatory effect will cause the change in F0 contour shape of a syllable to be assimilated with neighboring syllables.

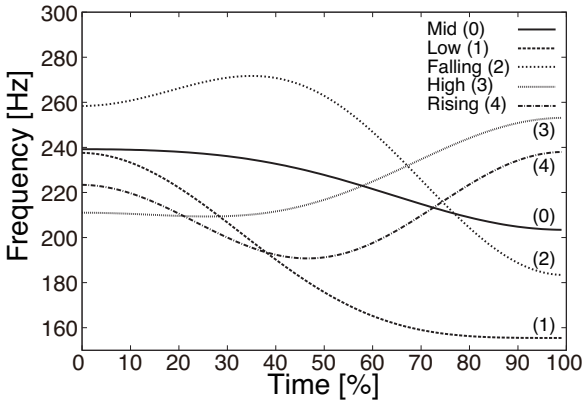

Figure 1: Typical F0 contours of Thai tones. Each contour represents the average of extracted F0 contours from the database TSynC-1.

In this paper, we examine stressed/unstressed effects on Thai tones, and propose a modeling technique using stress information to improve Thai tone correctness of HMM-based synthetic speech. We classify stressed and unstressed syllables manually by using the stress properties described in [7, 10], and incorporate the stress information into the context labeling. We compare the performance of the proposed and conventional methods through objective and subjective evaluations and show the effectiveness of the proposed method.

2. Tone and stress in Thai

Tone represents a change in the pitch of a syllable during its pronunciation. In Thai, every syllable is pronounced in one of five tones: mid (0), low (1), falling (2), high (3), or rising (4).

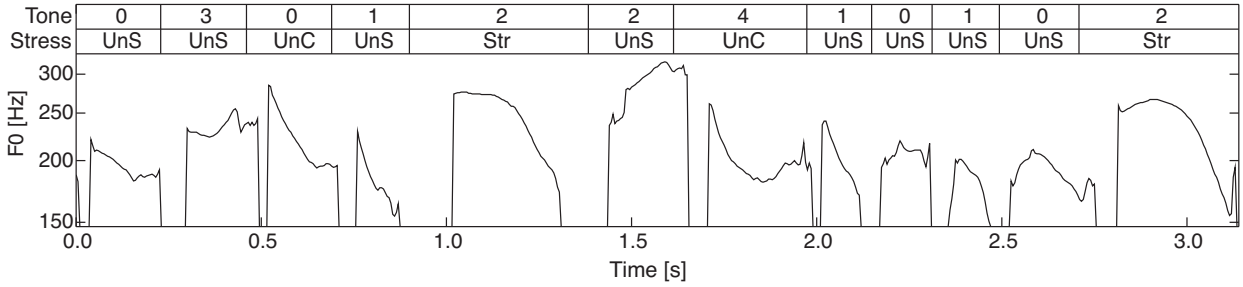

Figure 3: Stressed and unstressed syllables in natural speech (Str : Stressed syllable, UnS : Unstressed syllable, and UnC : Unclear syllable).

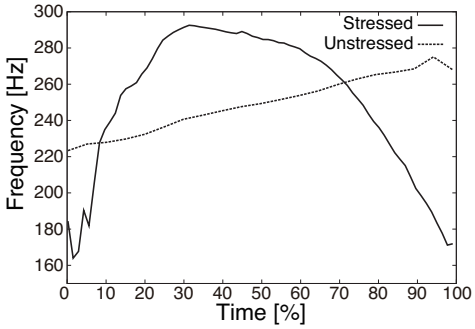
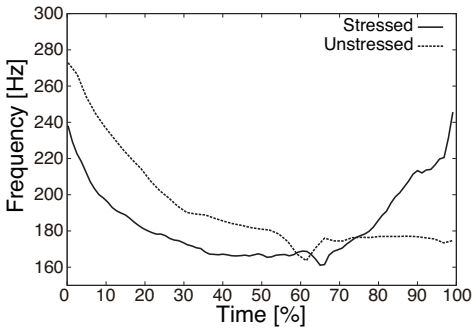


(a) Falling tone (2)



(b) Rising tone (4)

Figure 2: Example of F0 contours in (a) falling tone (2) and (b) rising tone (4) syllables.

The tone must be spoken correctly for the intended meaning of a word to be understood. The identification of a Thai tone relies on the shape of the F0 contour. Figure 1 shows the typical F0 contours of five different tones of isolated syllables. However every F0 contour shape does not always look like the typical one. The shapes depend on stress information of syllables [7]. Figure 2 shows an example of F0 contour shapes of falling tone (2) and rising tone (4) in stressed and unstressed syllables which were extracted from speech samples included in Thai speech database TSynC-1 [11].

The stressed F0 contour shapes are similar to the typical ones, whereas the shapes of unstressed syllables tend to be flat and have less movement of contour, especially in falling tone (2) and rising tone (4). Furthermore, the actual unstressed F0 contours are diverse. Several interacting factors affect F0 realization of tones, e.g., syllable structure, declination, tonal assimilation, stress, and speaking rate [7–10].

Figure 4: Decision trees for context clustering: (a) single tree structure and (b) stressed/unstressed separated tree structure.

3. Tone modeling with stressed/unstressed context

3.1. Annotation of stress information

As described in [10], stressed syllables have following characteristics:

- Long duation
- F0 contour similar to the prototypes
- High energy

Duration is the predominant feature in the distinction between stressed and unstressed syllables in Thai. The secondary feature is the range of F0 movement [7]. Generally, stressed syllables appear in the end of utterances, isolated phrases, and emphasized words. In other words, the characteristics of unstressed syllables are the opposite ones of stressed syllables.

Figure 3 shows an example of the F0 contour that includes stressed, unstressed, and unclear syllables. The utterance contains 12 syllables, of which the fifth and the twelfth ones are stressed, the third and the seventh ones have unclear stress information, and the others are unstressed.

In this study, we classified stressed and unstressed syllables manually. First, we listened to each syllable individually. If it clearly has the properties of stressed syllables, and it can be classified into only one tone, we annotate a *stressed* label on it. Otherwise, *unstressed* is annotated. However, there are some syllables that are not easy to distinguish, because they are indistinctly uttered by the characteristics between the stressed and unstressed syllables. Currently, we annotate *unstressed* labels for such indistinctly uttered syllables.

Table 1: Average F0 distortion between original and generated speech samples.

Method	RMS error [cent]	# of leaf nodes
Conventional	139.1	2532
Single tree	132.3	2470
Separated tree	132.6	2685

3.2. Context clustering using stress information

We examine two tone modeling methods using stress information. Specifically, we incorporate the stress information into the context clustering that is an essential process in the HMM-based speech synthesis [12]. The first method is adding the stress information to the context set. By incorporating stress information to the context set, the different characteristics are automatically separated during the decision tree clustering. We refer to this method as *single tree*. The second method is to use two trees separated by stressed and unstressed syllables using a manner similar to the tone-separated tree structure proposed in [1]. It is based on the facts that the characteristics of stressed and unstressed syllables are largely different and the frequencies of the stressed and unstressed syllables are imbalanced. In this method, the stress contexts of preceding and succeeding syllables are taken into account based on the results of [1]. We refer to this method as *stressed/unstressed separated tree*. Figure 4 illustrates decision tree structures of the proposed two methods.

4. Experiment

4.1. Training condition

A set of phonetically balanced sentences of Thai speech database named TSynC-1 from NECTEC [11] was used for training and evaluation. The sentences in the database were uttered by a professional female speaker with clear articulation and standard Thai accent with reading style. A speaker-dependent model was trained using 340 utterances from the database. We used 29 utterances for evaluation, which were not included in the training set.

Speech signals were sampled at a rate of 16kHz. F0 and spectral features were extracted by STRAIGHT [13] with 5-ms frame shift. The feature vector of phone-unit HMM consisted of 0-39th mel-cepstral coefficients, 5-band aperiodicity, log F0, and their delta and delta-delta coefficients. We used hidden semi-Markov model (HSMM) which has explicit duration distributions. The model topology was 5-state left-to-right context-dependent HSMM. The conventional method uses context clustering as described in [14]. Context clustering of the proposed method was extended from the conventional one by including stress information in the context set.

4.2. Objective evaluation result

The proposed and conventional methods were evaluated objectively. The measurements for evaluation were average F0 distortions that were calculated by RMS error between generated and original log F0s.

The results are shown in Table 1. The number of leaf nodes of F0 decision trees for context clustering is also shown in the table. The F0 distortions of the proposed methods were lower than the conventional method. However, there was only slight difference between the single tree and stressed/unstressed separated tree. In addition, the numbers of leaf nodes were not much different for all methods. Figure 7 shows an example of the F0 contours generated by all methods compared to the original speech. The sixth and eleventh syllables are the stressed syllable in the falling tone. The F0 contours of these syllables in Fig. 7 (a), which were generated by the conventional method, are not like the falling tone because they do not fall at the end of the syllable, but they are similar to those of the mid tone. In Figs. 7 (b) and (c), the F0 contours were generated by the proposed methods and they are similar to the original ones. The ends of the F0 contours are falling and were perceived as the falling tone. There is a slight difference in F0 contours between the single tree and stressed/unstressed separated tree structure methods.

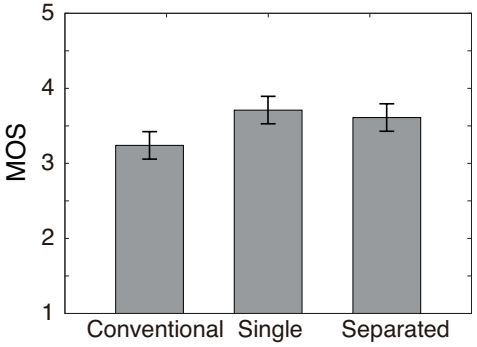

Figure 5: Mean opinion score of naturalness of synthetic tone comparison.

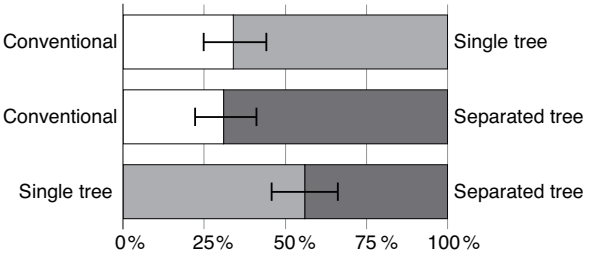

Figure 6: The results of forced choice preference test in tone intelligibility.

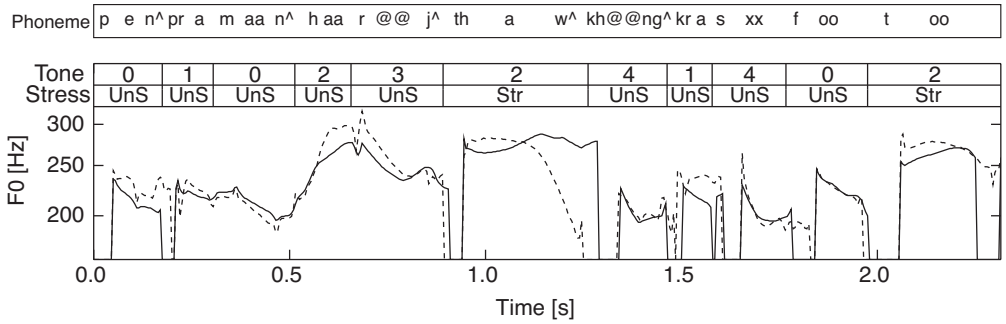
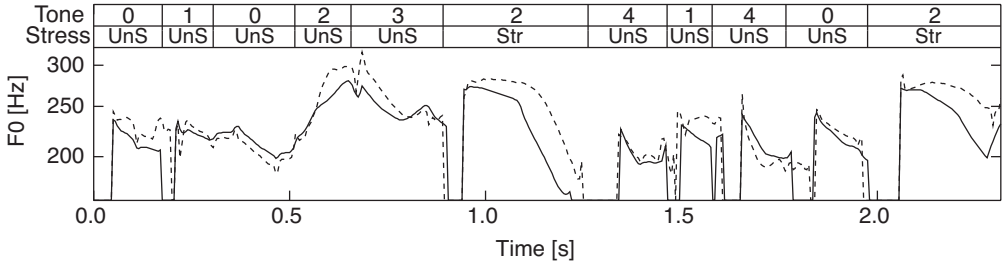
4.3. Subjective evaluation result

To ensure the effectiveness of the proposed methods, we evaluated the perceptual quality in terms of naturalness and tone intelligibility. Specifically, we employed mean opinion score (MOS) and forced choice preference tests.

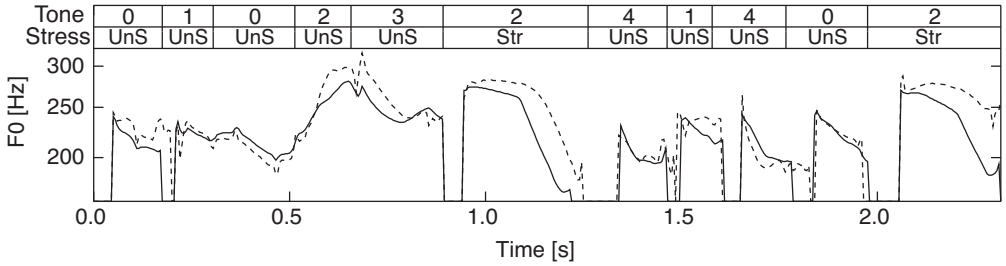
Ten utterances were randomly chosen from the synthetic speech samples used in the objective evaluation test. We assessed the synthetic speech from the proposed two methods and the conventional method. As a result, we compared three types of synthetic speech in the evaluation. Ten Thai native speakers listened to and evaluated the samples. In MOS test, the listeners evaluated each utterance on a five-point scale from 1 to 5 according to their satisfaction with the perceptual naturalness of tones. The definition of the rating was: 1-bad, 2-poor, 3-fair, 4-good, and 5-excellent. Listeners could repeat sentences to evaluate as many times as they required for ensuring that they were accurately evaluating. Figure 5 shows the result with



(a) F0 contours comparison between the original one in dashed line and the conventional one in soild line.



(b) F0 contours comparison between the original one in dashed line and the single tree one in soild line.



(c) F0 contours comparison between the original one in dashed line and the separated tree one in soild line.

Figure 7: Examples of F0 contours generated by (a) the conventional method, (b) the single tree method, and (c) the separated tree method. The sentence means that "it is about 500 times of the photoelectric." The tone numbers represent mid tone (0), low tone (1), falling tone (2), high tone (3), and rising tone (4).

95% confidence intervals. It can be observed that the proposed methods outperformed the conventional method. The scores of both proposed methods are not significantly different and it is consistent with the result of objective evaluation.

In the forced choice preference test, the listeners were asked to choose more natural-sounding tone from each pair of synthetic speech. The listener could repeat sentences as many times as they required in the same way as the MOS test. The results of the forced choice preference test are shown in Fig. 6. It is seen again that the proposed methods outperformed the conventional method. When comparing between the single tree structure method and the stressed/unstressed separated tree structure method, the listeners preferred the single tree method, but the difference is statistically not significant.

5. Conclusion

This paper has described a modeling technique of Thai speech synthesis using the stress information of syllables. Although stress is an important factor for tone perception in Thai, stress information has not been included in the context clustering in conventional techniques. This causes generation of incorrect tones. To overcome the problem, we added stress information to context clustering. The objective evaluation showed that the proposed method can reduce the F0 distortion significantly. The subjective tests also yielded results that corresponded to those from the objective tests. Although we have confirmed that the stress information could improve the tone correctness, there still exist unnatural tones in synthetic speech. For improvement of the tone naturalness, syllable-level unit might not be appropriate. Thus, in future work, we will investigate a tone modeling technique based on longer unit such as word or phrase.

6. Acknowledgements

We would like to thank Dr. Vataya Chunwijitra of NECTEC, Thailand, for providing us with helpful discussion and the TSynC-1 speech corpora. A part of this work was supported by JSPS Grant-in-Aid for Scientific Research 24300071.

Abstract

Voice conversion systems aim at finding a transformation function using statistical models. Mimicry (voice imitation) is a natural voice transformation technique which sounds convincing to the listeners. It thus seems advisable to study the transformation used by human beings who perform mimicry. The objective of this study is to examine the various components of speech that are modified during voice imitation. To transform a given speech utterance to sound like that of a target utterance, the process needs to be understood at both production and perception level. In this paper, the importance of source and system parameters and also the significance of different components of speech that contribute to the perception of imitation are studied. A flexible analysis-synthesis tool is used to modify the features of natural utterance and convert it to imitated utterance. Perceptual studies are carried out to understand if the modified features contribute to imitation. The results show that a combination of features is varied by the imitator to achieve imitation and they vary depending on the target speaker.

Index Terms: Mimicry, voice imitation, speech synthesis, speech prosody.

1. Introduction

Speech is a natural medium of communication among human beings. Speech signal carries information about the intended message, the identity of the speaker and the background. There are a few features in speech signal that enable us to differentiate between speakers. There are applications in gaming industry which require voices of celebrities for gaming avatars. Voice Conversion (VC) is a technique to transform an utterance of a source speaker so that it is perceived as if spoken by a specific target speaker. A variety of techniques have been proposed for the conversion function [1], such as artificial neural networks, dynamic frequency warping or Gaussian mixture model.

Human beings imitate voice for language acquisition, entertainment or for voice disguise [2]. Voice imitation is primarily used for entertainment, where the mimicry artist trains his voice to imitate the voice of a target speaker. An imitator cannot imitate all the features of the target speaker but tries to imitate features that are perceptually significant.

In the literature, analysis of voice imitation has been carried out and the closeness of features like fundamental frequency, duration, discrete Fourier transform spectra (DFT) and formant frequencies have been studied [3]. Different studies of professional imitators and their imitations suggest the possibility of getting close to target voice. Both perceptual and acoustic analysis confirm the flexibility of human voice [2]. It is also to be noted that an imitator might exaggerate a few important features while he may ignore a few less important features [4].

Mimicry is a natural voice transformation technique which takes into account the ignored aspects of speech synthesis research. Studying the way a professional imitator imitates will help in building better voice conversion systems. For voice transformation/conversion, the cues underlying a particular voice quality need to be identified and represented. It is not sufficient to just represent them; but they need to be modified in such a way that modified speech signal sounds natural. It is more likely that more than one feature is modified during imitation and these features vary depending on the target speaker. It is also possible that two different imitators may choose different features for the same target speaker. In this paper, the components of speech that are modified by an imitator are addressed by signal processing techniques. In this study, the speech data from a professional imitator who performed mimicry of various celebrities has been used [5]. The first study addresses the importance of source and system parameters in voice imitation. The second study examines the features modified by an imitator, few experiments are carried out to synthetically transform the natural utterance spoken by an imitator to the corresponding imitated utterance by varying different features of speech. This is carried out using a flexible analysis-synthesis tool (FAST) [6]. This tool was used to transform a neutral utterance to an emotional utterance and vice versa. In FAST, two utterances spoken by the same speaker are matched using dynamic time warping (DTW) algorithm to get two warping paths. These warping paths are used for understanding the way different features of speech are modified. The features correspond to both source and system characteristics of speech production mechanism.

The terminology used in the paper is similar to the one used in [7]. The utterance spoken by the Indian celebrity (actor) will be referred to as target (T). The utterance spoken by the imitator, when he imitates the target (celebrity), will be referred to as imitation (I). The utterance spoken by the imitator in his original voice will be referred to as natural (N). The terms mimicry and imitation are used interchangeably in this paper.

The paper is organized as follows: Section 2 discusses the data and the features of speech that will be used for modification of natural utterance. In Section 3, the following experiments are conducted: (i) to understand the significance of source and system parameters in imitation and (ii) to convert a natural utterance to an imitated utterance. The results of subjective studies on the experiments are also discussed. Section 4 gives the summary and conclusion.

2. Data and Feature Extraction

Database for the current study consists of recordings by a professional mimicry artist in Telugu language [5]. Voices of five popular Indian celebrities (MB, NG, PO, PR and SP) were chosen as target. These voices were collected from interviews and

movies. For each target voice, ten utterances of short duration were chosen. Utterances of short duration do not contain many prominent prosodic features, and the imitator has to be very good to imitate such utterances. All the target utterances were imitated by the professional imitator five times. Recording of the utterances was done in his natural voice as well. There are three parallel utterances corresponding to target (T), imitation (I) and natural utterance (N) in the database.

The source filter theory of speech states that speech can be described as the output of sound source being modulated by a dynamically varying filter. The speech signal carries information about the dynamic vocal tract system and the excitation source. The vocal tract system and excitation source parameters represent inherent characteristics of the speech signal, while duration and intonation are examples of acquired characteristics over a period of time. The features that are extracted for this study are vocal tract features, excitation source features and prosodic features.

The linear prediction coefficients (LPCs) are used to represent the vocal tract information. They are obtained using LP analysis method. The basic idea is that a speech sample at time instant n, can be approximated as a linear combination of the past p, speech samples.

$$\tilde{s}[n] = \sum_{k=1}^{p} a_k s[n-k] \tag{1}$$

where s[n] are speech samples, $\{a_k\}$ are the predictor coefficients and $\tilde{s}[n]$ are the predicted samples.

An all-pole filter H(z) is used to represent the vocal tract parameters of the speech signal in the frequency domain.

$$H(z) = \frac{1}{1 - \sum_{k=1}^{p} a_k z^{-k}} \tag{2}$$

The error in prediction is given by

$$e[n] = s[n] - \tilde{s}[n] \tag{3}$$

The representation in frequency domain is given as

$$A(z) = 1 - \sum_{k=1}^{p} a_k z^{-k} \tag{4}$$

As A(z) is the reciprocal of H(z), LP residual is obtained by the inverse filtering of speech.

The LP residual obtained from LP analysis is used for the representation of excitation source information. The successive samples in the LP residual are less correlated compared to the samples in the speech signal.

Prosodic features are represented by the pitch contour and duration parameter. The pitch contour which is modified by the imitator is derived using zero frequency filtering (ZFF) method [8]. The method involves passing the differenced speech signal twice through a digital resonator having poles at zero frequency. The trend in the output is removed by local mean subtraction using a window length in the range of one to two pitch periods. The negative to positive zero-crossings in the zero frequency filtered output give the glottal closure instants or epochs. The reciprocal of the interval between two successive epochs gives the instantaneous fundamental frequency.

Duration parameter of natural and imitated utterances are mapped frame-wise using dynamic time warping (DTW) algorithm. DTW is an algorithm used for measuring optimal match between two utterances which may vary in time or speed. The utterances are represented by a sequence of vectors which correspond to the vocal tract features. The DTW algorithm is constrained as the labelling of data is done phoneme-wise.

3. Understanding the relative importance of components of speech in imitation

3.1. Significance of source and system parameters

During imitation, the imitator tries to position his articulators in some specific way in order to imitate a few target speakers. Though there are physiological constraints on the vocal tract, there is some flexibility in positioning tongue and some articulators. This brings the changes in his system (vocal tract) parameters. The imitator has to modify the way he excites his vocal folds to produce some of the voice characteristics. This brings the changes in the excitation source characteristics.

A study was performed to understand the importance of source and system parameters in performing voice imitation. A 10^{th} order short-term (20 ms frame size and 10 ms frame shift) LP analysis is performed to compute the residual signal and LP coefficients. The LP coefficients are converted to 20 dimensional linear prediction cepstral coefficients (LPCCs). The LPCCs and residual are extracted for 'T','I' and 'N'. The speech signals are time aligned using dynamic time warping (DTW) with LPCCs as feature vectors. For synthesis, the residual of the imitated utterance is passed through LP filter corresponding to the system parameters of the natural utterance. All combinations of residual and LP coefficients of 'T', 'I' and 'N' of all celebrities (MB, NG, PO, PR, SP) were used for synthesis to know the importance of source and system parameters.

Table 1: *Subjective evaluation results for all combinations of source and system parameters of 'T', 'I' and 'N'.*

Experiment	Source	System	MB	NG	PO	PR	SP
E1	I	T	1	1	1	1	1
E2	T	I	1	1	1	1	1
E3	N	T	1	0	0	0	1
E4	T	N	0	1	1	1	0
E5	N	I	1	0	0	0	0
E6	I	N	0	1	1	0	0

The synthesized files obtained after interchanging the corresponding source and system features for all cases mentioned above are assessed by subjective evaluation. The evaluation is carried out by twenty listeners in the age group of 21-30. Each subject was given six synthesized files and asked to give a score of '1' if it is target (T)/ imitation (I), '0' if it is natural (N). The results of the evaluation are presented in Table 1. The scores in the table are arrived by majority voting. All the synthesized speech files were presented in random order, and were not grouped in any particular order.

The rows E1 and E2 show that when source parameters belong to 'I' and the system parameters belong to 'T' or vice versa, the synthesized speech sounds similar to target for all celebrities.

For celebrity MB, when system parameters of 'T' or 'I' are used, the synthesized file sounds closer to 'T' as seen from rows E3 and E5. When system parameters of 'N' are used, the synthesized file sounds like an unknown speaker. The listeners reported that the characteristic pause of 'T' was missing hence the synthesized speech sounds like unknown speaker. So the system parameters seem to play a bigger role in this case.

In the case of celebrity 'NG', the voice quality is breathy. So whenever source parameters of 'T' or 'I' are used, even if the system parameters belong to 'N', there is breathiness in the synthesized speech which gives an impression that we are listening to 'T' or his imitation. This can be observed from rows E4 and E6.

The source parameters play an important role in the case of celebrity 'PO'. This is because there is an increase in loudness when the source features of 'T' are used. The listeners could make out the difference clearly between the experiments where source parameters of 'T' or 'I' were used. The effect of source features of 'I' is similar to 'T' in terms of intonation but the level of loudness is low. The use of source parameters of 'N' makes the synthesized file sound like 'N' or unknown speaker.

The results of celebrity 'PR' is similar to that of celebrity 'PO', except for row E6. This may be because the source parameters in imitation 'I' are not well imitated in case of celebrity 'PR'.

The imitations of celebrity 'SP' is similar to target for rows E1, E2 and E3. The synthesized files for rows E4, E5 and E6 sound like 'N' or unknown speaker. The expectation is when source or system parameters of 'T' or 'I' are used, the synthesized file should be similar to 'T' or 'I', but the files sounds like an unknown speaker. This may be because the imitations of celebrity 'SP' were not well imitated.

3.2. Perceptual significance of features

The aim of this study is to understand the features that are modified during imitation. The imitator's natural voice and imitation are compared and the differences in features are studied. The features from the imitated voice are incorporated into the natural utterance of the imitator so that imitated voice can be synthesized from natural voice. To modify the natural utterance in order to make it sounds similar to imitated utterance, a flexible analysis-synthesis tool (FAST) has been used. The main feature of FAST is that it can be used to match two utterances of same lexical content spoken by same speaker to determine the warping path (WP). After time alignment, modification of features is carried out as per the warping path. The modified features are then used to synthesize the imitated utterance. The synthesis is carried out using prosody modification program [9].

A 10^{th} order LP analysis is performed on a speech segment of 20 ms for every 10 ms. The 11 LP coefficients are converted to 20 dimensional LPCCs. Time alignment of the natural utterance with the imitated utterance is carried out using the DTW algorithm. The optimal warping path obtained by DTW represents the best mapping between the natural and imitated feature vectors. Two warping paths are obtained for each pair (natural and imitated) of utterances. Warping path 1 (WP1) corresponds to the one in which all frames of the imitated utterance are used. Usage of WP1 will automatically modify the duration. Warping path 2 (WP2) corresponds to the usage of all frames of natural utterance. Figures 1 and 2 show the warping paths WP1 and WP2. Pitch contour of the natural utterance is mapped with that of imitated utterance using the warping path 2 (WP2), as shown in Figure 3. Pitch and duration are modified using the prosody modification program [9]. In the case of LPC modification, the LPCs of each frame of natural utterance are replaced by the LPCs of imitated utterance. For LP residual modification, the residual between two epochs is replaced by an Liljencrants-Fant (LF) model estimate [10]. The set of experiments described in [11] were performed. The features modified and the warping paths used are mentioned in Table 2, '0' in the feature column

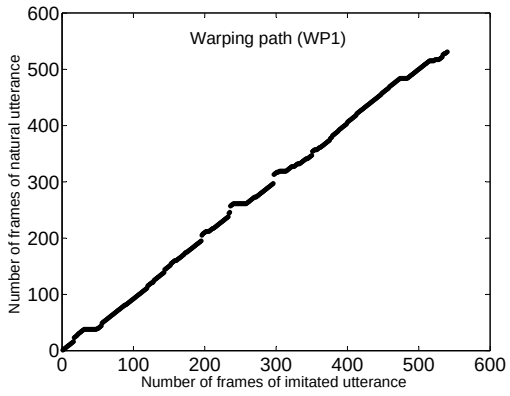

Figure 1: *Illustration of warping path (WP1) when imitated utterance is reference vector and natural utterance is test vector.*

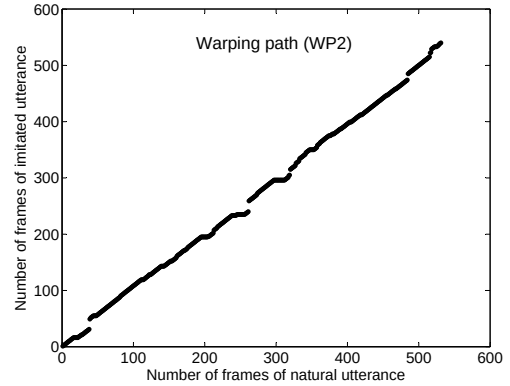

Figure 2: *Illustration of warping path (WP2) when natural utterance is reference vector and imitated utterance is test vector.*

indicates that the feature is not modified and '1' indicates that the corresponding feature is modified in this synthesis experiment.

Table 2: *Experiments and corresponding warping paths for modification of features of natural utterance.*

Experiment	Feature				Warping Path
	Residual	LPC	Duration	Pitch	
E1	0	0	0	1	WP2
E2	0	0	1	0	WP1
E3	0	1	0	0	WP2
E4	0	0	1	1	WP1
E5	0	1	1	0	WP1
E6	0	1	0	1	WP2
E7	0	1	1	1	WP1
E8	1	1	1	1	WP1

There are 10 imitated and 10 natural utterances for each of five celebrities in the database. For each utterance all the eight experiments listed in Table 2 are conducted. Ten listeners participated in the listening test to evaluate the synthesized speech

Table 3: Subjective evaluation results of synthesized imitated utterance.

Experiment	No. of features modified	Feature modified	MB-I	MB-T	NG-I	NG-T	PO-I	PO-T	PR-I	PR-T	SP-I	SP-T
E1	1	Pitch	2.89	1.71	3	2.71	2.85	1.71	3	2.28	2.67	2.28

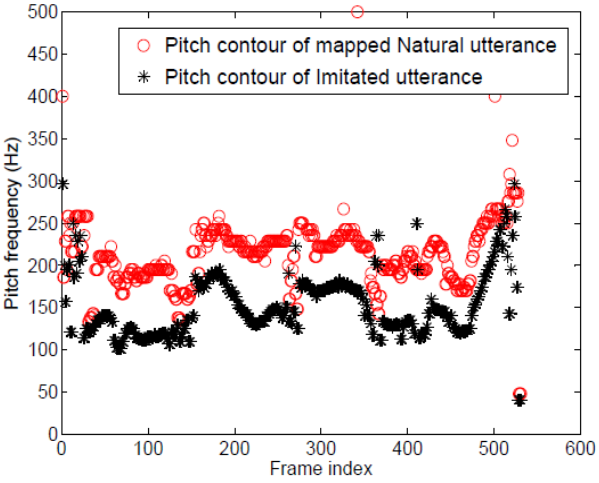

Figure 3: *Mapping of instantaneous pitch contour of natural utterance to that of imitated utterance.*

obtained after modification. The best imitated utterance of each celebrity is considered for subjective evaluation. Each subject is given a natural utterance, an imitated utterance, a target utterance and eight modified utterances which are synthesized by experiments 1 to 8 (presented in random order). The listener has to compare each synthesized utterance to imitated utterance and target utterance and give a score on a scale of 1-5 (1: highly dissimilar, 2: dissimilar, 3: somewhat similar and somewhat dissimilar, 4: similar, 5: highly similar). For example, if the synthesized utterance is compared to imitated utterance, a score of 5 indicates that synthesized file is very similar to imitated, while a score of 1 indicates synthesized file is very different from imitated. The results presented in Table 3 are the mean scores of all 10 listeners. The comparison of synthesized utterance to 'I' is performed and scores are presented in columns MB-I, NG-I, PO-I, PR-I, SP-I. Similarly the comparison between synthesized utterance to 'T' is performed and scores are presented in columns MB-T, NG-T, PO-T, PR-T, SP-T. It is expected that the scores for similarity of synthesized file to imitated utterance will be higher than the scores for similarity of synthesized file to target utterance.

The following observations are made from Table 3. The rows E1, E2 and E3 correspond to modification of one feature at a time namely pitch, duration and LPCs. The high scores in E1 indicates that pitch is a major suprasegmental feature that an imitator can modify easily and contributes more to the perception of imitation. The rows E2 and E3 show us that modification of duration and LPCs alone do not contribute as significantly as pitch modification. The rows E4, E5 and E6 correspond to modification of two features at a time. The rows E4 and E6 where pitch is modified along with duration and LPCs has better scores than E5 in which pitch is not modified. The row E4 gives lower scores for all targets except PR. This might be because duration modification is not aiding the feature pitch in perceiving imitation. The row E6 where pitch and LPCs are modified, shows significant high scores for 'NG','PO' and 'PR'. The combination of pitch, duration and LPCs seem to give significant improvement in the synthesized imitated utterance as can be seen from E7 especially for voices of 'PR' and 'SP'. E8 corresponding to the case where LP Residual is replaced by an LF model has higher scores. Though the residual is absent in this case, the perceptual scores are still high for celebrity 'MB' and 'SP'. In section 3.1, it was shown that system parameters play a big role in the imitation of celebrity 'MB', hence the absence of residual does not seem to affect the perceptual scores. The combination of pitch and LPC features give high scores for celebrities 'NG' and 'PO' but the combination of pitch, duration and LPC gives high score for celebrity 'PR'. The above results show us that the combination of features vary as per the target speaker.

4. Summary and Conclusion

In this paper, the various features of speech that contribute to the perception of imitation have been studied. The first study was to identify the contribution of source and system parameters. The subjective evaluation by listeners confirmed that source parameters were important for target speakers like 'NG' and 'PO' while system parameters were important for target 'MB'. The second study was modification of excitation source, vocal tract and prosodic features. The modification was performed using flexible analysis-synthesis tool. The synthesized files were evaluated for their closeness to imitation and target. The prosodic feature pitch contour seems to play a major role in contributing to the perception of imitation. Though duration and linear prediction coefficients individually do not contribute much to imitation but their combination along with pitch contour gives a good amount of similarity to imitation. The above observations are general ones but the combination of features also vary with the target speaker. The same combination of features need not give high perceptual scores for all target speakers. Further studies can be carried out by collecting mimicry speech from many professional artists to examine whether same features are modified by all of them for a given target speaker.

Abstract

This paper introduces and analyses a collaborative task for eliciting auditory-visual dialogs based on the viewing of two versions of the same cartoon film. The original film was edited and cut in such a way that the story must be reconstructed by joining information from two incomplete versions which however share between them all the scenes in a consecutive fashion. Our intention is to elicit a relatively balanced dialog between the two participants throughout the conversation as they are piecing together the story from the beginning to the end. The current paper describes the production of the auditory-visual corpus using audio, video and motion capturing of 22 pairs of Australian English speaking participants, and presents first results regarding turn-distribution and raw prosodic features. Our analysis shows that the task is indeed relatively balanced between talkers though this does not apply equally to all pairs. Analysis of raw prosodic features does not suggest convergence throughout the conversation, but replicates, for instance earlier findings of similarity between partners as compared to others.

Index Terms: auditory-visual prosody, dialog, turn-taking, F0, intensity, entrainment

1. Introduction

It is well established that seeing a talker (visual speech) influences auditory speech processing. Typically, research has focused on the perception of segmental information and has demonstrated that visual speech facilitates speech perception [1]. Indeed, the McGurk effect shows that information processing from the two senses is strongly connected and conflicting cues are resolved to form the most likely percept [1]. It has also been shown that the provision of visual speech can improve the perception of lexical tone in noise [3]. Moreover, recent research we have conducted suggests that visual speech influences the perception of speech prosody in interesting but possibly complex ways [4]. This work was based upon a corpus of spontaneous Auditory-Visual A/V monologs that was collected and annotated in terms of both acoustic as well as the visual properties. In addition, motion capture data was recorded and evaluated for non-verbal gestures.

In the analysis of this corpus, which involved the alignment of acoustic landmarks such as accents and boundaries with visible non-speech movements, a question arose as to which way the anchoring of movements should be achieved. In an initial approach only movements that occurred during accented syllables or syllables preceding a boundary were taken into account. However, this left a number of movements unanchored, where, for instance, these were located in syllables neighboring accented syllables. In order to determine how the alignment of acoustic and visual cues reinforce the perceived prominence of the same underlying syllable(s), and when separate events of prominence are perceived, a perceptual rating experiment was designed in which the distance between auditory and visual cues for prominence was systematically varied [5]. The results of this work were in good agreement with a separate production study that examined the timing of head and eyebrow movement with respect to the expression of corrective focus [6].

At this stage, however, it is unclear how the results of the above controlled experimental studies applies to spoken dialogus, since a limitation of corpus collected in [4] was that it only consisted of monologs that had been delivered to a (mute) listener. Plausibly, non-verbal gestures may play an important role in structuring dialogues, so we decided to collect a corpus of spontaneous dialogs in order to examine more closely how non-verbal gestures facilitate discourse and interact with prosodic cues (e.g., in negotiating turn exchanges).

In the current study we examine this corpus with respect to the balancedness of speaker contributions. As a first application of the data we explore the effect of entrainment, the phenomenon that talkers engaged in a dialog adjust their speech to one another, e.g., such as synchronizing (turn-by-turn coordination between interlocutors), or where speech properties become more alike, that is, the talkers attain convergence [7].

The remainder of this paper is structured as follows: In Section 2 we introduce the cartoon task and the collected corpus. Section 3 presents statistical results based on the structures of the resulting dialogs. Section 4 discusses analyses and preliminary results regarding the prosodic entrainment between the participants in the dialog, as reflected by their *F0* and intensity contours, as well as their voice quality. Section 5 offers discussion and conclusions.

2. Experiment Design and Corpus

A large number of different paradigms exist for eliciting spontaneous dialog data. These paradigms range from completely unrestricted designs, in which at most only a general topic is given, to guided exchanges based on structured task solving. Some of the authors of this paper have applied the well-known Map Task [8] in their prosodic studies [9]. Although this task has been thoroughly studied and documented, its nature produces relatively unbalanced dialogs, as the Giver usually supplies most of the information for guiding the Follower to the desired location and the Follower's reactions often consist of one-word acknowledgments such as "yeah", "alright". In contrast, the Video Task developed by Benno Peters [10] involves the interlocutors in a discussion about specially edited diverging versions of an episode of a soap opera. The resulting dialogs are relatively natural and balanced regarding the contributions of the two talkers.

This task, however, requires that interlocutors are familiar with the particular series and also know each other well. The idea of discussing conflicting video presentations is appealing; however we wanted the task to be more focused and generalizable, i.e., not requiring any previous knowledge of

the material or familiarity with the topic. Furthermore, since we ultimately plan to apply the same paradigm in different language and cultural environments, we selected an animated cartoon film of approximately eight minutes that had no dialog.

2.1 *Participants*. Twenty-two pairs of participants (five of them male, 14 female and three mixed) were tested. Participants were recruited from the University of Western Sydney, aged between 17 and 53 and native speakers of Australian English. Participants were either students or university graduates and knew each other previously. Most of the students participated for course credit, the remainder were paid.

2.2 *Materials*. Two (approximately) five minute versions of the film were created in which the first and last scenes were common, but subsequent shots were present only in one or the other. In this way, the complete story was only recoverable when information from both versions was combined.

2.3 *Procedure*. We informed participants that the experiment was about maintaining concentration and collaborating on a cognitive task. Participants were tested in pairs and were told that each person would view a different version of a short silent movie and that the versions were cut in such a way that they were going to see some scenes that their partner would not and vice versa. The cuts in the movie were made so that when a scene was missing the picture would cross-fade into the next scene and the missing scenes also recognizable by interruptions to the background music. We asked participants to memorize the sequence of events and the details of the scenes; they were told that subsequently they would be requested to interact with their partner in reconstructing the story. Specifically, participants were instructed that the story should be recovered cooperatively in chronological order and that they should avoid disclosing all the information they possessed at once, but rather piece together the sequence of scenes as the story develops.

For each participant of a dialog pair, 23 infra-red faces markers were applied in a standard configuration and three markers affixed to a head-worn rig (to track rigid head motion). Participants sat in a sound-treated room facing each other at a distance of about 1.5 m. Each was equipped with a DPA 4066-B head-worn microphone. In order for the facial markers not to be obscured the participants were asked not to raise their hands to their faces if possible.

After calibrating and adjusting the Vicon motion capture system (Lake Forest, CA) which consisted of 8 cameras (4 MX40; 4 MXF40), participants were provided with laptops and head phones for viewing the videos. After participants had finished viewing the video, we started two Sony HDR-PJ200E HD video cameras manually (MPEG4-AVC/H.264 - 1920 x 1080/50i) to have a visual record of each participant (see Figure 1). Following this, the motion capture system was started, capturing audio at 45kHz/16bit and marker motion at a frame rate of 100Hz and the participants were given a signal to begin. During the dialog no instruction were given to the participants. The recording was halted when the participants had decided that they had recovered the story as well as possible.

3. Analysis of Temporal Characteristics

The resulting two videos of each conversation were synchronized with the high quality audio from the motion capture system and joined in a single video that displayed both talkers along-side each other (see Figure 1). Then we performed text level transcription of inter-pausal units on the audio and also annotated non-verbal gestures such as audible breathing, smacks and laughter using the *Praat TextGrid* editor [11]. Based on these transcriptions we performed an analysis of talkers' contributions to the dialog in order to investigate whether the task was balanced.

Figure 1: *Combined videos of talkers A and B of Pair01.*

Table 1 provides information on the resulting 22 dialogs, including the total durations, each participant's percentage of contributions, as well as the percentage of overlaps and silent pauses. Figure 2 displays sample graphic representations of turns along the time axis for a duration of four minutes. In each panel the black areas indicate activity of talker A and the grey areas indicate activity of talker B. As can be seen, Pairs 11 and 17 are balanced with regard to overall contributions by talkers A and B. However, the pairs differ greatly with respect to the distribution of turns. In Pair 11, both talkers produce longer stretches of speech and have fewer turn exchanges, in contrast to the talkers in Pair 17. This indicates that talkers apply different strategies for reconstructing the film. In Pair 11 talker A begins the dialog and talks about several scenes of his version, and only after that talker B presents his observations. The entire dialog continues in this way. Talkers in Pair 17 reconstruct the film more collaboratively by providing shorter pieces of information consecutively and ask each other for missing facts. They interrupt one another more frequently in order to take turns. This is the reason why Pair 11 exhibits only 7% of overlaps, but Pair 17 15%, as can be seen in Table 1. These two examples are representative for most others of the 22 dialogues. Both strategies to reconstruct the film appear to be successful technically, but Pair 17 obviously shared a more vivid exchange and followed our instructions better than Pair 11, hence providing more instances of turn exchanges that we wish to study. We checked whether the version of the video influenced the percentage of talkers' contributions. On average talker A speaks for 48%, and talker B for 41% of the total dialog time. Paired-samples T-test suggests that this tendency is small, but significant ($T=2.239$, $df=21$, $p < 0.036$).

4. Acoustic Analysis

For the subsequent analysis of prosodic features we selected ten pairs (nos. 1, 2, 3, 7, 11, 12, 17, 18, 20, and 22) where the contribution of the two talkers was relatively balanced and where the minimum discourse duration was at least four minutes.

Due to the close proximity between the two talkers during the recording there was audible cross-talk in each of the audio channels, the channel separation being approximately 15-20 dB. By applying audio source separation [12] we yielded a gain of 6-8dB without audible deterioration of the speech signal.

Table 1: *Overview of the 22 dialogs with total durations, percentage talking time of talkers A and B, percentage common pauses and overlap between A and B.*

#	total dur. [s]	% A	% B	% common pause	% overlap	#	total dur. [s]	% A	% B	% common pause	% overlap

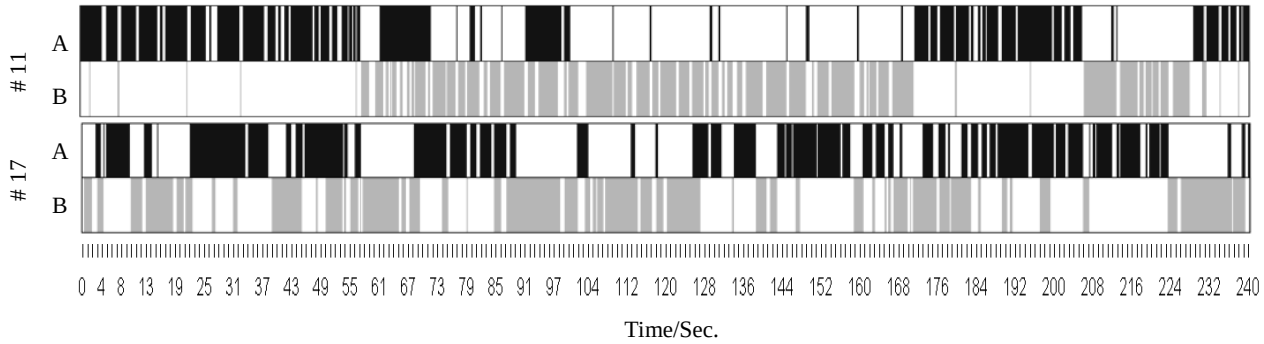

Figure 2: *Graphic representations of turns for two selected conversations displayed for chunks of four minutes. In each panel the black areas indicate activity of talker A and the grey areas indicate activity of talker B.*

We then extracted *F0* contours at a step of 10ms employing the *Praat* standard algorithm [11] with different *F0* floors and ceilings for male (50-300Hz) and female participants (130-400Hz). Along with the *F0* values the *Praat PitchObject* contains information on frame intensity as well as periodicity, a measure comparable to the harmonics-to-noise ratio. For each of the features *F0*, intensity and periodicity we calculated z-scores with respect to the male and female mean and standard deviations, respectively.

In principle our analysis follows the approach presented in [7]: in order to examine the prosodic entrainment between the two talkers in each conversation we calculated means, standard deviation as well as minimum and maximum values of the resulting feature z-scores for chunks of constant length in the conversations (since we do not yet dispose of a detailed transcription of inter-pausal units as well as annotation of turn exchanges).

We then performed two types of analysis: (1) Correlation analysis between the sequences of chunk-wise features for the entire conversation; (2) Statistical analysis of absolute differences between chunk-wise features depending on the talker, the pair, the distance between chunks, as well as the start time of the chunk with respect to the conversation.

After experimenting with several chunk sizes we employed durations of 20s for our subsequent tests. In order to ensure that chunk parameter sets contained averaged values from a sufficient number of speech frames, we required a chunk to contain at least 6s of speech by the talker examined, a speech frame being defined by the intensity reaching a fixed threshold.

On the conversation level, as a test for proximity, we calculated the correlations between sequences of chunk parameters by partners as well as non-partners. Since conversations varied in length, the number N of chunks employed for each analysis varied as well. Results are displayed in Table 2.

Table 2: *Conversation-wise inter-partner correlations (Pearson's r) of mean intensity and mean F0 for selected pairs.*

pair	N	r(mean int.)	p	r(mean F0)	P
01	24	.70	.001	.37	.072
02	10	.72	.020	-.12	n.s.
03	14	.91	.001	.53	.053
07	8	.11	n.s.	.86	.007
11	4	-.97	.035	.93	.067
12	10	-.10	n.s.	.36	n.s.
17	18	.31	n.s.	.39	n.s.
18	15	.39	n.s.	-.02	n.s.
20	8	.34	n.s.	.47	n.s.
22	12	.18	n.s.	.79	.003

Of all features only mean intensity and mean *F0* yielded inter-partner correlations that were significant or approached significance for some of the pairs. Results for pair 11 may be unreliable due to the small number of chunks in which both partners have a sufficiently high number of speech frames.

In our analysis of chunk-wise parameter differences we first calculated means and standard deviations of feature differences between chunks of the same talker (*self*) as compared to those by others (*other*, see Table 3). As expected, talkers were much more similar to themselves than to others.

We then performed intra-talker correlation analysis of chunk-wise feature differences as a function of the distance between the chunks compared. Only mean intensity (Pearson's r =.11, p <.001), intensity s.d. (r = 0.10, p < 0.005) and mean periodicity (r = 0.09, p < 0.02) indicated a weak tendency of the talker to be more dissimilar to him/herself between chunks in discourses that were spaced further apart.

Table 3: *Feature difference means and standard deviations self vs. other.*

	F0 mean	F0 sd	F0 max	int. mean	int. sd	int. max	per. mean	per. sd	per. max
self mean	.24	.22	1.67	.24	.22	1.04	.17	.09	.01
self s.d.	.24	.18	1.25	.22	.21	.92	.14	.08	.08
other mean	.55	.28	2.08	.35	.31	1.50	.29	.16	.18
other s.d.	.42	.22	1.46	.29	.27	1.07	.23	.14	.17

Turning to the relationship between talkers who were engaged in the same conversation (*partner*) as opposed to those in others (*other*), we conducted T-Tests on chunk differences. The results shown in Table 4 indicate that for most features the differences between talkers in the same conversation (*partner*) were smaller compared with talkers from a different conversation. For mean *F0* the difference between *partner* and *other* was significant as well, though the feature differences proper were larger between partners of the same pair.

An intra-pair correlation analysis of chunk-wise inter-talker differences was performed to see whether chunks spaced further apart were more dissimilar. However, we only found a rather weak dependency of mean *F0* on the distance between chunks (Pearson's r = 0.13, p < 0.002).

If we compare intra-pair chunk-wise parameter differences as a function of the onset times of the chunks by only including pairs of chunks occurring at the same time or neighboring one another, mean *F0* (r = 0.28, p < 0.001), intensity max (r = -0.20, p < 0.004) and periodicity s.d. (r = -0.22, p < 0.002) were weakly correlated with the onset times of the chunks in the conversation.

Table 4: *T-tests partner vs. other differences*

Feature	t	df	p-value	Sig.
intensity max	-2.8	7273	<0.001	*
intensity mean	-3.1	7273	0.002	
intensity s.d.	-3.2	7273	0.001	*
F0 max	-5.3	7273	<0.001	*
F0 mean	10.5	7273	<0.001	*
F0 s.d.	-2.7	7273	<0.001	*
periodicity max	-20.4	7273	0.005	
periodicity mean	-0.2	7273	N.S.	
periodicity s.d.	-2.5	7273	0.012	*

As a test of whether or not talkers in the same pair converged during the conversation we examined chunk differences calculated for chunks located in minutes 1 and 2 of the discourse with those in minutes 3 and 4, as only a few of the conversations were considerably longer than four minutes. Mann-Whitney independent sample U-Test suggests differences for intensity mean (p < 0.039) and intensity max (p < 0.017), however, the tendency was for talkers to become more dissimilar with respect to these features later in the discourse.

5. Discussion and Conclusions

This paper presented the first results from an auditory-visual corpus of spontaneous dialogs based on a collaborative task centered on the reconstruction of a cartoon film. Based on transcriptions of inter-pausal units and the inspection of graphical representations of discourse structures we found that conversations overall are relatively balanced between talkers, although pairs differed with respect to the total duration of the discourse as well as turn durations and the amount of overlap.

For a subgroup of relatively well-balanced pairs we examined the prosodic features *F0*, intensity and periodicity with respect to entrainment, the adaptation that can occur between talkers engaged in a conversation. We calculated chunk-wise means, standard deviations as well as min and max values of feature z-scores and examined the relationships between these features for chunks of 20s length. With respect to the whole discourse intensity means exhibited the highest correlations between partners, followed by *F0* max, however this was the case only in some of the pairs. This might reflect individual differences in discourse strategy between pairs. For example, in some dialogues, one partner took the lead and presented most of the information s/he had before granting a turn exchange. In these cases adjustment by the partner may be more difficult than in pairs where the information was delivered in balanced turns.

We investigated chunk-wise feature differences between talkers and themselves, their partners and talkers with whom they had not conversed. With respect to a number of features, especially intensity and *F0*, talkers were more similar to their partners than to other talkers. The similarity seemed to decrease with the distance between chunks in time, though the dependency was relatively weak. We did not find evidence of talkers converging during a conversation though this might simply be due to the short durations of most dialogs. It rather seemed that talkers diverged with respect to intensity, for instance. We believe that it will be necessary to perform a detailed annotation of turns and turn exchanges to better pin-point possible places of stronger coordination. We also require word, syllable and phone-based segmentations in order to test for the entrainment of duration information. In addition, future work will involve annotations of non-verbal facial or head movements followed by the analysis and modeling of the motion capture data.

6. Acknowledgements

We would like to thank Simone Simonetti at MARCS Institute for organizing participants and checking transcriptions and Yuanfu Liao of NTUT Taiwan for applying channel separation to the audio recordings. This work was supported by Deutsche Forschungsgemeinschaft international research grant Mi625/24 funding a stay by Mixdorff and Hönemann at MARCS Institute.

Abstract

Broadcast news is a distinctive register. Previous studies only provided some general descriptions of the prosodic features in broadcast news but with few concrete data. Most of them were also on English news. This study investigated the prosodic features of Cantonese TV broadcast news using acoustic data. Speech using the same materials from two groups was compared: eight Hong Kong professional TV news anchors, and a control group consisting of eight university students. The results show clear differences between the two groups in terms of speech rate, pitch range and variability of syllable duration (speech rhythm). It was found that the news anchors spoke significantly faster than the control group, also with an enlarged pitch range. They also produced more variability in syllable duration. There is clearly more prosodic variation in the news register than ordinary speech. Finally, we provide some possible reasons for these features, as well as directions for future studies.

Index Terms: news, broadcast, prosody, Cantonese

1. Introduction

This study investigates the prosody of Cantonese news broadcast in television read by professional news announcers and compares it to that read by non-professional speakers. Broadcast news has a distinctive style/register in different languages, but not many studies have examined its specific prosodic features. Most previous studies were on English news, while so far no study has examined the prosody of Cantonese broadcast news. This preliminary aims to fill this research gap.

The broadcast news register is easily recognizable even by lay people. Before the 1970s, news readers spoke in a very formal and solemn way, delivering news with much authority. Women were excluded from news broadcast due to their voices being too high-pitched or lack in authority [1]. After the 1970s, with technological advancements in voice capturing techniques and various social changes (e.g., the introduction of television in common households), the style of broadcast news has changed dramatically. Summarizing some previous descriptions on vocal characteristics of newsreaders, [2] suggested that an effective newsreading voice is characterized by a rich, warm, and resonant tone. News readers need to deliver the news clearly and succinctly, and with enthusiasm to capture the audience's attention, while at the same time sounding professionally distant and knowledgeable.

Cotter [3] proposed three factors which affect news prosody: text structure (condensed text written to convey newsworthiness and capture attention); an unseen audience and medium constraints (using voice only to signal various boundaries and emphasis). These factors contribute to the unique prosody of broadcast news register, which, according to [4], is between reading and spontaneous speech, having all the features of reading and some features of spontaneous speech.

Despite the easy identification of the news register, and the literature on general perception and opinions of good practice in newsreading (see summary in [2, 5]), surprisingly few studies have examined the prosodic features of broadcast news in detail. Bolinger [6] noticed that some American radio newscasters intentionally distorted expected sentence stress and put accentual emphasis on words whether semantically justified or not in order to attract attention. Cotter [3] compared news read by radio announcers and that by volunteers, and found that news prosody makes use of speech rate, pauses, pitch movement and other paralinguistic features in an identifiable way, incorporating features of spontaneous and public discourse. [2] compared professional newsreaders with student newsreaders and controls, and found that female newsreaders had a higher pitch than both students and controls; professionals also had greater pitch variability, spoke faster and made fewer errors than both students and controls. The professional newsreaders were also rated significantly higher by the judges on phrasing and overall performance. Moreover, more students reported consciously altering their voices and using more effort in newsreading than the professionals did.

The above studies are all based on broadcast news in English. Zou [7, 8] examined the prosody of broadcast news in Mandarin Chinese. He found that the mean syllable duration is longer in news announcements than in conversation spoken by the same presenters, i.e., the presenters spoke more slowly and clearly in news announcements, compared with their own conversation. Moreover, there is a wider pitch range variation in news announcements than in conversation. His data show that a distinct news register is also present in Chinese. However, it is unclear if these prosodic features in Mandarin news are also applicable to broadcast news in Cantonese, as broadcasters in China are specially trained for the profession with very strict standards on their speech characteristics, while it is not the case in Hong Kong. Also, news prosody can vary between languages [1, 9] and also between different ages of the same language [9, 10]. Therefore, more studies on the prosody of broadcast news in different languages are needed to thoroughly investigate the various prosodic features of this distinct speech style.

2. Method

The present study compares the news announced by professional journalists (anchors) in television news broadcast with those read by non-professional speakers (controls). The controls read exactly the same materials as the anchors for direct comparison.

2.1. Speakers and materials

Eight news anchors (four male, four female) from a mainstream local television broadcasting company in Hong Kong (TVB) were chosen. It is unknown if the company has any special voice/speech training for their news anchors, but the company is known for its insistence on a high standard of pronunciation, e.g., their anchors preserve some contrasts that

are already lost or used interchangeably by most Hong Kong people. Approximately one-minute of news announced by each anchor based on four different stories each was chosen from the 'News at Six-Thirty' programme aired between 23 March and 23 July 2013, videos of which could be found in YouTube. Criteria for choosing the anchors include their popularity and the availability of videos in YouTube. Table 1 summarizes the information about the speech samples of the eight anchors.

Table 1. *Summary of news materials by the anchors.*

Female				Male			
Anchors	# σ	# IP	# S	Anchors	# σ	# IP	# S
Cheng	246	20	5	Fong	278	16	5
Chow	246	19	5	Lau	262	22	6
Lau	266	15	6	Ng	279	19	5
Law	277	22	5	Pun	303	24	5

σ = syllables; IP = intonational phrases; S = sentences

The control group consists of eight local university students, also four male and four female, all native speakers of Hong Kong Cantonese. They were aged between 18 to 27, and none of them reported any speech or hearing impairment. Two speakers received course credits and another speaker was paid for their participation. The other five speakers participated on a voluntary basis.

2.2. Procedure

A pilot trial with one speaker (not in the control group) indicated that it would be very difficult and very slow for the control speakers to read the news materials fluently on the spot. In order to solve this problem, the control speakers were given the news materials a couple of days in advance and were asked to practise them well before the actual recording. Therefore, the control speakers knew the purpose of the experiment. This is unavoidable given the logistic constraints. This also means that the control speakers were performing at their best as 'mock anchors', based on their own perception of the news register.

The recording took place in a quiet room at the Chinese University of Hong Kong. A solid state recorder was placed approximately 20 cm away from the speakers. The speech materials were recorded with a sampling rate of 44100 Hz and 16 bits. The control speakers were asked to read aloud the stimulus sentences displayed on a computer screen one by one in a random order. If they made a mistake, they were prompted to re-read the sentence again immediately, so the recorded materials contain no speech errors or disfluencies. Two repetitions of the materials were collected.

In order to control for the gender difference, the control speakers only read the news materials produced by the anchors of the same sex.

2.3. Data analysis

As the sentences written for the news scripts were very condensed and very long, the sentences were divided into intonational phrases for analysis (see Table 1). Three types of data were examined to compare the prosodic features between anchors and controls: speech rate, pitch range and speech rhythm. Speech rate was calculated based on the average number of syllables per second. Since there is much individual variation between speakers' habitual pitch levels, pitch range is a better indicator of any stylistic pitch variation in news prosody than mean pitch is. We used two methods to estimate the pitch range. As Cantonese is a tone language, a good estimation of the pitch range can be obtained by comparing the F0 values at the midpoint of all Tone 1 syllables (a high level tone [55]) with those of Tone 4 (a low falling tone [21]), which respectively represent the highest and lowest pitch levels in a speaker's voice. The pitch level at the end of Tone 4 falls so low that it often results in creakiness. Measuring F0 values at the midpoint can ensure more valid data. In addition to the pitch differences between T1 and T4, we also calculated the pitch ratios between T1 and T4 as a normalized measure for all speakers.

We used the acoustic metrics on syllable duration, VarcoS and nPVIS, to compare speech rhythm. VarcoS shows the standard deviation of syllable duration in an utterance normalized for speech rate [11], while nPVIS shows the normalized pairwise variability of syllable duration [12]. VarcoS measures durational variability globally, while nPVIS measures variability locally between each pair of unit. Mok [13, 14] have shown that these metrics on syllable duration can be more robust than metrics on consonantal and vocalic durations in reflecting rhythmic differences. Moreover, the syllable structure of Cantonese is very simple. Segmenting the speech streams into syllables is quite easy and straight forward. It is noted that the rhythmic metrics have been under much criticism in recent years [15], but it is justified in our case because we compared exactly the same speech materials between anchors and controls. Cantonese is a typical syllable-timed language [13, 14, 16]. It will be interesting to see if more durational variability would be employed by the news anchors to enhance liveliness and to capture audience's attention.

3. Results

3.1. Speech rate

Table 2 shows the average speech rate of the eight anchors and the control speakers. It is obvious that the anchors spoke faster than the controls [$t(14) = 7.484$, $p < 0.0001$]. It is worth noting that the controls were already performing at their best as 'mock anchors', and no disfluency was included in their recordings. Nevertheless, they still spoke significantly slower than the anchors.

Table 2. *Average speech rate (# syllable / second).*

Source	Anchors	Controls*
Cheng	6.10	4.66
Chow	5.75	4.76
Lau	5.68	4.53
Law	5.19	4.53
Fong	5.51	4.97
Lau	5.62	4.84
Ng	6.19	4.90
Pun	5.75	4.93

* The control data are averaged across the reading of the same anchor's materials by four control speakers of the same sex.

3.2. Pitch range

Figure 1 shows the pitch differences in Hz of the anchors and those averaged across the four control speakers reading the materials by the same anchor. Each bar represents one

anchor's materials. Female and male data are shown separately. It can be seen that female anchors have a significantly larger pitch difference than female controls do [$t(6) = 7.147$, $p < 0.001$]. The pitch range is also generally larger for male anchors than male controls, although the difference is not significant [$t(6) = 1.669$, $p = 0.146$]. The larger pitch range indicates that the (female) professional anchors used more pitch variation in their news reading. It is interesting to note that there is also more individual variation in pitch range among the anchors than among the controls.

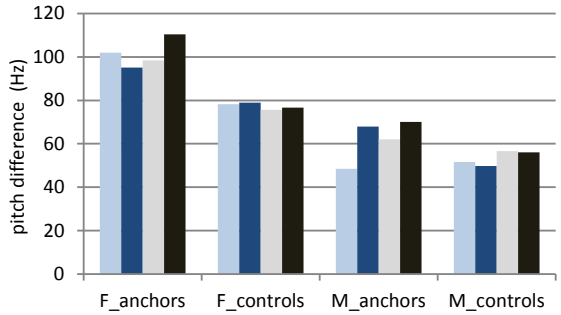

Figure 1: *Pitch difference of anchors and controls.*

In addition to the differences in Hz, we have also calculated the ratios of T1/T4 as a normalized measure of pitch range for both anchors and controls to verify the patterns observed above. Figure 2 shows the pitch ratios of both groups of speakers. Again, anchors have a larger pitch range than controls do, and the difference is significant for the female speakers [$t(6) = 5.344$, $p=0.002$], and is tending towards significance for male speakers [$t(6) = 2.075$, $p = 0.083$].

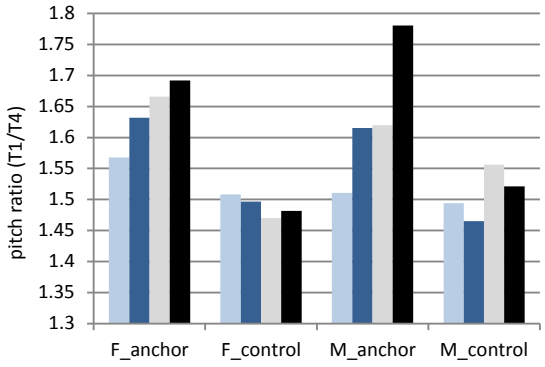

Figure 2: *Pitch ratio of anchors and controls.*

3.3. Rhythmic metrics

Table 3 shows the values of VarcoS and nPVIS for the anchors and those averaged across the four control speakers reading the materials by the same anchors. Anchors have significantly higher variability of syllable duration than controls do for both rhythmic metrics: VarcoS [$t(14) = 5.90$, $p < 0.0001$] and nPVIS [$t(14) = 4.503$, $p = 0.001$]. Moreover, if we examine the values more closely, those produced by the anchors are always higher than those averaged among the controls, even though they read exactly the same news materials. It is also true if we compare the anchor's data with each individual control speaker.

Table 3. *Rhythmic metrics on syllable duration.*

Source	Anchors		Controls	
	VarcoS	nPVIS	VarcoS	nPVIS
Cheng	28.59	30.17	23.31	25.05
Chow	25.20	28.44	22.89	25.77
Lau	28.11	27.95	24.22	25.84
Law	29.24	32.05	24.97	27.90
Fong	30.62	33.61	23.73	26.31
Lau	27.62	31.42	25.72	30.02
Ng	29.68	30.83	25.39	28.10
Pun	28.42	31.01	25.18	28.06

4. Discussion

The study has found clear differences in the prosodic features between news read by professional anchors and by control speakers. Some differences can be expected, e.g., speech rate, while others are rather interesting, e.g., speech rhythm.

The best versions produced by the control speakers are still significantly slower than those produced by the anchors. In order to speak clearly as 'mock anchors', the controls produced the materials carefully and thus had slowed down the speech rate, as what most people would do. However, the anchors could speak clearly and quickly, as they need to deliver as much information as possible in a short period of time. The demands on time necessitate a faster speech rate. So in addition to the three factors (text structure, unseen audience and medium constraints) proposed by Cotter [3] which influences news prosody, time pressure is another important factor contributing to the unique prosody of broadcast news.

In addition to saying things more slowly, listening to the recordings tells us that another reason why the controls were slower is that they made more pauses and/or paused longer than the anchors.

Furthermore, given that news anchors can speak clearly and quickly, it will be interesting to examine their speech articulatorily to see if there are differences between their articulation in news reading and that of control, and also between the news speech and the 'normal' speech by the same anchors. Do anchors simply move their articulators faster or do they have different articulatory strategies in news reading? For example, would there be more gestural overlaps in their news reading? A faster speech rate usually results in more gestural overlaps [17], but the demand for clarity would result in less overlaps [18]. Would the anchors increase the magnitude of their gestures in order to accommodate these contradicting demands? Interesting patterns are likely to be found.

Professional news readers need to capture and sustain the attention of the audience, and to highlight different important information in the scripts that are already very condensed. A useful strategy is to increase variability in speech. Our data show that the anchors did so in both pitch and duration.

The pitch ranges produced by the female anchors were significantly larger than those by the female controls. Thus, the 'tone space' is larger for the anchors, and their lexical tones would be more distinct than those by the controls. In addition to having more distinct tones, more fluctuating intonation patterns would also result in a larger pitch range. It is quite likely that both aspects have jointly contributed to their larger pitch range. Further studies should devise ways to evaluate the contribution of lexical tone and intonation

separately.

It is interesting to notice that although the male anchors had a similar pattern of generally having a larger pitch range than the male controls did, the difference is not significant. The pitch range for male speakers is naturally smaller than that of female speakers, so the increase in pitch variability would probably be proportionally smaller as well, although Figure 2 shows one male anchor having a higher ratio than the female anchors. Probably, the more subtle increase is harder to show up statistically.

A further reason for the insignificant result is that one male control speaker had a pitch range larger than other male speakers, including three male anchors. The authors were familiar with this control speaker. When listening to his recordings, it is obvious that he had prepared the materials well and spoke with more pitch variation in the news reading than in his ordinary speech. He performed well as 'mock anchors'. This shows us that even lay speakers have a hunch of the pitch patterns and variation in the news register, which are confirmed statistically by our female data.

Last, but certainly not the least, our results indicate that the anchors had also increased the variability of syllable duration in their news reading. This finding is particularly interesting given that Cantonese is a very typical syllable-timed language, even more so than French and Italian [19]. One may expect that variability of syllable duration would be the least likely aspect to be manipulated. Our significant findings confirm that even such unlikely aspect is used in news prosody. All the anchors consistently had higher variability than the controls as a group had, and also consistently higher variability than each individual control speaker.

When we listened to the recordings, it is obvious that the anchors were skillful in compressing some common or familiar phrases, while speaking more clearly and slowly for other important information. For example, the title and the name of the President of China, Xi Jinping (國家主席習近平) produced by one female anchor had the following characteristics: she had parsed the whole phrase into two parts (the title with four syllables and the name with three syllables). The duration for the first part with four syllables is 531ms, while it is 552ms for the second part with only three syllables. In addition to such strategic compression and extension, since the speech rate is so fast, the anchors may be actively using syllable duration for phrasing and creating boundaries. Also, they may produce strong focus when important terms come up, resulting in longer syllable durations in certain phrases. All this explains very well why the rhythmic metrics for syllable duration are significantly higher for all anchors than for the controls. Much skill and experience in information selection is needed in order to manipulate this prosodic feature well. Further studies on Cantonese news prosody should especially examine this interesting feature.

Our study is a preliminary study on the news prosody in Hong Kong Cantonese. It provides concrete acoustic data as evidence, supplementing the many general descriptions of features of news prosody in the literature. Nevertheless, one shortcoming is that the data, although well controlled for comparison, is quite limited. Further studies using a larger data set are needed to corroborate the findings in this study.

5. Conclusions

A distinct register of broadcast news is found in Cantonese. Professional news readers speak significantly faster than control speakers do. They also have more stylistic variations in both pitch and syllable duration. It will be interesting to compare the news register in different languages in the future to confirm which prosodic features are common for news reading in general, and which features are language-specific devices to cater for this special speech style.

Abstract

The aim of this paper is to present an algorithm that automatically segment a text in prosodic chunks for a dictation by conforming to the rules and procedures used in real settings to dictate a text to primary school children. A better understanding and modeling of these rules and procedures is crucial to develop robust automatic tools that could be used in autonomy by children to improve their spelling skills through dictation with the use of speech synthesis. The different steps used to derive the prosodic chunks from a given text will be explained through concrete examples. The proposal made here relies on the analysis of a corpus of 10 dictations given to children in French and French Canadian elementary schools, and more precisely during their first three years in elementary school (i.e. cycle 2 in the French school system). The phrasing observed in the data is described. It is thus simplified in order to develop an algorithm that automatically generates prosodic chunks from texts.
Index Terms: speech synthesis, prosodic phrasing, automatic parsing.

1. Introduction

The use of software and automatic tools in language teaching offers several advantages among which we may mention the ability to adapt to the learner needs and to provide an environement for him to work in autonomy. Despite these advantages, there are nowadays in France few softwares which are currently used in primary schools to teach reading and writing skills with the use of speech synthesis (e.g. Lectramini[1] and PLATON[2]).

One of the goal of the collaborative ANR research project Phorevox (`http://www.phorevox.fr/`) is to develop this kind of tools, with special emphasis given to the acquisition of writing skills. The software will automatically propose some practice exercises which allows children improving their written skills. Thus, dictations may be given to the children to work on specific grammatical or orthographical aspects.

In order to use automatic procedures and speech synthesis systems for dictation, it is necessary to (i) provide a very intelligible synthesized speech to allow children to hear all the words and sounds to be written, (ii) divide the texts to dictate into chunks that allow accessing all relevant grammatical information, while being of a reasonable size, and (iii) provide a user-friendly typing environment that takes into account the typing speed of the different children. Among these issues, we will focus in this paper on the ability to automatically divide a text to dictate into chunks. To develop an automatic chunking procedure for dictation, we have first analyzed a set of dictations made in primary school. The results of the data observation were used to select and formalize the rules used by the algorithm which generates the dictation.

The paper is organized as follows. In section 2, the rules that are used to derive the prosodic chunks in standard French are briefly presented, and the main characteristics of prosodic phrasing in French are described. The segmentation procedure used by our speech synthesis system are then explained. In section 3, the data and methodology chosen to study the phrasing patterns of dictations in French are presented. The phrasing rules extracted from the observation of the data are listed in section 4. Section 5 explains which pieces of information are taken into account to develop the algorithm that automatically provides a chunking to any text.

2. Background

Studies on French prosody have traditionally pointed out that accentuation, phrasing and intonation are closely intertwined (see, among others, [3], [4] and [5]). In French, the lack of lexical stress causes a syncretism between intonation and accentuation.

In the studies on prosodic phrasing, two or three distinct levels of phrasing above the word are argued for. The lower level, i.e the minor phrase (MiP) – which is also called accentual phrase (see [6] and [7], among others), phonological phrase (see [4] among others) or rhythmic group (see [8] among others) – plays a crucial role. This unit is characterized by the realization of a phrasal stress on its last metrical syllable, which indicates its right edge. In the literature, there is a broad consensus about the definition of this unit: it corresponds minimally to a lexical word and to all the function words that this word governs (see, among others, [4], [6], [7] and [8]). The sentences in (1) are segmented in Minor Phrases as shown in (2).

(1) a. *Les enfants sont venus dans l'après-midi.*
The children came in the afternoon.

b. *Bernard est rentré de son voyage en Asie.*
Bernard came back from his travel to Asia.

(2) a. (Les enfants)$_{MiP}$ (sont venus)$_{MiP}$ (dans l'après-midi)$_{MiP}$.

b. (Bernard)$_{MiP}$ (est rentré)$_{MiP}$ (de son voyage)$_{MiP}$ (en Asie)$_{MiP}$.

In addition to the level of the MaP, two additional levels of phrasing are often referred to: the intermediate phrase or ip (see,

among others, [7] and [9]), which is also called major phrase (see, among others, [10]) or restructured phonological phrase (as in [4]); and the intonational phrase or IP (see, among others, [3], [4], [6] and [7]), which is also called the Breath group. Even if there is no broad consensus on the existence of the ip, this level of phrasing is often requested when the morphosyntactic structure is relatively complex. As to the Intonational phrase or IP, it is the largest prosodic unit in the prosodic hierarchy. It is characterized by a presence of an intonational contour at its right edge, the strongest degree of phrase-final lengthening, and also often followed by a pause. In sequences of clauses, each clause is normally phrased as an independent IP.

In section 4, the prosodic phrasing observed in the data, and the information requested to generate these phrases will be explained in details. It will allow evaluating what differentiate phrasing in standard French from phrasing in dictations.

3. Corpus and methodology

3.1. Corpus

To study prosodic chunking and intonation in dictation, a set of dictations has been gathered. This set consists of dictations that have been given to children enrolled in first to third year elementary school in France and Quebec (Canada). The data come from three different sources:

- Four short dictations come from the website of the Canadian association "Fondation Paul Gerin-Lajoie"[11], in particular, the dictations for first year level (CP in France);
- Four dictations come from the French website La-dictée.fr[12], which offers a wide range of dictations and grammatical exercises to school children;
- Two dictations have been recorded in class situations by some researchers belonging to the Phorevox project.

The choice of the dictations has been done in order to cover the various levels we are interested in for the software development. Moreover, as they come from different sources, some variation may occur in the way to dictate a text, in particular for the repetition of certain sequences. Some teachers repeat each sequence a few times (two or even more), while some others don't. The software will allow the user to configure such repetitions for any given dictation.

3.2. Methodology

The dictations have been annotated by two of the authors. The annotation indicates for each text two distinct types of information: the phrasing obtained (i.e. the way the texts were segmented into chunks during the dictation); and the form of the tonal contours that occur at the end of the various chunks.

The annotation has been achieved by means of a perceptual and instrumental data analysis. The perceptual analysis was done by a careful listening of the data, and allowed determining the chunking and the form of the pitch contours at the end of the various chunks. The acoustic analysis, achieved with the Praat software [13], confirmed what was perceived. Special attention was given to the occurrence of pauses to determine the segmentation in chunks, and to the form of the tonal contours occurring at the end of the prosodic chunks.

4. Data analysis: defining chunking rules

Before describing in details the rules used to derive the prosodic chunks, and the procedures at stake to repeat and introduce new chunks, we want to mention three major features that have been observed in all the analyzed dictations. First, the title and the whole text are said once at a relatively slow rate at the beginning, and then the dictation proper begins. Second, during the dictation proper, the whole sentence is usually repeated once after all its parts have been dictated in separate chunks. Third, punctuation marks are pronounced at the position they occur in the written text for the children to encode them as shown in (3) and (4), where the orthographic transcription of what has been pronounced is given.

(3) *Avec Papa. Point. Je marche dans la nature avec Papa. Point.*
With Daddy. Full stop. I am walking in the country with Daddy. Full stop.

(4) *A l'école, virgule, je travaille toujours avec lui. Point.*
At school, comma, I am working with him. Full stop.

Nevertheless, variation occurs in the pronunciation of the punctuation marks: the pronunciation of commas may be omitted when the sentence as a whole is repeated for the last time, whereas the pronunciation of stops may be done only when the sentence as a whole is produced. Since the latter realizations are not systematic, they will not be taken into account in the elaboration of the dictation algorithm presented in section 5: punctuation marks will always be pronounced in the position where they occur in the written text.

4.1. Phrasing and prosodic structure observed

In the observed data, the chunks used during the dictation proper correspond, in more than 95% of the cases, to minor phrases (see section 2), that is to lexical words preceded by the function words they syntactically govern. In a prepositional phrase, for instance, the noun is always phrased with the preposition and the determinant as in (5a), and, in the same vein, an auxiliary is phrased with the verb as in (5b).

(5) a. *Je marche dans la nature avec Papa* $\rightarrow$ (Je marche)$_{MiP}$ (dans la nature)$_{MiP}$ (avec papa)$_{MiP}$

b. *Il se demande si sa maman a trouvé les bons médicaments* $\rightarrow$ (Il se demande)$_{MiP}$ (si sa maman)$_{MiP}$ (a trouvé)$_{MiP}$ (les bons médicaments)$_{MiP}$

Note however that two Minor Phrases, which are derived from morphosyntactic information, may be restructured in a single one when the size of the phrase is inferior to two syllables. In many cases, for instance the copula *être* is restructured with what follows as shown in (6). The restructuring fails sometimes to apply, in particular when the resulting phrase would be relatively long as in (7).

(6) *Le lac est bleu* $\rightarrow$ [Le lac] [est bleu]

(7) *C'est mon meilleur ami* $\rightarrow$ [C'est] [mon meilleur ami]

As for the prosodic realization, each prosodic chunk is treated as an IP, be it in isolation as in (8) or integrated in a sentence as in (9), when the whole sentence is produced at the beginning or at the end.

(8) *Avec mon ami.* $\rightarrow$ [avec mon ami]$_{IP}$ [point]$_{IP}$

(9) *Je joue dans l'eau avec mon ami* → [Je joue]$_{IP}$ [dans l'eau]$_{IP}$ [avec mon ami]$_{IP}$ [point]$_{IP}$

This means that in dictation as a speaking style any prosodic group that would be a minor phrase in a normal reading style is realized with the major prosodic features of an IP such as an important final lengthening and a presence of a pause. Such a phrasing has been described as completely appropriate in French by [8]. It results from what [8] called the *élasticité prosodique* (i.e. prosodic elasticity), and account for the fact that any MiP could be realized as an IP, without any further restructuring.

The segmentation procedure used to dictate the text could thus be based on a parsing which introduces a major break after the words categorized as nouns, verbs, adjectives or adverbs if they are not modifying the following word. This latter principle should allow phrasing together in the same IP prenominal adjective and noun as in "le petit garcon", modifier adverb and adjective as in "très ennuyeux", or verbal auxiliary and past participle as in "est arrivé".

4.2. Procedures of repetition

Apart from the segmentation and the pronunciation in chunks, new chunks and sentences are introduced by special procedures that will be described in the following subsections. From the observation of the data, it was possible to infer three distinct procedures

4.2.1. Procedure IP by IP

This procedure consists in pronouncing the whole sentence where each MiP is realized as an IP first, and then to produce each IP in isolation (be they repeated or not). When all IPs have been uttered, the whole sentence is pronounced once again. For the sentence in (10), this procedure will lead to the chunking and the realization in (11). Each line break indicates that the chunk is uttered isolated from the preceding ones.

(10) Je joue dans l'eau avec mon ami.

(11) [je joue]$_{IP}$ [dans l'eau]$_{IP}$ [avec mon ami]$_{IP}$ [point]$_{IP}$
[je joue]$_{IP}$
[dans l'eau]$_{IP}$
[avec mon ami]$_{IP}$ [point]$_{IP}$
[je joue]$_{IP}$ [dans l'eau]$_{IP}$ [avec mon ami]$_{IP}$ [point]$_{IP}$

This procedure has mostly been used for the dictations given to the younger children (first year in elementary school).

4.2.2. Procedure by IP chaining

The procedure by IP chaining relies on a dictation of the sentence IP by IP, each IP consisting of what would be a MiP in colloquial speech. When the first IP has been realized once, it is repeated followed by the next IP, then the added IP is also produced in isolation once. For the sentence (12), this procedure will lead to the chunking and pronunciation in (13).

(12) Le chien s'étire sur le tapis.

(13) [Le chien]$_{IP}$
[Le chien s'étire]$_{IP}$
[S'étire]$_{IP}$
[S'étire sur le tapis]$_{IP}$ [Point]$_{IP}$
[Sur le tapis]$_{IP}$ [Point.]$_{IP}$
[Le chien]$_{IP}$ [s'étire]$_{IP}$ [sur le tapis]$_{IP}$ [point]$_{IP}$

Even if this procedure has been used in approximately 25% of the case in our data, it has some serious drawbacks, in particular in case of more complex sentences. In a sentence with a branching NP subject the verb is not uttered with the subject as shown in (14). Such a way of dictating is really error prone, as the subject-verb agreement cannot be interpreted in a straightforward manner.

(14) La porte de la chambre s'ouvre.
[La porte]$_{IP}$
[La porte]$_{IP}$ [de la chambre]$_{IP}$
[De la chambre]$_{IP}$
[De la chambre]$_{IP}$ [s'ouvre]$_{IP}$ [point]$_{IP}$
[S'ouvre]$_{IP}$ [point]$_{IP}$
[La porte]$_{IP}$ [de la chambre]$_{IP}$ [s'ouvre]$_{IP}$ [point]$_{IP}$

4.2.3. Procedure sentence by sentence

The last procedure consists in dictating the text sentence by sentence. Each sentence is pronounced once or twice, depending on its size, at a relatively slow rate. The segmentation in IP should be clearly realized as in (15), where a succession of two sentences is given.

(15) Le lac est bleu. J'aime le lac.
[Le lac]$_{IP}$ [est bleu]$_{IP}$ [point]$_{IP}$
[J'aime]$_{IP}$ [le lac]$_{IP}$ [point]$_{IP}$

In cases of complex or long sentences, the segmentation proceeds clause by clause. Clause refers here to different types of elements:

- Comma clause such as peripheral adjunct followed by a clause as the underlined sequence in (16).
- Subordinated or coordinated clauses as in (17)

(16) A l'école, je travaille toujours avec lui.

(17) Mon père rentre très tard à la maison parce qu'il est musicien.

When such a sub-segmentation is used, the sentence as a whole is repeated once when all parts have been dictated.

5. Adaptation of the rules and procedures for speech synthesis

The achieved segmentation and observed procedures have been used to automatically dictate any text with a speech synthesizer. The implementation of the various elements just described was achieved by generating the chunks, and producing the text while respecting the various features mentioned at the beginning of section 4.

5.1. Chunk generation

To explain how we generate the chunk list from an input text, we are going to take the following French sentence as an example:

(18) *En réalité, c'est un hélicoptère. Avec une cheminée qui crache de la fumée, comme une locomotive à vapeur.*
Actually, this is an helicopter.With a smokestack to expel smoke, like a steam locomotive.

5.1.1. *Main algorithm*

To generate a word chunk list, we first need to determine the syntax tree associated to the dictation text. This is given by the Synapse pos tagger[14]. We suppose that the nodes are corresponding to a syntactic phrase and each leaf is associated to a word.

For a given node N_0, we identify the children of N_0 by $(N_1 \dots N_n)$. Each node N_j represent a chunk of words. So N_j is defined by $N_j = (s_j, ej)$ where s_j is the first word's index and e_j the index of the chunk's last word. The syntax tree has the following properties which implies an order between children: $s_0 = s_1$; $e_0 = e_n$ and $s_j = e_{j-1} + 1$

The goal of the main algorithm is to find the "syntactic group" sequence which could be used as baseline chunks. To achieve this goal, we suppose a user defined parameter w representing the ideal number of words contained in a chunk. Based on this parameter, we define a cost function $C(N_j)$ associated to a node:

$$C(N_j) = |(e_j - s_j + 1) - w|$$

By using this cost function, the idea is to locally determine if, by splitting the current group N_0 into smaller syntactic groups $(N_1 \dots N_n)$, we approach the ideal chunk size or not.

This recursive algorithm distinguishes three cases:

1. if N_0 is a leaf, the recursion is stopped and the chunk is defined by the word contained in N_0,
2. if $(C(N_0) < \sum_{j=1}^{n} C(N_j))$ and N_0 is not a leaf, we consider two cases:
   - if $(N_1 \dots N_n)$ contains only leaves then the chunk is defined by N_0,
   - else we try to recompose the node sequence $(N_1 \dots N_n)$ by eliminating leaves.

     To do this, we try to merge each leaf to the preceding group in an incremental way. We identify by $(N'_1 \dots N'_{n'})$ the obtained node sequence. If $(C(N_0) >= \sum_{j=1}^{n} C(N'_j))$ then we apply the current algorithm by considering $N_0 = N'_j$. In the other case the chunk is defined as N_0 without considering the merging step.
3. in other cases, we apply the current algorithm by considering $N_0 = N_j$ for each N_j in $(N_1, \dots, N_n)$;

By applying this algorithm on the previous example, we achieved the segmentation presented in figure 1(b).

5.1.2. *Post-processing*

The previous stage results in a chunk sequence which is not yet optimal. If we consider the example, we can see that some chunks are composed by only one word ("comme"), other chunks contains punctuation in the middle which is not good in a dictation context ("en réalité, c'est").

In order to improve the consistency of the chunks, we have defined a post-processing stage, using a rule-based approach. Three steps are achieved in this stage: a splitting step, a merging step and finally an annotation step.

The splitting step goal is to isolate punctuations and split large chunk according to part-of-speech information. Punctuations have to be isolated because of their special treatment in dictations. Furthermore, for the moment, we split a chunk into two parts only before a coordinating conjunction. By applying this step, we achieved the segmentation presented in figure 1(c).

The merging step goal is to deal with two constraints. The first one aims to avoid any isolated word or any chunk starting with a non-alphabetical character. The objective of the second rule is to assess a minimum number of syllables in each chunk. As we don't have access to a segmentation in syllables (since we deal with a written text), we made the assumption that number of non-consecutive vowels in the text gives an approximation of the number of syllables. The minimum number of syllables in a chunk is then defined in a parametric way. Consequently, we merge a chunk to the previous one if it contains only one word, if it starts with a non-alphabetical character or if the number of consecutive vowels included in both chunks are inferior to the number selected as parameter. The result of this step is presented in figure 1(d).

5.2. Entire text dictation procedure

Once the text has been segmented into chunks, it is possible to automatically dictate it. To do so, the entire text is first copied while using the chunking automatically generated. In a second stage, each chunk is annotated in such a way as to be pronounced in isolation (followed by pause), the punctuation marks being made explicit. This leads for (18) to the final segmentation and the pronunciation given in Fig. 1(d).The text is then given to the TTS system that can treat it, while using a synthesized voice that has been specifically designed for dictation.

6. Conclusion and perspectives

The paper presents a chunking algorithm that allows segmenting any text into chunks that are comparable to the ones we observed in dictation data. Further research is currently achieved in order to (i) decide which procedure is more appropriate depending on the level of the pupils; an (ii) provide a closer analysis of the intonation contours used at the end of the different non-final IPs.

Within- and Between-Speaker Variability of Parameters Expressing Short-Term Voice Quality

Jitka Vaňková, Radek Skarnitzl

Institute of Phonetics, Faculty of Arts, Charles University in Prague, Czech Republic
jitka.vanka@gmail.com, radek.skarnitzl@ff.cuni.cz

Abstract

This study focuses on short-term acoustic correlates of voice quality. It assesses the within-speaker stability (across different speaking styles) and between-speaker variability of measurements which compare the amplitudes of various spectral events – H1*-H2*, H2*-H4*, H1*-A1*, H1*-A2* and H1*-A3*. Although speakers do differ with regard to the compactness of the parameters in read and spontaneous speaking styles, the parameters H1*-H2*, H1*-A1* and H1*-A2* appear both considerably stable for one speaker in different speaking styles and efficient in between-speaker comparisons. Though not directly applicable in forensic settings, these glottal parameters outperformed vowel formants in classification using LDA.

Index Terms: voice quality, spectrum, speaking styles, Czech

1. Introduction

Voice quality has long been recognized as an independent and full-fledged prosodic dimension [1]. It is a multidimensional phenomenon, which has made it difficult to describe in other than negative terms (i.e., what it is not) [2]. Since Laver's seminal work [3], voice quality has been defined in two ways: narrowly, referring only to the vibration of the vocal folds and its perceptual impact; and broadly, referring also to the perceptual impact of the movements and longer-term settings of supraglottal organs. In this study, we are interested in the narrower sense of the term voice quality, in phonatory modifications.

Since the perceptual evaluation of voice quality is far from straightforward (see e.g. [4], [5]), various acoustic correlates of different aspects of voice quality have been proposed. In this regard, we may talk about both long- and short-term acoustic manifestations of voice quality. The long-term average spectrum (LTAS) shows the frequency distribution of the speech signal over a longer (typically at least 30 seconds) stretch of speech [6], [7], [8]. By averaging over a long portion of speech, spectral differences due to individual segments are evened out, and the method thus yields information pertaining to general voice quality. LTAS has been successfully applied in various phonetic and speech pathological tasks (see e.g. [8] for a summary), with various parameterizations of the LTAS being proposed. Most of these reflect spectral slope, or spectral tilt, in other words the energy decrease with increasing frequency (e.g., the alpha value [9], the Hammarberg index [10], or more recent attempts [11]). In addition, the prominence of a specific peak in the LTAS – called the singer's or speaker's formant – has been correlated with qualities like resonance or sonority of the voice [12], [13].

Short-term manifestations of voice quality may be extracted from individual speech sounds, typically vowels. Jitter and shimmer quantify the degree of fluctuations of the voice source, in the frequency and amplitude domain, respectively; however, it has been suggested that these do not constitute useful correlates of voice quality [14]. Another group of parameters concerns the degree of additive noise in voice: harmonicity, or harmonics-to-noise ratio (HNR) whose measurement has been proposed in various domains [15], [16], [17], the glottal-to-noise excitation ratio (GNE) [18], and others. The last group of parameters to be mentioned here reflects, similarly to the LTAS, spectral slope. In this case, however, it is the spectral slope of a single vowel that is quantified [19], by means of comparing the amplitudes of various events in the acoustic spectrum (see [20] or [21] for an extensive review). The parameter H1-H2 (the amplitude of the first harmonic relative to that of the second) has been correlated with the open quotient. H1-A1 (the amplitude of the first harmonic relative to that of the first formant) is regarded as an indication of F1 bandwidth (B1), which is in turn an indication of the degree to which the glottis fails to close completely during the closing phase. H1-A3 (the amplitude of H1 relative to that of F3) is a reflection of spectral slope. These measures on the speech spectrum are most frequent, although others have also been proposed, such as H2-H4 or H1-A2 (e.g. [22], [23], [24]).

In the current study, we are interested in the stability of voice quality parameters across different speaking styles within one speaker and, at the same time, in inter-speaker differences. We will focus on those parameters which rely on the comparison of the amplitudes of various harmonics (or spectral peaks) – i.e. H1-H2, H1-A1 etc. – one of the reasons for this choice being the fact that Hanson [20] does mention a considerable degree of speaker specificity of these parameters but does not explore this question further.

Theoretically, a low degree of within-speaker variability and a high degree of inter-speaker variability may be useful in phonetic speaker recognition [25], [26], [27]. However, it appears that direct applicability of even such a positive finding in most forensic phonetic casework is problematic, as illustrated by Nolan [28]. The greatest drawback consists in the fact that most recordings of unknown speakers are telephone speech in which (at least) the first two harmonics of male voices are lost. In addition, the widespread use of mobile phones leads to various kinds and levels of background noise. While it is also true that voice quality may differ significantly with speaking style and a mismatch in speaking style thus may lead to false eliminations [28], we believe that the within-speaker variability of parameters like H1-H2 or H1-A3 – which would belong to the long-term segmental strand in Nolan's model [29] – does merit further investigation.

In her study, Hanson [20] suggests that, in order to enable comparison of these measures across different speakers (and vowels), the amplitudes of the first and second harmonic, H1 and H2, need to be corrected for the boosting effects of the first formant (frequency and bandwidth), while F3 amplitude needs to be corrected for the boosting effects of the lower formants. The corrected values are then denoted with an asterisk, thus for instance H1*-H2*, H1*-A1, or H1*-A3*. It will be these corrected measures that will be applied in this study. Specifically, we are interested in the stability of these measures within speakers across speaking styles, as well as in differences across speakers. The performance of the target measures will be compared with that of mean formant values, which will serve as a sort of benchmark here.

2. Method

2.1. Material & subjects

The material for this study was taken from the VASST corpus, which focuses on the variability of speaking styles and which has been collected in various regions of the Czech Republic. Recordings were obtained in quiet rooms in people's homes via a professional portable recorder Edirol HR-09, with a 48-kHz sampling frequency (later down-sampled to 32 kHz). In the present study, we analyzed recordings of spontaneous and read speech produced by six adult male native speakers of Czech aged 28–65 (mean age = 40).

The spontaneous speech sample involved a semi-structured interview in which the speaker was encouraged to speak freely about selected topics. As for the read speech sample, the speakers were asked to read a coherent text in a natural way after sufficient preparation.

We analyzed the Czech open central monophthongs /a/ and /aː/ in various consonantal contexts – only vowels in the context of /ɦ/ were excluded, as the glottal fricative may introduce additional breathiness into the spectrum of the vowel. The boundaries of the target segments were manually adjusted following the suggestions of [30] in Praat [31]. Each token was marked for syllable status with respect to word stress and for its position in utterance (final or non-final). For each speaker and style, we analyzed 50 vowel items, yielding the total of 600 tokens (6 speakers × 2 styles × 50 items). 10 of those had to be removed from analyses since they were not assigned glottal parameter values (see below).

2.2. Parameter extraction and analyses

All parameter values (spectral magnitudes of H1, H2, H4, A1, A2 and A3, as well as the formant frequencies of F1–F4) were automatically extracted by VoiceSauce (VS) [32], [33], a free stand-alone software, using the labelled Praat TextGrids.

To locate and measure the harmonics, VS relies on the extraction of F0. The default algorithm for F0 extraction in VS is STRAIGHT [34], which was also used in our study. In traditional FFT analysis, changing the analysis window can change the features of the extracted spectrum. Here, amplitudes of the harmonics are computed pitch-synchronously (over a 3-cycle window), which eliminates much of the variability in spectra computed over a fixed time window. The method is equivalent to using a very long FFT window but enables considerably more accurate measurements without relying on large FFT calculations [32], [33]. As only male voices were examined, the settings were slightly adjusted: maximum F0 was lowered to 400 Hz and minimum F0 raised to 60 Hz. All other default settings have been preserved.

As for the formant frequencies (F1–F4), they were likewise automatically extracted by VS, using the default algorithm for formant detection, the Snack Sound Toolkit [35]. Snack is an algorithm based on LPC, which uses as defaults the covariance method, pre-emphasis of 0.96, window length of 25 ms, and frame shift of 1 ms, so as to match the F0 estimation by the STRAIGHT algorithm [36].

From the values extracted at 1-ms intervals, the mean value was computed from the middle third (33–67%) of each vowel. Subsequently, 10% of the lowest and 10% of the highest values of the four formants and F0 were manually checked for extraction errors and, if necessary, corrected by direct estimation from the spectrogram (in the case of formants) and the waveform (for F0). Extraction mistakes were not numerous, apart from one speaker whose vowels occasionally manifested diplophonia [37]. The corrected F0 values were then reloaded into VS and the glottal parameters of the corresponding items computed again.

The computation of glottal parameters in VS differs slightly from that mentioned in [20]. VS uses for the corrected measures an algorithm developed by Iseli et al. [38] where H1*-H2* is corrected for the boosting effect of not only F1 but also F2, and F1 through F3 are used for the computation of H1*-A3*. In addition, VS computes H1*-A1* (*cf.* H1*-A1 in [20]).

To investigate the within- and between-speaker variability of these parameters, we performed several analyses. First, the stability of the glottal parameters within a speaker and across the two speaking styles was examined by means of the Kolmogorov-Smirnov (K-S) test, which compares two distributions of values. Second, the K-S test was also applied, in pairwise comparisons, to examine between-speaker variability. Finally, the effectiveness of the glottal parameters to discriminate between speakers was compared to that of formant frequencies by means of Linear Discriminant Analysis (LDA).

3. Results

The main aim of this study was to assess the stability of short-term voice quality parameters across different speaking styles (read and spontaneous) within one speaker, as well as their between-speaker variability. For these purposes, the Kolmogorov-Smirnov (K-S) test was used as it is also sensitive to differences in the general shapes of the distributions (such as differences in dispersion and skewness) in the compared samples.

3.1. Within-speaker stability

Let us first have a look at how stable the parameters are within one speaker. Figure 1 displays for each parameter which of the speakers (labelled S1–S6) did not yield any significant differences across the two styles ($p > 0.05$; above the line,

denoted with a +) and which of the speakers did yield significant differences ($p < 0.05$; below the line, denoted with a –). As we can see, speakers differ with respect to parameter stability: while the parameter differences in the two speaking styles are always insignificant for S1 – i.e., the values are stable in the two styles – S4, on the other hand, yields significant differences in 4 out of the 5 parameters. The figure also suggests that the most stable parameter is H1*-A2* followed by H1*-H2* and H1*-A1*, while H2*-H4* and H1*-A3* appear the least successful in expressing within-speaker stability of our sample.

	H1*-H2*	**H2*-H4***	**H1*-A1***	**H1*-A2***	**H1*-A3***	
				S1		
	S1		S1	S2		
	S2	S1	S3	S3	S1	
	S3	S3	S5	S5	S2	
+	S6	S4	S6	S6	S5	+
–	S4	S2	S2	S4	S3	–
	S5	S5	S4		S4	
		S6			S6	

Figure 1. *Within-speaker stability of voice quality parameters in the two analyzed speaking styles: insignificant differences between the styles appear above the line (also denoted with a +), significant ones below the line (with a –).*

Example distributions are given in Figures 2 and 3; Figure 2 shows the values of parameter H1*-A1* (in dB) for speaker S5 whose distribution did not differ across the two speaking styles ($p > 0.05$), while Figure 3 shows the values of H1*-H2* for speaker S4 which differed significantly ($p < 0.05$).

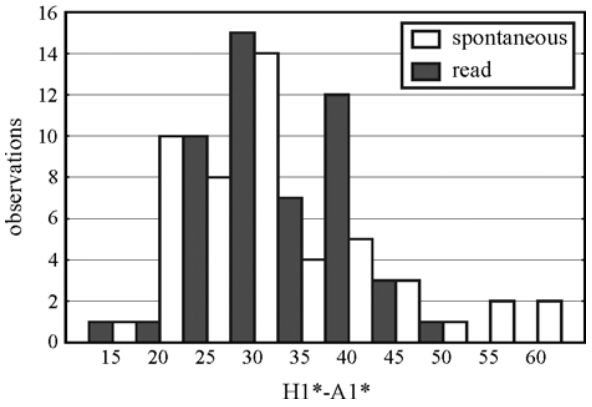

Figure 2. *The distribution of speaker S5's H1*-A1* (in dB) in read and spontaneous speech.*

3.2. Between-speaker variability

We were further interested to what extent these parameters can capture differences between speakers. To illustrate this, we present the results of pairwise comparisons between speakers for the most successful parameter in expressing between-speaker variability, H1*-H2*, in Table 1. The table shows that all 15 possible comparisons – having 6 speakers allows 15 pairwise comparisons – are statistically significant (denoted by an *), most of them highly significant (denoted by **). Moreover, speakers S1 and S5 show statistically highly significant differences from all other speakers, thus being clearly discriminated by their distribution of H1*-H2* values from the others.

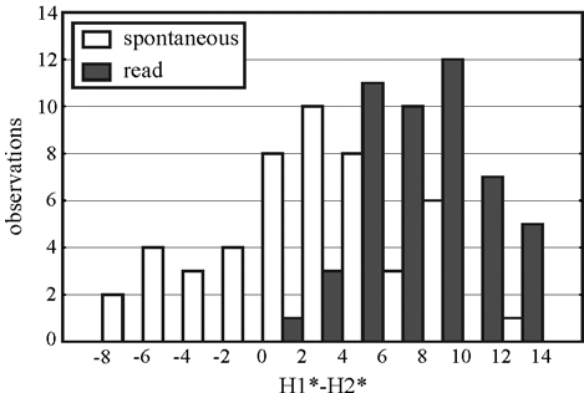

Figure 3. *The distribution of speaker S4's H1*-H2* (in dB) in read and spontaneous speech.*

	S1	S2	S3	S4	S5	S6
S1	X	**	**	**	**	**
S2		X	*	**	**	**
S3			X	**	**	**
S4				X	**	*
S5					X	**
S6						X

Table 1. *Between-speaker variability of H1*-H2* in pairwise comparisons (** $p < 0.001$; * $p < 0.05$).*

Not only H1*-H2* but also the other parameters appear to be efficient in expressing between-speaker differences. The overview of between-speaker pairwise comparisons for all 5 parameters is presented in Table 2. As already stated above, H1*-H2* is the most successful parameter in this respect, though it can be seen that also H1*-A1* yields statistically significant differences for all possible comparisons. H1*-A2* and H1*-A3* perform only slightly worse (one statistically insignificant comparison), while H2*-H4* turns out to reflect between-speaker variability the least, with 4 of the 15 comparisons being statistically insignificant.

	$p < 0.001$	$p < 0.05$	$p > 0.05$
H1*-H2*	13	2	0
H2*-H4*	8	3	4
H1*-A1*	12	3	0
H1*-A2*	14	0	1
H1*-A3*	14	0	1

Table 2. *Significance levels of between-speaker pairwise comparisons for all analyzed parameters.*

Figures 4 and 5 again provide example distributions. Figure 4 shows a similar distribution of H2*-H4* of speakers S1 and S3, while Figure 5 shows distinct distributions of H1*-H2* of speakers S1 and S6 (note that the depicted parameters did not differ in these two speakers across the two speaking styles; see Figure 1). Speaker S6's voice thus appears to be breathier, as suggested by the positive values of H1*-H2* [20].

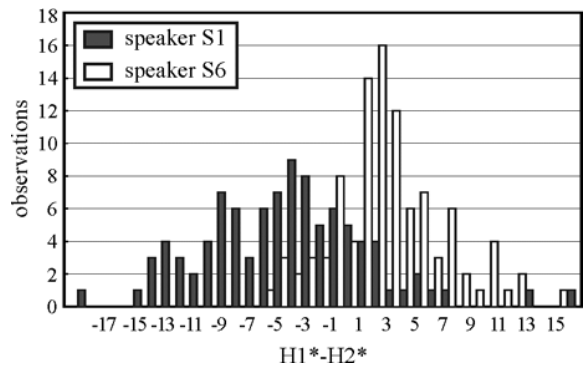

Figure 5. *The distribution of H1*-H2* (in dB) of speakers S1 and S6.*

3.3. Comparison with formant frequencies

Our final objective was to compare the effectiveness of the glottal parameters in discriminating between speakers with that of formants (F1–F4), which are often employed for these purposes and were thus used as a benchmark. This comparison was based on Linear Discriminant Analysis (LDA).

The classification rates for the two sets of parameters are presented in Table 3. The glottal parameters perform slightly better (52.6%) than formants (48.3%), both being well above the chance classification rate of 16.7%. Also, both models are statistically highly significant: F (25,2148) = 36.7; $p < 0.001$ for the glottal parameters, and F (20,1927) = 32.1; $p < 0.001$ for the formants. Table 3 also reveals considerable differences between the discriminability of individual speakers, as well as differences in the performance of the two models for the six speakers, which is most marked for speaker S1.

The values of Wilks' λ complement these tendencies: overall λ equals 0.267 for the glottal parameters and 0.385 for formants, which indicates that the variability in our data is better accounted for by the former.

Speaker	Glottal parameters	Formants
S1	62.5	12.5
S2	39.2	56.1
S3	24.2	39.4
S4	51.5	74.5
S5	84.0	72.0
S6	53.5	34.3
Total	**52.6**	**48.3**

Table 3. *Classification rates (in %) for the glottal parameters and formant values.*

The values of Wilks' λ for the individual parameters also support our findings that the most useful parameter for differentiating between speakers in our model is H1*-H2* as its removal would impair its efficiency the most, while H2*-H4* contributes to its efficiency the least. As for formants, F3 appears to be most and F1 least useful.

4. General discussion and Conclusions

This study analyzed short-term voice quality parameters from the viewpoint of their within- and between-speaker variability, as well as of their potential to discriminate between speakers.

As for within-speaker stability, our results suggested considerable differences between speakers with regard to their compactness in read and spontaneous speaking styles (*cf.* speakers S1 and S4 in Fig. 1). The results also indicate that H1*-A2* is the most stable parameter, followed by H1*-H2* and H1*-A1*. The same parameters also manifested high between-speaker variability (Table 2). This finding points to the importance of the relative amplitude of H1 for distinguishing voice quality (*cf.* [20], [23], [24]).

Between-speaker comparisons also revealed that some speakers are clearly differentiated from all others, specifically speaker S1 and S5 (see Table 1 and also Table 3). Interestingly, S1 was our youngest subject (28 years old), while S5 was our oldest one (65 years old). Our results are thus in accordance with previous studies [38] which showed an age dependency of H1*-H2* and H1*-A3*.

The comparison of the speaker-discriminating potential of the glottal parameters and formant values suggested that the glottal parameters slightly outperform formants overall, though individual differences may be observed. By way of conclusion, let us repeat, however, that the findings cannot be directly applicable in forensic casework due to the band-limited telephone signal, and that our main point of interest was the stability of the voice parameters across the two speaking styles; in this respect, we believe, our study indicated their usefulness for future research.

Do Korean L2 learners have a "foreign accent" when they speak French? Production and perception experiments on rhythm and intonation

Bénédicte Grandon, Hiyon Yoo

Abstract

French and Korean are two languages with similar prosodic characteristics as far as rhythm and intonation are concerned. In this paper, we present the results of production and perception tests where we describe the prosodic characteristics of Korean L2 learners of French. Our aim is to analyze the impression of "foreign accent" for two prosodic components (intonation and rhythm) of speech produced by Korean L2 learners of French and the perception of this "accent" by native listeners of French (L1). We show that the productions of Korean learners and French native speakers present minor differences but that they do no translate into cues for determining clearly the presence of a "foreign accent".
Index Terms: L2 prosody, intonation, rhythm, production, perception, Korean, French

1. Introduction

Through the past decades, several second language (L2) acquisition models have shown that similarity is more problematic than difference for the L2 learner. Researchers, among others [1], in his Speech Learning Model but also [2] and [3] for intonation and [4] for rhythm, posit that L2 acquisition is more difficult for sounds and prosodic units where the contrast with L1 is poor. What happens then when L1 and L2 share most prosodic characteristics? In this paper, we investigate the impression of "foreign accent" (i.e. non-native production, see among others [5] and [6]) for two prosodic components (intonation and rhythm) in speech produced by Korean L2 learners of French and the perception of this "accent" by native listeners of French (L1).

French and Korean are both described as "syllable-timed" languages ([7] for French, [8] for Korean), with common prosodic features: (1) Primary stress, realized through syllabic lengthening, is located on the last syllable of the last lexical word of a phrase (among others [9] and ([7] for French, [8] for Korean), (2) non-stressed syllables have a constant duration ([7] for French, [10] for Korean), and (3) declarative utterances have a falling pitch contour beginning on the first accented syllable in French [7] and on the utterance's second syllable in Korean [10] and continuing through the end of the sentence. Furthermore, the intonation of modality is seen as the result of the realization of the fundamental frequency (F0) at the end of utterances both in French ([11], [9]) and Korean ([8]). Finally, the declination slope is steadily declining in both languages, no matter the length of the utterances ([12] for Korean and [13] for French).

Since French and Korean share these prosodic characteristics, we expect that (1) French native speakers and Korean learners of French (L2) produce overall similar intonational and durational patterns of vowels at the end of chunks and (2) that these similarities, along with minor differences in the production of Korean speakers cannot be perceived as the manifestations of a "foreign accent". In the next sections, we present the production and perception analyses we conducted to test these hypotheses.

2. Rhythm and intonation in L2 Korean productions of French utterances

In order to determine the prosodic proximity between French L1 and L2 productions, we built a comparative reading experiment with L2 learners of French and French native speakers. The aim of this experiment is to locate the prosodic differences concerning intonational patterns and rhythmic organization that can be seen in L2 productions and to measure variation from native L1 productions.

2.1. Corpus and experimental procedure

The corpus consisted in declarative utterances following the pattern "$NP_{subject}$-V-NP_{Object}", where each chunk has an identical number of syllables (varying from 1 to 10 syllables). Three examples (from the shorter to the longest utterance) are given below in French, with English translation:

(1) utterance 1x3 (9 syllables)
$(\text{Barbara})_{SUBJ}$ $(\text{a perdu})_{V}$ $(\text{son vélo})_{OBJ}$
(Barbara) $_{SUBJ}$ *(lost)* $_{V}$ *(her bike)* $_{OBJ}$
(2) utterance 5x3 (15 syllables)
$(\text{Les amis d'Alice})_{SUBJ}$ $(\text{ont voulu cueillir})_{V}$ $(\text{les pommes du jardin})_{OBJ}$
(Alice's friends) $_{SUJ}$ *(wanted to pick)* $_{V}$ *(the apples from the garden)* $_{OBJ}$
(3) utterance 10x3 (30 syllables)
$(\text{La voisine de ma cousine Annabelle})_{SUBJ}$ $(\text{a vraiment dû hésiter à porter})_{V}$ $(\text{cette affreuse paire de chaussures noires et vertes})_{OBJ}$
(The neighbour of my cousin Annabelle) $_{SUBJ}$ *(must really have hesitated in wearing)* $_{V}$ *(this ugly pair of black and green shoes)* $_{OBJ}$

Two female native speakers of Standard French and four native speakers of Standard Seoul Korean (three female and one male), with variable proficiency levels in French were asked to read the sentences that were presented to them. All speakers were students in their twenties living in Seoul at the time of the recordings. The corpus gathers a total of 20 utterances presented five times in a random order and mixed with distractors that were not taken into account (a total of 600 utterances were analyzed).

The recordings took place in a quiet room, using the Audacity software [14] (in mono, using a sampling frequency of 22050 Hz ad 32bits) on a laptop, with an external microphone. Annotations of the sentences and extraction of durations and F0 values were done first automatically with the Easyalign software [15] and Praat scripts [16], and then checked manually.

Three acoustic parameters were analyzed: rhythm, intonation patterns and declination. For better objectivity in the normalization of the data, we chose the vowel over the syllable as the unit of analysis; thus for rhythm, we used a ratio of the duration of each occurrence produced by the speaker divided by the mean duration of the corresponding vowel in all her/his productions, which allowed us to eliminate both "inter-speaker" (resulting from speakers' different speech rates) and

"intra-speaker" (resulting from different intrinsic vocalic duration) variations, as well as variation resulting from different syllabic structures. For intonation, F0 raw values (three measures per vowel) were converted into semi-tones relative to each speaker's mean F0[1].
The R software [17] was used to run the ANOVA tests.

2.2. Results and discussion[2]

2.2.1. Rhythm

For the final vowel of each chunk (subject, verb and object), we considered that a vowel is lengthened when its normalized duration is 1.2 or above (mean + 20%). We considered that choosing the mean value was not sufficient enough to determine a lengthening compared to the threshold of 1.2, above which lengthening can clearly be perceived
Figure 1 shows the variation of mean vocalic durations for the two groups of speakers (French L1 and Korean L2) for three sentences (3x3=9, 3x5=15 and 3x10=30 syllables).
In most cases, both French L1 speakers and Korean L2 learners lengthen the last vowel of the subject chunk. French speakers almost never lengthen the end of a verb, which shows that they tend to group the verb with its object and to place lengthening only at the end of the sentence. Korean speakers present more diverse results, with vocalic lengthening found in six cases out of ten (sentences with 3x4, 3x5, 3x6, 3x7, 3x8, 3x10 syllables), which might correspond to a more frequent segmentation of the utterance for learners than for native speakers. Vowels at the end of object chunks (which represents also the end of utterances) are systematically longer for French speakers while Korean learners do not produce this expected lengthening (vocalic lengthening of 1,2 can be seen only for sentences with 3x2, 3x4 and 3x10 syllables).
We ran ANOVA tests to compare the realizations of vowels at the end of chunks for the two groups of speakers. Thus, for sentence 3x3 syllables, it appears that the third and the ninth vowels produced by French speakers is longer than the adjacent vowels, even though the normalized values never cross the threshold of 1,2. Results of ANOVA tests show a significant difference for both groups, except for the utterance-final vowel ($F(1,56) = 5{,}737$ $p=.0199$).
The durations of 3x5 syllable utterances, are similar for both groups of speakers: both groups lengthen the 5th and the 15th vowels (for this last vowel, the lengthening is much more important for French speakers than for Korean learners), while the 10th vowel is lengthened only by Korean speakers. Notice that the ANOVA test is significant between the two groups only for the 10th syllable ($F(1,50) = 14{,}657$ $p=.0004$).
For the 3x10 syllable utterances, there is a lengthening of the 10th, 15th and 30th vowels for French speakers and of the 3rd, 10th, 16th, 20th and 30th vowels for Korean speakers. The differences between the two groups are significant for the 10th vowel ($F(1,51) = 5{,}666$ $p=.0211$) and for the 30th vowel ($F(1,51) = 9{,}16$ $p=.0039$) but not for the 20th vowel ($F(1,51) = 0{,}866$, $p=.3565$).

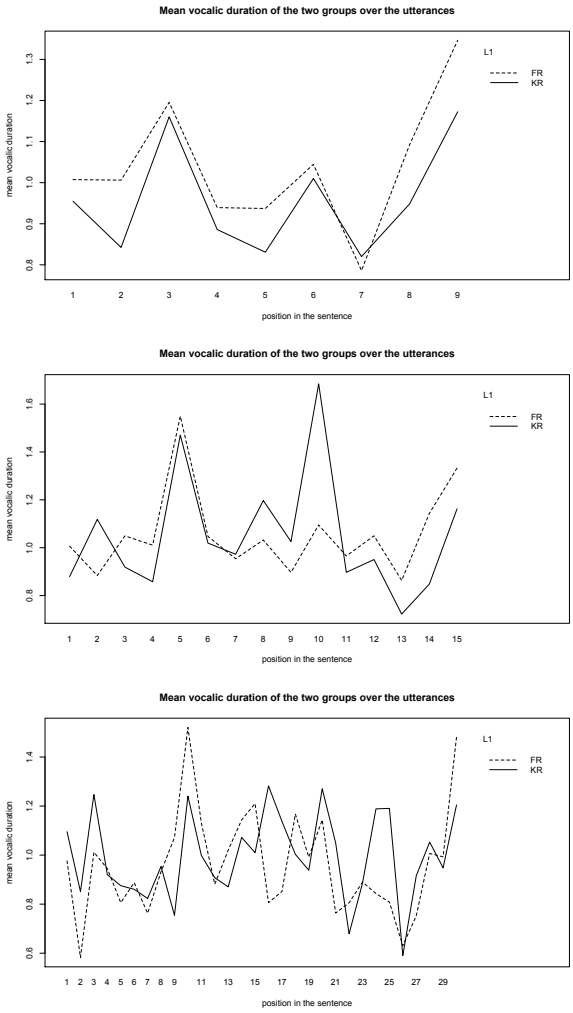

Figure 1: Mean vocalic duration of the two groups for 3x3, 3x5 and 3x10 syllable utterances.

Results show a main difference between the two groups for the final vowel of the utterance, which is lengthened systematically by French speakers while Korean speakers present less homogeneous results for vocalic durations at this position. The findings correspond to what is expected for French rhythm ([7], [9]) where lengthening of the last syllable of an accentual group is a main rhythmic characteristic in French. Lengthening at subject-final level seems to indicate the presence of an accentual group boundary on this position, while the absence of lengthening at verb-final level indicate a grouping of the verb and its object, putting the two chunks into a unique group with only a final lengthening.
Korean learners produce vocalic lengthening less systematically but more frequently. Rhythm is organized in terms of group weight: They have a tendency to re-segment the utterances in order to obtain a maximum of six/seven syllables per group ([9] among others posit that accentual groups in French contain seven syllables), and to lengthen the end of these new groups, no matter the syntactic description. Moreover, lengthening is less marked for Korean learners than for French speakers.

[1] We used the following formula taken in [9] for the computation of semi tones:
F0(ST) = 12*(Log(F0/speaker's_meanF0))/Log(2.00)
[2] ANOVA tests were conducted for every type of sentences, but because of limits of space, we show the results for three utterances, illustrating our purpose.

2.2.2. *Intonation*

For intonation, we compared the F0 values for the last vowel of each chunk (subject, verb and object). Results show that the two groups (French native speakers and Korean learners of French) produce very close patterns.

Thus, at the end of utterances (i.e. at the end of object phrases), both French and Korean speakers produce massively a HL pattern (utterances 3x2, 3x3, 3x6, 3x8, 3x9, 3x10), which can be followed by a small rising (utterances 3x2, 3x6, 3x8). Korean learners have more random productions with more final risings, and even a rising pattern for utterance 3x7. However, the ANOVA test reveals a non-significant difference for F0 realizations of the two groups of speakers on the last vowel of the utterance.

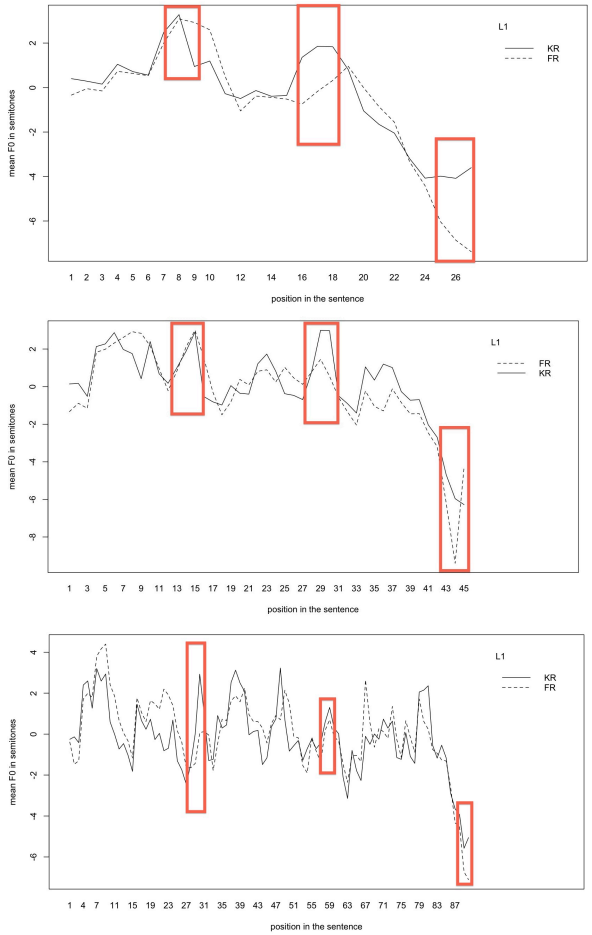

Figure 2: Mean F0 of the two groups for 3x3, 3x5 and 3x10 syllable utterances.

The F0 realization on the last vowel of the subject is also similar for both groups. However, the type of pattern can vary, with a fall-rise pattern for utterance 3x1, a rising pattern for utterances 3x5, 3x6 and 3x10, and a falling pattern for utterance 3x7. The realizations of the two groups of speakers differ for utterances 3x2, 3x3, 3x8 and 3x9 syllables

Results are less homogeneous at the end of verbs. Within the group of French speakers, the last vowel at this position is produced as a flat pattern in short sentences (3x1 and 3x2 syllables), a rising pattern in utterances 3x3, 3x7 et 3x9 syllables, a rise-fall pattern in utterances 3x5 and 3x10 and a falling pattern in utterances 3x4, 3x6 et 3x8. Korean learners realize also the same patterns but not for the same utterances: rising pattern is found in utterances 3x3, 3x5 and 3x7, a flat pattern in utterances 3x1 and 3x8, a rise-fall pattern in utterances 3x2, 3x9 and 3x10, a falling pattern in utterance 3x4, and a falling pattern followed by a rise in utterances 3x6.

Figure 2 illustrates the differences and similarities of the F0 measures for the two groups of speakers (French L1 and Korean L2 speakers) for three utterances (3x3=9, 3x5=15 and 3x10=30 syllables).

Thus, for utterances 3x3, even though the main shape of the F0 curve is similar for the two groups, the ANOVA test reveal significant results for: 1) the last vowel of the verb (at onset ($F(1,39) = 11,479$ $p=.0016$), at mid-point ($F(1,56) = 10,045$ $p=.0025$) and at end-point ($F(1,44) = 9,303$ $p=.0039$) of the vowel) and 2) at end-point of the vowel of the object ($F(1,33) = 5,883$ $p=.0209$).

For utterances 3x5, the ANOVA test shows that there is a significant difference for the verb (at mid-point ($F(1,51) = 14,255$ $p=.0004$) and at end-point of the final vowel of the verb ($F(1,40) = 13,974$ $p=.0006$)) and the object (at mid-point of the final vowel of the object $F(1,43) = 5,453$ $p=.0243$). The ANOVA test is not significant at subject–final level.

For utterances 3x10, the main F0 shapes are similar for both groups. However, the ANOVA test reveals a significant difference at the subject position (at mid-point ($F(1,52) = 11,827$ $p=.0012$) and at end-point ($F(1,35) = 36,713$ $p<.0001$) on the last vowel of the subject), mainly because of the more important rise produced by the Korean learners.

For intonation, it appears that overall F0 shape is similar for both Korean learners and French native speakers, but statistical analysis show significant differences in some positions of contour, especially at the end of the verb and at the end of utterances. The F0 contours produced by Korean learners are less systematic and present more variety than those produced by French speakers.

2.2.3. *F0 declination slope*

We used a regression-analysis in order to measure the overall declination slope of the F0 ([18] and [13]). The slopes of the regression line were calculated by taking into account the three F0 values (converted in semi-tones) on the last vowel of each group. Results given in Table 1 show that the two groups have the same attitude in regards to this prosodic characteristic, with an overall progressing F0 declination from the beginning to the end of utterances.

However, results show that the declination slope is slightly more important for French native speakers than Korean learners (the slopes of regression line are always negative, and have a higher absolute value for the French speakers than for the Korean speakers). This observation can also be seen in the study of [2] who noticed that declination slope is less marked in L2 speakers than L1 speakers. Finally, contrarily to what has been observed by [12] for Korean, there is a correlation between the length of the utterances and the declination slope: when the utterance is longer, the declination slope is less steep, but the highest F0 point at the beginning of the utterance and the lowest point and the end of the utterance remain the same, no matter the length of the utterance.

Since the production analyses revealed slight but statistically significant differences between French native speakers and Korean learners, the next step of our procedure was to test if these differences are perceived, and if they represent sufficient

cues to identify a foreign accent. We present the results of the perception experiment in the next section.

Number of syllables per chunk	Slopes of regression line for French speakers	Slopes of regression line for Korean learners
1	-1,201	-0,722
2	-0,393	-0,377
3	-0,228	-0,187
4	-0,116	-0,110
5	-0,112	-0,080
6	-0,980	-0,690
7	-0,940	-0,048
8	-0,055	-0,032
9	-0,054	-0,029
10	-0,036	-0,025

Table 1: Slopes of regression line for all utterances and for the two groups of speakers (French an Korean)

3. Perception

Since the production experiment showed only slight differences in production in French by French and Korean speakers both for rhythm (vocalic durations) and intonation (F0 contours and declination lines), we expect that these differences in the Korean speakers' production at a prosodic level are not sufficient enough to be perceived by naive French listeners as a « foreign accent » in comparison to the French speakers' production. In this section we present the results of a pilot experiment built to test the perception of this "accent".

3.1. Experimental procedure

The perception experiment is built in three different conditions. First, we neutralized segmental information: we synthesized the intonation and rhythm of two French and two Korean speakers who participated at the production experiment with the voice of a French native speaker, which allowed us keeping segmental information but changing the prosodic profile of the utterances (we thus obtained synthesized sentences with different prosodic profiles on a same French voice). Second, segmental and rhythmic information have been neutralized: thus, we coupled a long /a/ sound with the intonational tier of the four speakers used in the first condition while rhythm is neutralized for all syllables: in this test, we chose to keep only part of the initial stimuli (3x4, 3x6 and 3x8 syllables were not used) since the listening task of utterances with no segmental information is quite difficult to perform for naïve listeners. The third test is the control condition: stimuli remain unmodified productions of the same speakers, without any manipulation of segmental information, rhythm and intonation. The perception experiment is created and run on Praat [16]. Eight native speakers of French took part in the experiment which was conducted on a laptop and using headphones. The experiment is a forced choice task in which they are asked to judge if the stimulus is pronounced by a speaker with a foreign accent or by a French native speaker.

3.2. Results and discussion

When segmental information has been neutralized and only rhythm and intonation remain (test 1 of Tables 2 and 3), answers for "foreign accent" are only slightly above chance (62.5 to 67.2%) for shorter sentences (1 to 3 syllables per group). Results gradually improve for longer sentences (4 to 9 syllables per group) and reach 87.5% for "foreign accent".

When only the parameter of intonation is kept as the only cue, results for shorter sentences are low (42.2 to 54.7% for "foreign accent"), improve when sentences are longer (5 and 7 syllables per group) but remain around average for the longest tested sentences (9 syllables per group). The analyses of answers chosen per stimulus show that listeners identify the stimuli of native speakers of French correctly in only 42.7% of cases, which indicate that in this test, choices are made randomly.

In the control condition (Test 3 of Tables 2 and 3), results are as expected for all types of sentences (above 95.3%): segmental variation has not been analyzed in this study, yet it seems to be strong enough for the listeners to identify a foreign accent.

Number of syllables in the sentence	**Condition**		
	Test 1	Test 2	Test 3
3x1 = 3	62,5%	53,1%	100%
3x2 = 6	67,2%	42,2%	98,9%
3x3 = 9	62,5%	54,7%	95,3%
3x4 = 12	82,8%	-	98,4%
3x5 = 15	78,1%	67,2%	100%
3x6 = 18	73,4%	-	96,9%
3x7 = 21	79,7%	60,9%	96,9%
3x8 = 24	87,5%	-	100%
3x9 = 27	87,5%	50%	87,5%

Table 2: Percent of answers for "foreign accent" for the three conditions for each utterance (1/L2 rhythm and intonation, 2/Intonation only, 3/ no modification)

		Stimulus produced by	
		French speaker	Korean speaker
Answers for Test 1	French speaker's production	82,6%	31,3%
	Foreign Accent	17,4%	68,7%
Answers for Test 2	French speaker's production	42,7%	33,3%
	Foreign Accent	57,3%	66,7%
Answers for Test 3	French speaker's production	95,5%	1,7%
	Foreign Accent	4,5%	98,3%

Table 3: Results sorted by types of stimuli (produced by French or Korean speaker)

4. Conclusion

The production experiment showed that as far as rhythm is concerned, Korean learners of French tend to change boundaries and to lengthen the end of these groups, no matter the syntactic structure. Otherwise, strategies for intonation and declination slope are quite similar for both language groups.

This pilot perception experiment gives a first indication of the difficulty for native listeners to clearly perceive slight, randomly distributed differences in the production of L2 learners of French. It also reveals that the identification of "foreign accent" is easier when utterances are longer. This result is consistent with [3]'s results on German and US-English production and perception. It appears that the perception of a "foreign accent" is linked to prosodic proximity of the two tested languages. Ongoing work includes more listeners but also the dissociation between the two main parameters, rhythm and intonation. Moreover, a further production and perception study with the same material in French with speakers of a typologically different language could help understanding and confirming our findings.

Abstract

From early months of life prosody has a prominent contribution to segmentation: prosodic boundaries overlap with syntactic ones and facilitate the extraction of syntactic regularities both at word and at phrase level. Therefore, the long-term representation of rhythmic features of the native language, especially the stress templates derived from regularities are assumed to play a particular role in pre-lexical processing. We examined the nature of early stress representation in a language with a fixed stress pattern in an electrophysiological experiment (acoustic passive odd-ball paradigm, 10 month-olds: 28 infants; 6 month-olds: 21 infants, 400 items, deviant: p=20%) using bi-syllabic Hungarian pseudo-words to follow how prosodic features contribute to processing saliency and how word stress templates based on regularities may emerge. We used legally and illegally stressed stimulus both in standard and deviant positions in separate conditions.

In the legal standard condition two mismatch responses (MMRs) temporally synchronized to each syllable could be recorded. On the contrary, in the illegal standard condition no significant response was found. It seems that language environment influences the processing of speech prosody and the MMR correlates of word stress processing are related both to saliency and to stress templates emerging during the first year of life.

Index Terms: language development, prosody, mismatch response

1. Introduction

Infants acquire their native language quickly and accurately among suboptimal conditions, as the utterances of adults around them are usually imperfect, non-segmented and changing with personal characteristics. One of the first problems infants need to solve is how to extract meaningful units from the continuous speech stream, without having any lexical knowledge. Originally Gleitman and Wanner [1] then later Anne Christophe and her colleagues [2] proposed that since prosodic cues like lexical stress may reliably signal word boundaries they can act as bootstrapping mechanisms by helping to locate words in the speech stream. These presumed prosodic bootstrapping mechanisms help infants to generate and apply rules extracted from distributional patterns of spoken language [3, 4, 5]. Therefore prosody, among other cues, such as allophonic, phonotactic and statistical or distributional cues [6], is assumed to facilitate early language acquisition. The extraction of prosodic regularities is based on acquiring the rhythmic segmentation procedure that allows infants segmenting their first patterns [7, 8, 9] which soon issue in that infants show a strong trochaic bias in languages that apply this pattern (i.e. English, German or Hungarian) in contrast to infants whose native language applies an iambic one. This implies that infants are able to detect specific patterns of distinct acoustic features related to prosody, and that the exact nature of this mechanism is mostly dependent on the native language specificity. Our research focuses on the development of representation resulted from extracting language-specific patterns.

The early segmentation hypothesis relies on adults' segmenting ability. According to the electrophysiological data of Honbolygó and Csépe the perception of stress pattern is based on long-term, pre- lexical, language-specific representations of stress information among Hungarian adults that they called stress templates [10]. Development of such a template should occur already in early infancy, as infants are sensitive to specific salient acoustic features and are able to extract rules given in patterns quite early. However, neither the relationship of these acoustic cues nor the developmental timing of them is clear yet. In our study we were interested in when the representation of native language's specific prosodic pattern signaling word boundaries could be abstracted and how these patterns are utilized when listening to new utterances. Hungarian language has some special characteristics as it is a syllable-based language like French, although has a strong stress initial rule as German, while vowel duration is a segmental feature in contrast to both.

Studies using electrophysiological methods refined our understanding of prosodic information by examining the underlying mechanisms without relying on behavioural responses. This method enables us to filter out the behavioral readiness of infants, as it measures only the brain activity correlating with automatic linguistic process that is independent of willpower. Most of the electrophysiological experiments applying the method of passive oddball paradigm are looking for deflections in event-related brain potentials (ERP) related to stress processing. Among adults, the Mismatch Negativity (MMN) event-related brain potential component is elicited when an unexpected change occurs in the auditory environment. The expectations can be generated either via forming a short-term memory trace of the actual stimulus set (with a series of identical stimuli) or resulted from this trace affected by long-term memory representations [11]. The unexpected change of suprasegmental information (prosody) evokes mismatch responses, where latency, amplitude, and polarity, all depend on the familiarity of the stimulus [12]. A cross-linguistic study [13] underpinned that language environment promotes different discrimination abilities no later than at the age of 4 months as French and German infants showed different ERP waveforms to different stress patterns by four-months of age. This bias was congruent with the deviation of language related stress cues and regularities: while in German the dominant stress pattern is stress on the first syllable, in French stress is on the second one (among bi-syllabic words). In an oddball paradigm infants responded with a positive mismatch response (MMR) only to the illegally stressed pseudo-words of their own native

language. The authors used salient cues typical for German such as duration and intensity. However, syllabic stress is not determined by the same acoustic features in other languages, so stress is not uniform from an acoustic point of view. For example infants show high sensitivity to duration [14, 15] very early, while intensity or other features may show a different developmental trajectory. Dividing salient acoustic feature processing and prosodic template processing is a critical issue in all languages. The most important acoustic features defining stress pattern vary across languages, so discriminating phoneme duration or pitch or f0 alone does not allow us to shed light on detecting stress pattern deviations. This ability is derived as a rule extraction based on the early language experience. The ERP studies focusing on prosodic information varied mostly the duration of speech sounds; consonants [16] or vowels [13, 17, 18]. In Hungarian vowel duration is a segmental cue, where young learners have to extract a typical stress pattern while taking complex variations (acoustic perturbations in case of long vowels) into account. However, we took advantage of the expressed regularity characteristic for Hungarian with word-initial stress for all words (except for compound words), a pattern correlating with linguistic units, and therefore providing a strong unvarying environment for forming stress-related expectations [19, 20].

As lexical stress used in the Hungarian language (always word-initial) is associated perfectly with the words' beginning, this allows us to follow how these features contribute to processing saliency and how word stress templates based on regularities might emerge.

The objective of our ERP study was to reveal the ability 6 and 10 month-old infants to use acoustically rich stress information, including pitch and f0 changes, the two most important features characteristic for syllabic stress in Hungarian. We assumed that besides processing salient distinct features only, 6 month old infants have already extracted a specific rule regarding the stress pattern of their native language and violation is detected on a higher level as a long- term representation of stress.

2. Methods

We used the experimental paradigm of Honbolygó and Csépe [1] designed for testing the saliency versus template hypothesis. Legally and illegally stressed pseudo-words were presented in a passive oddball paradigm. We recorded ERPs in two conditions: the standard and deviant stimuli were simply reversed in order to see if only the absolute differences lead the discrimination or the relative pattern was also taken into account.

2.1. Participants

A total of 60 infants were recruited for the experiment, 48 were included in the statistical analyses. 12 infants were excluded due to extensive artifacts. The recordings were taken at the mean age of 196 days (*SD*=13) in the 6 month-olds' group and 316 days old (*SD*=13) in the 10 month-olds' group. Mean GA was 39.2 weeks while mean birth weight was 3346 g with 548 g standard deviation, with no significant difference between the two age groups. All infants were born to monolingual families and raised in a monolingual environment. None of them had known hearing problems, neurological impairments or any known developmental delay. Parents gave written consent for their child's participation after having detailed information. The experiment was approved by the Ethical Review Committee for Research in Psychology.

2.2. Stimuli

Two types of stimuli, stress variants of a Hungarian pseudo-word ('bebe') with duration of 539 ms, were used. The two stimulus types differed only in their stress pattern. In Hungarian stress is always on the first syllable [21], so for the legal version stress was on the first syllable ('BEbe'). The illegal version was created by reversing the order of the two syllables ('beBE') in order to minimize the difference between the two pseudo-words apart from stress pattern (using Praat [22]). The two syllables were spoken digitalized utterances that differed in three features: maximum intensity (2.42 dB), maximum f0 (15.77 Hz) and rise time (16 ms) respectively, and in contrast to former studies, not in duration. The source stimulus was uttered by a native female speaker in sentence context and edited for computing its illegal variation (for further details read Honbolygó and Csépe [10]).

2.3. Procedure

The procedure was the same as in the Honbolygó and Csépe [1] study. Stimuli were presented in a passive oddball paradigm in random order (deviant probability of 20%). In order to avoid rhythmic affects stimulus onset asynchrony (SOA) varied randomly between 730 and 830ms. We used two stimulus presentation conditions:

• *Legal standard* condition: the legal stimulus was the standard and the illegally stressed pseudo-word was the deviant stimulus.

• *Illegal standard* condition: the stimulus positions were changed, the illegal stimulus was presented as the standard and the legal one was the deviant stimulus.

The order of the two conditions was counterbalanced across subjects. Each condition contained 100 deviants in two blocks. The adult version of the experiment was shortened in order to adapt it to the infant participants [23]. Recording lasted approximately 12 minutes, in order to avoid fatigue among the infants. Stimuli were presented via loudspeaker (Soundkey MS-310, 70 *dB*) that was placed at the distance of 100 cm from the subjects. The experiment was performed using Presentation software (version 12.1, http://www.neurobs.com). The total experimental time was 1 hour including preparation and pauses. Infants were sitting on their parents' lap and were kept calm by presenting cartoons and puppets silently by an assistant.

2.4. Data collection

The EEG was recorded at 500 Hz sampling rate with Ag-AgCl electrodes using an appropriate sized electrode cap (BrainVision Recorder, BrainAmp amplifier, BrainProducts GmbH). Electrodes were attached to F3, Fz, F4, C3, C4, T3, T4, P3, Pz, P4, O1, O2, M1, M2, the reference electrode was Cz. Ground was placed between Fz and Fpz on the midline. The electrode locations corresponded to the international 10-20 system. Offline data analyses were done with BrainVision Analyzer software (BrainProducts GmbH). Recordings were re-referenced to the average reference of M1 and M2 and were band-pass filtered (0,5-20 Hz, 24 dB/oct). Raw EEG data were segmented into 800 ms epochs, including a 100 ms pre-stimulus baseline. Electrophysiological responses to deviant

stimuli and to standard appearing right before the deviant were taken into analysis. EEG responses exceeding ±150μV within a sliding window of 300 ms in any channel were rejected automatically. 12 infants' data were rejected because of contaminated recordings. Statistical analyses were carried out in 21 six-month-old and 27 ten-month-old infants for two time windows (300-400 ms, 450-550 ms) based on the grand averages. Epochs were averaged separately for each condition, electrode and participant for all deviants, and for the preceding standards.

3. Results

Difference waves computed by subtracting the averaged standard responses from the deviants are displayed on Figure 1.

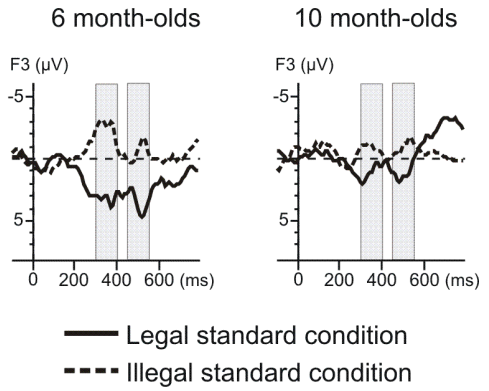

Figure 1: *Difference waves shown for the F3 electrode in two experimental conditions. Responses obtained in the legal standard condition are shown with thick lines, in the illegal standard condition with dotted lines. The time windows -– marked by grey bars show the latency ranges (300-400ms and 450-550ms) where the statistical analysis was run.*

For statistical analysis average areas were computed in the two time windows (300-400 ms; 450-500 ms – right after the syllables). We analyzed the main effect of the conditions performing a 3×2×2 mixed ANOVA with within factors Electrodes (F3, Fz, F4) and Stimulus (standard vs. deviant) and Age (6 MO vs. 10 MO) as a grouping variable in both legal standard and illegal standard conditions. Because of a possible violation of the sphericity assumption we used Greenhouse-Geisser (G-G) adjusted univariate tests where it was necessary [24]. Main effects are reported, effect size were calculated.

In the legal standard condition a Stimulus main effect was revealed confirming the presence of a positive mismatch response (MMR) in both time windows (300-400 ms: $F(1,46)=4.96$, $p<.05$, $r=.31$; 450-550 ms: $F(1,46)=4.76$, $p<.05$, $r=.31$). No Age effect ($p=.76$), or any other significant effect was found.

The statistical analysis did not reveal any significant effect in the illegal standard condition.

4. Discussion

Different ERPs were obtained in the different conditions (role as standard or deviant changed) with the two stimuli. While in the legal standard condition two MMRs were seen, though without any age difference, no significant difference was found in the illegal standard condition. If the responses were based on simple salient acoustic processing only, the automatic change detection reflected by the MMRs would rely on short-term (often called sensory) trace of the stimuli contributing to very similar responses in the two conditions, as the physical differences to detect were the same In contrast, repeating the legal stress pattern as standard enhanced the detection accuracy, so that the illegal pattern used as deviant could activate both a comparison with the long-term representation and with the actual trace of the salient acoustic feature of the stressed initial syllable Moreover, participants had difficulties in detecting stimuli when the illegal version served as standard and the legal one was contrasted with it. In the illegal standard condition we repeated a pattern that contrasted with the long-term representation even if only a weak template has emerged yet, so contrasting it with the legal form as deviant could rely neither on saliency nor on template. Therefore, we interpret our MMR data as electrophysiological evidence of a delicate developmental stage where saliency and emerging stress template representation show a particular dynamics in the first year of life.

Conclusion

Fitting in with the former electrophysiological results in case of other stress- and syllable-timed languages our results have strengthen the view that language specific environmental cues strongly influence the early sensitivity to suprasegmental patterns. Hungarian is a syllable-based language as French, with a word-initial stress pattern as German. Hungarian infants hear trochaic pattern more often, their result are in line with the German infants. Our results imply the existence of a possibly universal developmental pattern of rule abstraction. Relying on rhythmic segmentation procedure infants extract language-specific patterns from their environment, and start to generate expectations. The exact timing of the emergence of a long-term representation is still not clear, although the development of this processing seems to occur in a rather early stage of language acquisition. However, the crucial features of the assumed template as well as their interference with other acoustic attributes of spoken utterances are still unclear. There is a great difference of processing the cues depending on the native language characteristics. According to earlier results, stress based languages provide good conditions for early discrimination of stress, however there are controversial differences regarding syllable based languages [25]. Further investigational question is the nature of long-term stress representation in case of syllable-based languages in accordance with earlier results [26, 27].

Abstract

The study investigated the L2 speech rhythm of Chinese English speakers (L1 = Mandarin) using the metrics of ΔV, ΔC, %V, VarcoV, VarcoC, rPVI-C and nPVI-V. Five native speakers of American English and Mandarin were recruited to record five sentences in English. In addition, the Chinese speakers also recorded five Mandarin sentences. One-way ANOVAs were conducted to see if significant differences exist on each of the metrics among L1 English, L2 English and L1 Mandarin. Results show that the two L1's are categorically distinct on all metrics, conforming to the perceptually distinct rhythmicities of English and Mandarin. However, no significant differences were found between L1 and L2 English (which have different intuitive rhythmicities) on almost all the metrics, suggesting that the metrics are inadequate to capture the suprasegmental details that give the final make-up of speech rhythm. Finally, new directions of speech rhythm research and new applications of the rhythm metrics are sketched.

Index Terms: rhythm metrics, inadequacy, L2 English

1. Introduction

Most human communities have certain speech styles that are constrained to fit an external or imposed periodic intervals or beats, manifesting rhythmic patterns [1, 2]. This music-like feature makes poetry and nursery rhymes possible. Apart from this artificially created artistic feature of speech rhythm, languages, in their non-artistic forms, have repetitive patterns that are at least intuitively detectable. Moreover, rhythm is among the first acquired phonological features in first language acquisition. According to [3], "during the last trimester of intrauterine development, the fetus is known to be actively processing the sound of its mother's speech." After being filtered through the amniotic fluid (analogous to a low-pass filter), the fetus can only recognize the "melody and rhythm of the language" [3: 43]. Through the non-nutritious sucking technique, researchers discovered that neonates were able to distinguish rhythmically different languages from their mother tongue [4, 5, 6]. Perceptual experiments among adults and monkeys [7, 8, 9] also yielded similar results that languages of different rhythmicities are distinguishable, whereas rhythmically similar languages are not discernable.

Early researchers [10, 11] proposed two major classes of speech rhythm, i.e. "Morse-code" and "machine-gun" rhythm, which correspond to the widely used terminologies as "stress-timed" and "syllable-timed" respectively mentioned in [12: 54] as simple rhythm units. [13] adopted this dichotomy and claimed that languages either have isochronous feet (i.e. inter-stress intervals) or isochronous syllables (i.e. inter-syllable intervals). However, later investigations on the acoustic signals, nevertheless, failed to find exact isochrony in neither inter-stress nor inter-syllable intervals, for example [14], [15]. [16] even rejected "stress-" and "syllable-timing" as metalinguistic terms, due to the failure to find true isochrony instrumentally, and claimed that the rhythmic differences between languages were the result of phonologic rule idiosyncratic to different languages.

Departing from finding absolute syllabic or foot isochrony, researchers began to delve into the structural characteristics of languages and proposed that the two types of languages have varied degrees of vowel reduction and different complexities in syllable structures: Germanic languages such as English and German tend to reduce or centralized unstressed vowels and have more complicated syllable structures, whereas Romance languages such as French and Italian normally do not have obvious vowel reductions and have less syllable weights [14, 17].

[8] quantified this idea by calculating the durational standard deviations of vocalic intervals (linear composition of adjacent vowels) and consonantal intervals (linear composition of adjacent consonants) in an utterance (ΔC and ΔV respectively), and the proportion of vocalic duration out of the whole utterance (%V). Instead of measuring the global variability of interval durations, [18] and [19] averaged the durational differences between consecutive vocalic or consonantal intervals, and called their metrics the pairwise variability indices (PVIs). Moreover, the calculation of vocalic PVI is normalized (nPVI-V) to account for tempo changes, and the raw PVI (rPVI-C) is retained to calculate consonantal PVI. [20] also normalized the speech rate by taking the ratio between ΔC (or ΔV) and the mean duration of the intervals being analyzed (VarcoC and VarcoV). These rhythm metrics have fair success in categorizing canonical "stress-timed" and "Syllable-timed" languages (Germanic languages vs. Romance languages), for example [8], [19], [20], and [21]. Moreover, the metrics have been applied in L2 prosody [22, 23], pathological speech [24], and musicology [25, 26] as well.

However, whether these metrics are robust measures of speech rhythm is strongly debated [45, 46]. Based on different elicitation methods and materials, [48] analyzed the speech rhythm of six languages and concluded that the metrics scores were easily influenced by elicitation methods and materials, and therefore, unsafe to classify languages. Also, the metrics do not have much success in distinguishing intuitively very different L2 speech from the L1 in terms of rhythm [23]. This study aims to partially replicate [23] with different speakers to further examine the robustness the metrics on L2 speech.

2. Method

2.1. Informants

Five native speakers of American English and five native speakers of Mandarin Chinese participated in the study. The native English speech data were originally part of the pathology-free data set in [24], and were made accessible to the author after passing a web-based course "Protecting Human Research Participants" with a certificate issued by The

National Institute of Health Office of Extramural Research (USA). The Mandarin speakers (all Beijing natives) were third-year English majors in a Chinese university, and therefore were deemed post-intermediate or advance English learners. The average age of the speakers were 20 at the time of their participations, and the mean onset age of English learning is 13. They received a small remuneration upon the completion of the recording. Both groups read and recorded five English sentences; besides, the Chinese group also read and recorded five Mandarin sentences. Therefore, both between-subjects and within-subjects comparisons between L1 English, L2 English and L1 Mandarin can be made.

2.2. Materials

The English sentences were the ones used in [21, 22, 24] and the average length is 16.2 syllables per sentence. Mandarin sentences were created to reflect natural syllabic distributions in daily usage, i.e. less used syllables were avoided to frequent the sentences. Similar to the English sentences, distribution of stress and unstressed syllables was uncontrolled for [21]. Glides (/w/ and /j/) and liquids (/l/) were avoided because the boundary between an approximant and a vowel is hard to discern on the spectrogram [21]. The average length is 16.6 syllables à Mandarin sentence. The annex lists all the sentences.

2.3. Apparatus and procedures

The Chinese speakers were recorded individually in a quiet room. Before the recording started, they were given adequate time to familiarize the reading materials. They were required to read sentence by sentence at normal speed. In case of stuttering, they were asked to read the problematic sentence again until totally at ease with that particular sentence. In addition, they were encouraged to reduce the number of unnecessary pauses; however, they could pause at the end of a prosodic phrase, which is normal in daily speech. They were required to read Mandarin sentences first and English sentences next. All recordings were made by the Microtrack 24/96 solid state recorder with the Audio Technica 8531 headset microphone (Sampling rate = 48 kHz, bit-depth = 16). The sound files were later transferred to the computer hard disk for further analysis.

2.4. Segmentation and measurements

The author identified and labeled the vocalic and consonantal intervals by visual inspection of waveforms and wideband spectrograms displayed in Praat [27] with the assistance of audio signals. All speech data were segmented according to the segmentation protocol set forth in [21]. The durations of vocalic and consonantal intervals were measured using a Praat script. The metrics scores were calculated on the Excel spreadsheet, and statistical testing was done using R [28].

3. Data analysis and results

3.1. Descriptive statistics and data normality

Means and standard errors of the metrics scores across L1 English, L2 English and L1 Mandarin are presented in Table 1. Both Kolmogorov-Smirnov test and Shapiro-Wilk test were employed to assess data normality. Results of both tests all indicated that the data are normally distributed (all p's > 0.05, two-tailed, see Table 2 for test statistics), meeting the normality assumption of parametric statistics.

3.2. Inferential statistics

One-way ANOVAs were conducted on all the metrics scores, and the main effect of language was found on ΔC ($F(2, 12) = 46.03$, $p < 0.0001$, adjusted $R^2 = 0.8655$), ΔV ($F(2, 12) = 11.61$, $p < 0.005$, adjusted $R^2 = 0.6026$), %V ($F(2, 12) = 15.54$, $p < 0.0005$, adjusted $R^2 = 0.6751$), VarcoC ($F(2, 12) = 11.65$, $p < 0.005$, adjusted $R^2 = 0.6033$), VarcoV ($F(2, 12) = 15.32$, $p < 0.0005$, adjusted $R^2 = 0.6716$), rPVI-C ($F(2, 12) = 41.56$, $p < 0.0001$, adjusted $R^2 = 0.8528$), and nPVI-V ($F(2, 12) = 36.05$, $p < 0.0001$, adjusted $R^2 = 0.8335$). The effect sizes (R^2) are large according to [29]'s criterion.

Tukey HSD post hoc multiple comparisons (please also see Table 1 for reference) indicated that L1 Mandarin is significantly greater than L1 English on all the metrics except %V (significance levels range from $p < 0.05$ to $p < 0.0001$), and is significantly lower than L1 English on %V ($p < 0.0005$).

Similarly, L1 Mandarin is significantly greater than L2 English on all the metrics except %V (significance levels range from $p < 0.01$ to $p < 0.0001$). On %V, L1 Mandarin is

Table 1. *Means (std. errors) of the metrics. The wave line enclosed part are not statistically different (α = 0.05)*

	ΔV	ΔC	%V	VarcoV	VarcoC	rPVI-C	nPVI-V
L1 English	46.1004 (1.40705)	56.9879 (1.87970)	41.5554 (.83937)	59.3842 (4.17688)	48.9780 (2.16890)	67.5853 (.56329)	66.7095 (2.41580)
L2 English	52.6955 (3.12098)	59.0983 (1.91801)	44.6327 (.60266)	51.7630 (1.89642)	47.3238 (2.07840)	69.1565 (3.33706)	57.4366 (1.00518)
L1 Mandarin	36.8405 (2.16055)	34.5581 (2.20080)	51.5982 (2.01049)	35.6646 (2.77137)	35.2209 (2.34678)	41.7336 (2.37952)	39.5189 (3.00890)

Table 2. *Results of the Kolmogorov-Smirnov and Shapiro-Wilk tests (two-tailed).*

		ΔC	ΔV	%V	VarcoC	VarcoV	rPVI	nPVI
Kolmogorov-Smirnov Test	D	0.830	0.379	0.792	0.538	0.558	1.022	0.707
	p	0.497	0.999	0.557	0.935	0.914	0.247	0.700
Shapiro-Wilk Test	W	0.9702	0.9660	0.9433	0.9200	0.9469	0.9324	0.9461
	p	0.8616	0.7946	0.4254	0.1926	0.4765	0.2965	0.4657

significantly lower than L2 English ($p < 0.01$).

No significant differences were found on almost all the metrics except nPVI-V (all p's > 0.1) between L1 and L2 English. Nevertheless, L1 English is significantly greater than L2 English ($p < 0.05$) on nPVI-V.

To sum up, the rhythm metrics have fair success in distinguishing canonically "stress-timed" L1 English from "syllable-timed" L1 Mandarin. However, they were insensitive to the differences between L1 and L2 English, a result quite similar to [23].

4. Discussion

4.1. Metrics scores of L1 English and L1 Mandarin

As the results suggested, L1 English is significantly higher than L1 Mandarin on ΔV, VarcoV and nPVI-V. This conforms to the fact that English have higher degrees of vowel reductions in unstressed syllables. Besides, English has phonemic distinctions between tense and lax vowels. The concomitant length differences also contribute to the higher variability in vocalic interval durations. Likewise, the proportion of vocalic duration out of the whole utterance duration is significantly lower in English than in Mandarin, also because of the occurrence of reduced vowels.

Moreover, L1 English is significantly higher than L1 Mandarin on all the consonantal metrics (ΔC, VarcoC and rPVI-C), showing a greater durational variability in consonantal intervals. Such higher variability reflects the more complicated syllable structure of English. An English syllable can be as light as V, or as heavy as CCCVCCCC; whereas even the most complicated Mandarin syllable has a simpler structure of CGVN or CGVG (N refers to the nasal; G refers to the glide, which is often acoustically realized as part of a diphthong) [31]. Such results as shown by the vocalic and consonantal metrics scores have successfully distinguished between English and Mandarin, two typical languages showing "stress-" and "syllable-timing" rhythm, agreeing with previous studies, such as [19] and [23].

4.2. Insensitivity of rhythm metrics on L2 English and critiques of the rhythm metrics

Although rhythm metrics have fair success categorizing typical languages, it fails to measure the difference between L1 and L2 English as the results of this study indicate. Intuitively, L1 English and L2 English by Mandarin speakers are rhythmically different, and [23] even claimed that Chinese L2 English was impressionistically "syllable-timed". However, L1 and L2 English are not significantly different on all the metrics except nPVI-V.

Such results suggest that the participants in the study have achieved a high level of English learning, and have already acquired such phonological aspects as vowel reductions, weak forms, and syllable structures. It would not be difficult to imagine that if our Mandarin-speaking informants were beginners of English learning, the metrics scores would have been closer to those of Mandarin, because the L1 would have still taken a substantial proportion in the interlanguage system (see [32]'s Ontogeny and Phylogeny Model of L2 phonological development that sketches the chronological trajectories of L1, L2 and language universals in the interlanguage).

Insofar as syllable structure is concerned, inexperienced learners whose L1 has simpler syllable structure always epenthesize a vowel to break down a consonant cluster or delete one or more consonants to slim down a syllable onset or coda to fit the complex L2 syllable into a legitimate one of the L1 [32]. For example, [33] discovered that the epenthesis of the schwa was common among L1 Mandarin speakers' English production (e.g., /vɪg/ → [vɪ.gə]) to conform to the syllable structure of Mandarin. This way, longer consonantal intervals are truncated, resulting in lower durational variability of the consonantal intervals. Furthermore, [34] found that experienced and inexperienced L1 speakers of Mandarin and other languages differed in their production of lax/tense vowels in that experienced learners produced more accurate distinctions between pairs of vowels like /i:/ and /ɪ/. Since the segmental length difference is often a concomitant of lax/tense distinction, inexperienced learner's speech would manifest less variability in vocalic intervals, resulting in vocalic metrics scores more similar to those of Mandarin.

That experienced L2 English learners have acquired the syllable structure and segmental length difference can easily hoax the metrics that rely solely on interval duration variability. Therefore, L2 English is classified as similar to the L1 variety, although it sounds rhythmically different from L1 English. Hence, the metrics are not sensitive enough to capture such suprasegmental characteristics of L2 English at all stages of interlanguage development, at least for Mandarin speakers as shown in this and [23]'s studies.

At the methodological level, differences in interval duration variability are not the whole story of speech rhythm, thus using the metrics as the litmus test of speech rhythm overlooks many aspects in the speech signal. Rhythm (and not just speech rhythm) is characterized by the occurrence of prominent elements at regular or semi-regular intervals. In human speech, potential cues to prominence include f0, intensity, spectral quality and duration, and languages may be different in the selection of the cues. For instance, [35] discovered that f0, intensity and duration all play a role in cueing prominence as perceived by native English speakers; however, only f0 is functional in cueing prominence in Mandarin. In a preliminary attempt to examine the difference of other cues between L1 English, L1 Mandarin and L2 English, the author analyzed the same speech data in the present study in terms of syllabic intensity (measured as dB_{SPL}) variability, and found that the difference between L1 Mandarin and L2 English was due to chance alone; however, both L2 English, L1 Mandarin were significantly different from L1 English [36], suggesting that other prosodic aspects should be included in speech rhythm research.

4.3. New directions of speech rhythm research

Apart from interval durations and intensity variability, f0 is proved effective to signal prominence or has the effect of changing the perceived duration [37, 38, 39, 40, 41]. [42] discovered that native speakers of Swiss German and Swiss French/Metropolitan French differed in the weighting of pitch cues and durational cues in perceived rhythm. [43] incorporated the language-specific weighting values of pitch and duration into combined pitch-duration PVI, and found more similar scores than otherwise would be if calculated by traditional PVIs. This suggests that perceived rhythm may not be that divergent across-linguistically if the calculation is

scaled by language-specific weightings of different acoustic cues.

Moving away from the duration-based approach to speech rhythm, [44] adopted an amplitude-based approach that examines the amplitude modulation in the speech envelope, which is modeled as a nested hierarchy with tiers representing different prosodic units, such as feet and syllables, and the hierarchy captures different metrical patterns in nursery rhymes as different phase-locked patterns between foot amplitude modulations and syllable amplitude modulations, suggesting a methodological innovation in speech rhythm research.

4.4. New applications of rhythm metrics

Although rhythm metrics are strongly debated in speech rhythm research [45, 46], they are potentially useful in the forensic milieu, because the metrics scores manifest high individual idiosyncrasies [46, 47, 48]. With explicit emphasis on forensic applications, a series of research done at the Phonetics Laboratory of Zurich University proved that rhythm metrics are useful in speaker identification [49, 50, 51, 52].

5. Conclusion

The study investigated the robustness of rhythm metrics among L1 English, L2 English and L1 Mandarin. The results indicated that L1 English and L2 English were not significantly different on almost all the metrics, although they are impressionistically dissimilar. Such results conform to [23]'s findings. The results indicate that rhythm metrics are not adequate to quantify L2 suprasegmental characteristics and speech rhythm in general. For further research, a larger sample size including L2 learners of Mandarin who speak English as L1 is also desirable. Finally, new directions of speech rhythm research and new applications of rhythm metrics were briefly introduced.

6. Annex

6.1. English sentences

1) The supermarket chain shut down because of poor management.
2) Much more money must be donated to make this department succeed.
3) In this famous coffee shop they serve the best doughnuts in town.
4) The chairman decided to pave over the shopping center garden.
5) The standards committee met this afternoon in an open meeting.

6.2. Mandarin sentences

Standard Romanization [30], phonetic transcriptions, and English translations are shown:

1) *Dàjiě jīntiān zǎochén gēn māma qù zhèjiā chāoshì mǎi jiǎozi.* /ta tɕiə tɕin tʰian tsau ʈʂʰən kən mamə tɕʰy ʈʂɤ tsia ʈʂʰau ʂɻ mai tɕiao tsɥ/
   'My sister went to the supermarket with my mom this morning to buy some dumplings.'
2) *Tā hǎoxiǎng tīng dàjiā chàng nàbù diànshìjù de zhǔtí qǔ.* /tʰa xau ɕiaŋ tʰiŋ ta tɕia ʈʂʰaŋ na pu tian ʂɻ tsy tə ʈʂu tʰi tɕy/
   'He wants to listen to the theme song of that TV show sung by everybody.'
3) *Fùjìn zhèjiā kāfēitīng mài quánshì zuìhǎo de zhīshì dàngāo.* /fu tɕin ʈʂɤ tɕia kʰa fei tʰiŋ mai tɕʰyɛn ʂɻ tsui xau tə ʈʂɻ ʂɻ tan kau/
   'The coffee shop nearby serves the best cheesecakes in town.'
4) *Xiàozhǎng juédìng jiāng xuéxiào de zúqíuchǎng chóngxīn fānxīu.* /ɕiao ʈʂaŋ tsyɛ tiŋ tɕiaŋ ɕyɛ ɕiau tsu tɕʰiəu ʈʂʰaŋ ʈʂʰuŋ ɕin fan ɕiu/
   'The schoolmaster decided to refurbish the school pitch.'
5) *Tā gēn tóngxué shuōhǎo jīntiān zǎochén zài Kěndéjī ménkǒu jiànmiàn.* /tʰa kən tʰuŋ ɕyɛ ʂuo xau tɕin tʰian tsau ʈʂən tsai kʰən tɤ tɕi mən kʰou tɕiɛn mian/
   'She and her classmates decided to meet at the KFC franchise this morning.'

Please note that the non-IPA symbols [ɻ] and [ŋ] represent the rhotacized and non-rhotacized non-open central unrounded apical vowels in Mandarin [53].

7. Acknowledgements

I thank Dr. Satsuki Nakai in the School of Philosophy, Psychology and Language Sciences at The University of Edinburgh for her suggestions on the study and for having helped me with the acquisition of the native American English speech data. Thanks also go to Prof. Wu Hongyun in the School of Foreign Languages at Renmin University of China for providing me with working space during data collection, and for helping me find Chinese participants.

Abstract

This paper examines how pitch range declination and reset contribute to turn-taking organisation. This is part of a broader study of voice prosody, i.e., how pitch, voice quality and temporal features combine for various prosodic functions, both linguistic and paralinguistic. The present study first investigates the effect of the speech unit position in a turn on its pitch range. We also test the effect of the number of speech units in a turn as well as the turn duration on the turn-initial f_0 peak height at the beginning of the turn. Our results suggest a pitch range declination trend between the Initial and Median speech units of a turn but a violation of this declination for the Final units of the turn. They also demonstrate that the higher the number of speech units in a turn or the longer the turn, the higher the turn-initial f_0 peak height. We discuss our findings along the debate on Projection and Reaction theories and that of Hard vs. Soft pre-planning of speech production. We address how these findings may be useful to formulate a holistic model of prosody and to enhance human-machine interactions.

Index Terms: pitch range, declination, reset, pause, gap, turn-taking, reaction vs. projection theories, hard vs. soft pre-planning.

1. Introduction

Spoken interaction is a joint activity where all participants are involved in the co-construction of meaning and in the establishment and maintenance of social relationships. Turn-taking organisation is an instance of such coordination, for which participants agree on who speaks, when to talk, listen, hold and take turns [1].

Depending on the situational context, turn-taking (employed herein as speaker change) can be realised with a silent interval (or gap), no-gap-no-overlap (when the start of one speaker's turn perfectly coincides with the end of the other speaker's previous turn) or with a transition overlap (when the start of one speaker's turn overlaps with the other speaker's previous turn, excluding backchannels). In this organisation, turn-holding (employed herein as speaker hold) corresponds to several utterances of the same speaker within a turn, that are separated by a silent interval (or pause).

To manage turn-taking, speakers would produce, perceive and react to a set of signals (prosodic, pragmatic, syntactical, semantical, visual) (*Reaction Theory* e.g., [2, 3, 4, 5, 6]) or would anticipate or project the end of the turn from contextual and structural information (*Projection Theory*, e.g., [1, 7, 8]). Within the frame of Reaction Theory, it has been reported that, in many languages, a level pitch accent or a flat contour at the end of an utterance is indicative of a turn-holding while any other terminal contour (such as rises and falls) is indicative of turn-taking [4, 9, 10, 11, 12, 13].

Works in the study of prosody have often reported that, in read speech, fundamental frequency declines over the course of an utterance [14, 15, 16]. Declination is thought to be the by-product of some physiological processes (e.g. subglottal pressure [14, 17], activity of the laryngeal muscles [18], tracheal pull [15]) or 'controlled' by the speaker and may have some specific linguistic and paralinguistic functions. It may however be violated in certain instances of terminal rises associated with questions or hesitations [19].

Evidence of f_0 declination at supra-utterance levels (e.g. above the level of the Intonation Unit) has also been reported in many languages, with paragraph initial utterances of spoken texts having higher and wider pitch range than paragraph final utterances [20, 21, 22, 23, 24]. This pitch range declination over the paragraph (or f_0 supra-declination) may participate in signaling the organizational and hierarchical structure of the discourse (e.g. signaling topic changes). [24] reported, for Dutch, that the lower a text segment is embedded within the hierarchy of a text, the lower the pitch range. [23] observed that, in French, intonation units at the beginning of a paragraph have a wider pitch range than medial and final position intonation units, the difference being greater between the initial and medial units than between the medial and final units.

We hypothesize that, in interactional speech, f_0 declination can also be observed, both at the utterance and at the turn (supra-utterance) level, and that it plays an important role in turn-taking organisation. Speech units in conversational speech may be embedded within turn units, as speech units in read speech are embedded within paragraph units. As suggested by Couper-Kuhlen [25], describing data of conversational speech, a downward shift or decrease in f_0 across successive utterances by the same speaker may indicate that they belong to the same turn, while an upward shift or increase would signal turn changes. In particular, she suggests that : "*Beginning an intonation phrase relatively high in one's voice range allows room for subsequent intonation phrases to be positioned lower and thus affords the possibility of declination units, which can be used to structure a 'big package'. Because high onsets initiate pitch declination units, they can be thought of as projecting 'more to come' in this case, further intonation phrases within the declination unit. In this sense, they provide prospective prosodic cues to the 'big package' that is under way*" ([25]:43).

It has been further argued that the height of the f_0 peak at the beginning of an utterance is indicative of the utterance length, with longer utterances being marked by higher f_0 peaks [26, 27, 28]. Similarly, we hypothesize that, in interactional speech, the first unit of a speaker's turn may be marked by a pitch reset whose height depends on the number of speech units within the turn or on the turn duration. Note that the relation between initial f_0 peak height and utterance length is still controversial as other studies did not observe any [29, 30].

In this paper, we investigate (i) whether pitch range declination operates in interactional speech at the level of the turn and (ii) whether pitch reset at the beginning of a turn depends on the number of utterances within the turn or on the turn length.

We test two hypotheses:

- **Hypothesis H1**. Initial Inter-Pausal Units (IPUs) within a turn have a higher and wider pitch range than Median and Final IPUs. To test this, the effect of the IPU's position (Initial/ Median/ Final) in a turn on the IPU's pitch range is investigated.
- **Hypothesis H2**. The f_0 peak at the beginning of a turn is higher when the number of IPUs in the turn is larger or when the turn is longer. To test this, we investigate the effect of the number of IPUs in a turn and the turn duration on the turn's initial f_0 peak.

It should be noted that most prosodic research on turn-taking has tended to focus on the duration of silent intervals, and on the chunk of speech preceding these intervals. In examining f0 declination trends, we focus particularly on the initial portions of utterances, as well as the relationships among the utterances of a turn. This work complements parallel work on the final intonational contours in the same data [41] as well as ongoing research exploring voice quality and temporal features and their correlation with melodic characteristics.

2. Experiment

2.1. Data

The speech data was extracted from a corpus of task-oriented dyadic interactions in Irish English [31]. It consists of 6 gender-paired interactions (involving 6 female and 6 male speakers). The interactions are based on a shipwreck scenario game where participants are presented with 15 items and are given 10 minutes to rank them in order of usefulness to their survival. Recordings were carried out with participants in separate isolation booths using a professional Neumann microphone connected to an Apple Mac-based Digidesign Pro-Tools Mbox2 recording system. The audio signal was digitised at 96 kHz/24 Bit and recorded using Pro-Tools software as two separate audio streams. Audio was then downsampled to 16 kHz/8 Bit.

2.2. Annotation and measurement

2.2.1. Annotation

The data was annotated in terms of speech units and silences automatically, similarly to [32]. A binary voice activity detection (VAD) was carried out on both speaker channels for each dyadic interaction, using the VAD algorithm proposed in [33].

Pauses, gaps, no-gap-no-overlaps (NGNO) and transition overlaps (TOV) were determined from the binary VAD on both speaker channels. A schematic output of the annotation is shown in Fig. 1. A minimum duration for pauses was set to 100 ms (threshold set empirically to avoid speech events like plosives to be annotated as pauses), which means that every speech unit separated by a pause of less than 100 ms were chunked together into a single speech unit. Note that decisions on such threshold settings may significantly affect the resulting duration distributions [34]. This automatic procedure resulted in 176 gaps, 121 TOV and 498 pauses.

Herein, TOV were excluded from the analyses. Speech units separated by a pause are referred to as Inter-Pausal Units (IPU). A turn is defined as a speech unit composed of one or several IPUs. The terms 'turn-taking' and 'speaker change' are used interchangeably. No annotation of backchannels (BC) have been included, which means that BC have been automatically annotated as speaker changes.

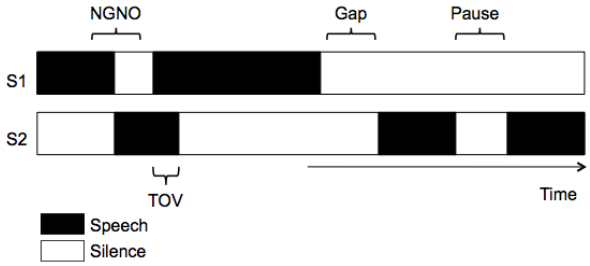

Figure 1: Schematic of a dyadic conversation between speaker 1 (S1) and speaker 2 (S2), illustrating occurrences of pauses, gaps, no-gap-no-overlaps (NGNO) and transition overlaps (TOV).

In the data, turns are composed of one to thirteen IPUs (mean=2.5, sd=2.12). Most common turns contain one IPU (40% of the data). To test Hypothesis H1, we excluded turns composed of one IPU as pitch range declination across several IPUs cannot be investigated in such turns. We also excluded turns composed of more than six IPUs as they are underrepresented in the data (less than 3%). From the resulting subset, IPUs were labelled Initial, Median and Final according to their position in a turn. In total, 292 IPU were labelled Initial, 243 Median and 311 Final. To test Hypothesis H2, the subset of selected data consisted of turns composed of one to six IPUs.

2.2.2. Measurement

Pitch range corresponds to the tonal space actually used in speech and is commonly described along two dimensions : its level (height) and span (range) [19]. Pitch range declination corresponds to the f_0 downward shift or decrease in pitch range across successive utterances within a turn and can be compared to the concepts "paragraph declination" [35], "supra declination behavior" [22] or "superordinate f_0 declination" [36] used in the literature for read speech.

Different acoustic measurements have been used to estimate pitch range level and span. Descriptive measurements such as f_0 mean and median based on f_0 values extracted every 0.01s on voiced segments or based on f_0 inflection points (or tonal targets, e.g. peaks and valleys) have been employed to account for utterance f_0 level. Measurements such as the difference between f_0 maximum and minimum values of utterances, f_0 95th and 5th percentiles, f_0 90th and 10th percentiles of utterances as well as f_0 standard deviation have been used to account for utterance f_0 span.

In this work, for each IPU and turn, standard descriptive measurements (f_0 maximum, minimum, median and the difference between f_0 maximum and minimum), representative, respectively, of an IPU's and a turn's initial f_0 peak, final valley, pitch range level and span, were computed (cf. Table 1). All these measurements are given on a logarithmic scale, the octave scale (i.e. log2(Hertz)), which is equivalent to the semitone scale. To account from cross-speaker differences, the data was normalized using z-scores. Pitch measurements were extracted using the phonetic software Praat [37]. To avoid possible pitch tracking errors at the pitch curve extrema, and enable their auto-

Features	Measurement	Abbreviation
initial f_0 peak	maximum f_0	$f_0$max
final f_0 valley	minimum f_0	$f_0$min
pitch level	median f_0	$f_0$med
pitch span	$f_0$max$-f_0$min	$f_0$maxmin

Table 1: Features computed for each turn (T) and Inter-Pausal Unit (IPU). Initial f_0 peaks are extracted at the beginning of each T and IPU, final f_0 valley at the end.

matic extraction, pitch floor and pitch ceiling, when creating a Pitch Object, were automatically adjusted to the speaker's pitch range (cf. [38] for more details).

2.3. Statistical analyses

A series of statistical analyses were carried out to test the effect of the independent variables (i.e. IPU position and number of IPUs in a turn) on the dependent variables (i.e. pitch range measurements). The analyses included a series of linear mixed models [39]. In our models, the position of the IPU (IPU-POS), the number of IPUs in a turn (N-IPU) and the duration of a turn (TDUR) were treated as fixed factors. Speaker was included as a random factor to take into account inter-speaker variability. The p-values were calculated using the method of Monte Carlo sampling by Markov chain (pMCMC = Monte Carlo Markov Chain [40]). In all our models, significance is set at a pMCMC $\alpha < 0.01$.

3. Results

3.1. H1 - Declination at the turn level

The effect of the speech unit position (IPU-POS) - 3 levels, Initial/ Median/ Final - on the IPU's pitch range is investigated. We assume that Initial IPUs have higher and wider pitch range than Median and Final IPUs. For the dependent variables $f_0$min, $f_0$max, $f_0$med and $f_0$maxmin, IPU-POS is tested as fixed factor and SPEAKER as random factor.

Results reveal a significant effect of IPU-POS on $f_0$min, $f_0$max, $f_0$med and $f_0$maxmin, being respectively higher and wider for Initial-IPUs than for Median-IPUs (respectively : t= -2.102, pMCMC$<$ 0.01; t= -1.921, pMCMC$<$ 0.01; t= -1.129, pMCMC$<$ 0.01;t= -1.316, pMCMC$<$ 0.01). This suggests a pitch range declination trend (i.e. lowering and narrowing of the pitch range) between the Initial and Median IPUs of the turn. The declination is however violated at the end of the turn, as it may be confounded with instances of rises associated with certain question forms or hesitations.

Two examples of pitch range declination trend observed in the data are given in Fig. 2 and 3. In Fig. 2, the turn is characterized by a declination trend over the three IPUs, the final IPU having a lower and narrower pitch range than the preceding IPUs. In Fig. 3, the turn is characterized by a declination trend over the first two IPUs which is violated on the final IPU, the latter having a higher pitch range than the preceding IPU.

3.2. H2 - Turn's initial f_0 peak as a function of the number of IPUs in a turn and turn duration

We investigate the effect of the number of IPUs (NIPU) in a turn and the turn duration (TDUR in log) on the turn's initial f_0 peak. We assume that the f_0 peak at the beginning of a turn is higher when the number of IPUs in the turn is larger or when the turn is longer. The models include NIPU and TDUR as fixed factor and SPEAKER as random factor.

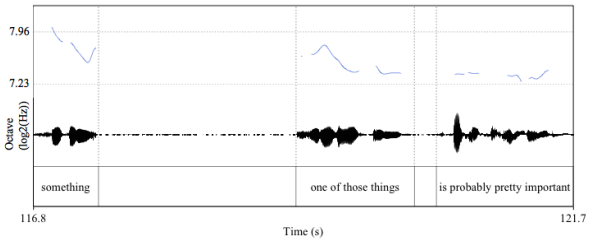

Figure 2: Example of a turn composed of 3 IPUs, uttered by a female speaker.

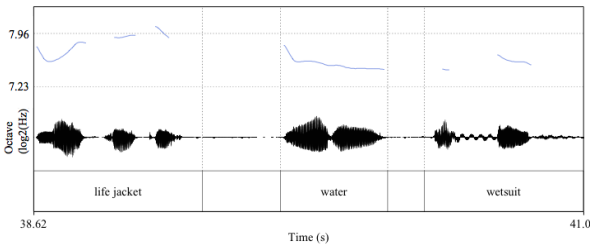

Figure 3: Example of a turn composed of 3 IPUs, uttered by a female speaker.

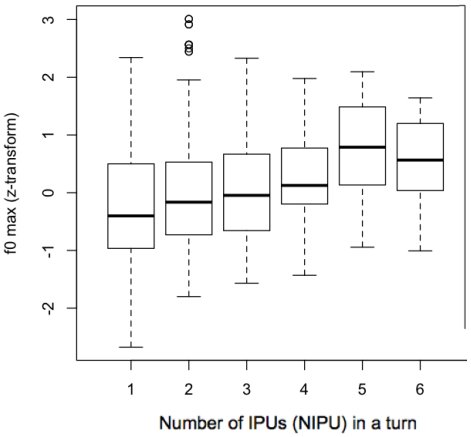

Figure 4: Turns' initial peaks (or $f_0$max) according to the number of IPUs in a turn.

Results reveal a significant effect of NIPU (pMCMC$<$ 0.01) and TDUR on $f_0$max (t=12.208, pMCMC$<$ 0.01). The higher the number of IPUs in a turn and the longer the turn, the higher the initial f_0 peak of the turn. Figure 4 indicates how the height of the f_0 peak increases with the number of IPUs in a turn. These findings suggest that the initial f_0 peak of a turn may be a salient cue in projecting the end of a turn. They corroborate earlier studies that observed a strong relation between an utterance's f_0 peak height and the utterance duration.

4. Discussion and conclusions

In this paper, we have investigated how pitch range declination and reset contribute to turn-taking organisation. We have

first tested the hypothesis H1 that Inter-Pausal Units in dialogue speech are embedded into turns as utterances in read speech are embedded into paragraphs, in such a way that Initial IPUs are higher and wider in pitch range than Median and Final IPUs. Our results suggest a declination trend (lowering and narrowing of the pitch range) between the Initial and Median IPUs of the turn, but not over the final IPU.

In a parallel study, using the same data, we have shown that 49% of units preceding a change of turn are declaratives, 35% questions and 10% backchannels and that these communicative types are associated with a falling tune (in 67% of the cases) or a low-rise tune (in 29% of the cases) [41]. The proportion of rises is the lowest in Declaratives (10%), it is higher in Incomplete Declaratives and WH questions (17%), and is the highest in Backchannels (24%). In Incomplete Questions, the pitch is predominantly rising (only 12% of samples have falling pitch). In Yes/No Questions, both falling and rising pitch pattern is used, with a slight preference for rises (about 54% in total).

Taking into account the effect of the utterance communicative type (e.g. declarative, incomplete, Wh-question, Yes/No question, hesitation, backchannel) on pitch modifications will allow us to better understand its singular role in turn-taking organisation. Pitch variations convey multiple functions in speech, e.g. signaling questions vs. statement, focus, topic changes and turn-taking, as well as in the signaling of intentions, attitudes and affect. The many linguistic functions of f0 changes were not controlled in the present experiment and may explain the variability encountered in the data. Future work will investigate the role of pitch variation at different levels, and will further attempt to link these to other prosodic variables, voice quality and temporal structure.

[23] observed that, in read speech, the difference in pitch range between the Initial and Medial units of a paragraph is greater than between the medial and final units. The present data show similar results. It would be interesting to investigate whether this pitch range 'break' between the initial and median units is indicative of a turn length, therefore may be used to signal turn change.

We have then tested the Hypothesis H2 that the f_0 peak at the beginning of a turn is higher when the number of IPUs in the turn is larger or when the turn is longer. Our results show that the higher the number of speech units in a turn and the longer the turn, the higher the initial f_0 peak height. This corroborates earlier findings on the relation between the initial f_0 peak height and the duration of an utterance [26, 27, 28].

These findings generally raise the debate of Hard vs. Soft pre-planning of speech production. On the one hand, it is proposed that speakers would be able to plan f_0 contours at a phrase level by adjusting the f_0 height at the beginning of the utterance to the utterance length. A higher initial f_0 may suggest a look-ahead or preplanning mechanism, by which utterance initial f_0 values are raised proportionate to utterance length [29]. On the other hand, it is suggested that speakers may proceed at a more local level, accent by accent. A lower f_0 at the end of the utterance may mean that adjustment is made on-the-fly. Our preliminary results suggest that speakers may plan their turn, adjusting its f_0 initial peak according to the turn length.

Overall, our findings suggest that pitch at the beginning of a turn and the break between the Initial and Median IPUs of a turn may contribute to turn-taking organisation. This means that not only syntactic and pragmatic information but prosody as well, appears to be used in projecting a speaker change.

We believe that both Reaction and Prediction theories can account for the underlying functioning of turn-taking organisation. As explained in [42], "*Redundancy is a well-studied and recurring principle of human language in use on virtually every level, and it is likely that a phenomenon as important as the taking of turns is orchestrated by a number of redundant control methods*" ([42]:566). In this view, we propose that speakers may anticipate the end of a turn based on the f_0 peak height at the beginning of the turn (as well as other signals) and may react to the lately uttered signals, adapting on-the-fly, by readjusting predictions if needed.

These findings could be directly applied to the modeling of human-machine interactions. A lot of work has been lately dedicated in improving the flow of conversation between a human and a computer or virtual agent. Standard methods have used a fixed duration threshold for the computer to begin speaking after the human interlocutor stops [43]. This strategy however does not really mirror what is usually done by humans. They, indeed, rather than wait for a silence to come, rely on syntactic, prosodic, pragmatic as well as visual cues to take the turn. Some studies have therefore investigated the use of these cues (prosodic and syntactic mainly) just before a silence to predict a speaker's hold or change [44].

In a parallel study [41], using the same data, we have shown that the combined discriminative power of functional and intonation labels (derived from speech-chunks immediately preceding pause and gap intervals) allows for differentiating turn-taking from turn-holding (mean classification error of 15%). In the present study, our results suggest that prosodic information at the beginning of a turn may also be a relevant cue to manage the conversation flow. The height of the initial f_0 peak of a turn could be used by a system to predict the end of the turn and the signals at the end of the turn (such as a final rise or fall vs. a flat tone) may be used to readjust prediction. This will be particularly addressed in our future classification experiments.

Abstract

This paper deals with the adaptation of AuToBI annotation for speech synthesis purposes. AuToBI is a tool that automatically determines and classifies the standard ToBI labels for American English. AuToBI annotation is performed word-by-word. However, for speech synthesis applications that use various layers of linguistic annotation (syntax, semantic information and prosody structures) and, in particular, for the detection of the correlation between the information structure and prosody, a labeling of intonation patterns at the intonational phrase level is essential. We present a rule-based procedure for initial AuToBI annotation and its adaptation a phrase-based annotation, avoiding thus a post-processing stage of the extracted labels. To validate our proposal, the outcome of the procedure is compared with manual annotation and with patterns prognosticated by information structure–prosody correlation argued for by main stream theories.

Index Terms: prosody, annotation, ToBI, AuToBI, thematicity, theme, rheme, speech synthesis.

1. Introduction

Prosodic features, such as rhythm, intonation, and stress are instrumental for the naturalness of speech and play thus an important role in the context of the "semantics–syntax–intonation" language interface in all speech-oriented Natural Language Processing (NLP) applications, especially in speech synthesis. The importance of prosody in NLP led linguists and speech technologists establish annotation standards for labeling prosodic events. One of them is ToBI (Tone and Break Indices) [1], a widely used convention thanks to its easy adaptation as a markup language for open-source speech synthesizers such as Festival [2].

The decade following the introduction of the ToBI convention, speech technology experienced an increasing interest in automated prosody labeling, mainly to avoid the time-consuming procedure of manual annotation.[1] As a consequence, a rather exhaustive number of works focused their interest on the automatic detection and annotation of prosodic events in speech; see, among others, [4, 5, 6, 7, 8]. One of the most well-known of them is AuToBI [9] for automatically detecting and classifying ToBI labels for American English. However, AuToBI labels prosody word by word, while what is required for NLP applications is segmentation at the phrase level that is based on a simplified converging model. Word-by-word segmentation is far too detailed to facilitate the connection between the other layers of annotation of the abovementioned "semantics–syntax–intonation" interface, especially when dealing with information structure [10].

In this paper, we discuss a rule-based procedure for the adaptation of AuToBI's word-by-word output to the needs of expressive speech synthesis, with the goal to be able to automatically establish a link between the information structure of an utterance and its prosody structure. The procedure groups AuToBi's word labels into intonational phrases (IPs) and proposes a single intonation pattern for each IP on the grounds of a set of criteria based upon the more detailed word-by-word labeling. Note, however, that we do not aim to address the general problem of phonologic/acoustic recognition of intermediate intonational phrases ('level 3' in ToBI terminology) that still pose a challenge for the state of the art; we merely aim to fit the needs for our research on the "semantics–syntax–intonation" interface.

The corpus that we label in our experiments is also manually annotated with the basic categories of the information structure theme and rheme (referred to as *thematicity*), which allows us to establish the correspondence between the prosodic patterns and themacity structures. This correspondence is used to validate our proposal of automatic prosodic pattern annotation and to contrast our work with the classical work of Steedman [10], which states that theme tends to be associated to the patterns L+H* and LH% (a clear increasing Low-High pattern), while rheme tends to be associated to the patterns H*L and H*LL% (clearly decreasing High-Low)—although both theme and rheme may be associated with other patterns as well.

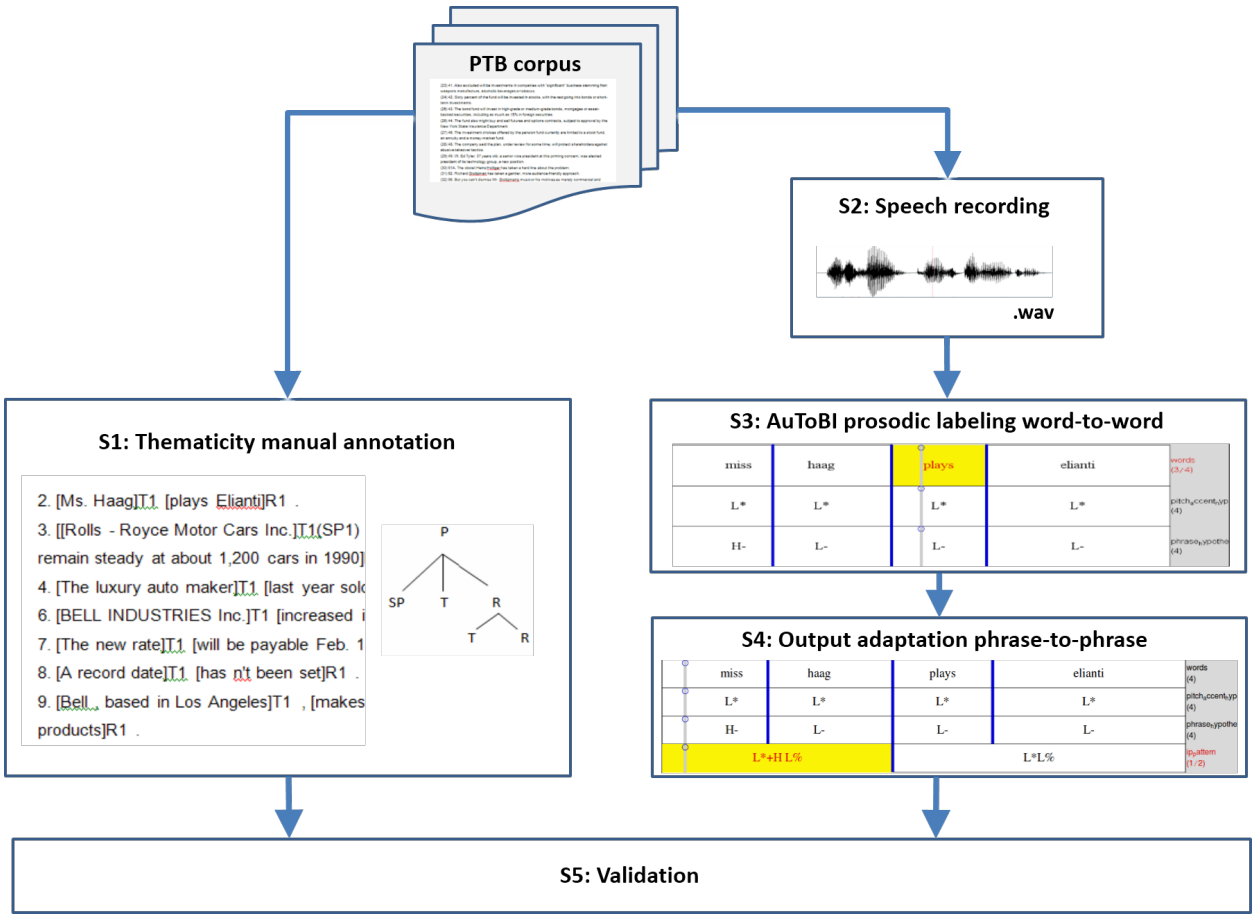
The paper is structured as follows. Section 2 describes the complete procedure of automatic annotation of phrase-based prosodic patterns, which involves both the AuToBI system and its adaptation to speech synthesis applications. Section 3 presents the annotation results and its validation through themacity structures, before Section 4, finally, summarizes the conclusions we draw from our preliminary work.

2. Annotating the Information–Prosody Interface

Our annotation procedure consists of five different stages, as shown in Figure 1: (1) thematicity annotation, (2) corpus recording, (3) AuToBI annotation, (4) output adaptation, and (5) validation of the results using manual reference annotations and the outcome of stage (1). In the first stage (S1), a reference corpus is annotated with the information structure (as pointed

[1]Syrdal et al. [3] estimated that experienced labelers could need between 100 and 200 times of the real time speech episode to annotate it.

Figure 1: *The stages of the proposed prosodic pattern annotation procedure and its validation.*



out above, we focus on the thematicity categories theme and rheme). In the second stage (S2), the reading of the corpus (or, as in our case, of a subset of the corpus) by a native speaker of American English is recorded. In the third stage (S3), the recorded speech is automatically labeled with the AuToBI tool. In the fourth (adaptation) stage (S4), the AuToBI word-by-word labels are transformed into IP pattern labels in accordance with our criteria. A final stage (S5) is used to assess the obtained patterns by comparing them with manual annotations and validate them with Steedman's theory [10] on the correlation between prosody and theme/rheme structures.

Next, stages S1 to S4 are described in more detail; the validation stage S5 is presented in a separate section that follows.

2.1. Thematicity annotation stage (S1)

The annotation of thematicity is assumed to be carried out manually over a plain text containing the consecutive sentences. In our experiments, this has been done in a series of blocks of about 40-50 sentences of a fragment of the Wallstreet Journal corpus extracted from the Penn Treebank [11], in accordance with the hierarchical thematicity structure of the Meaning-Text-Theory (MTT) [12].[2] In Figure 1, square brackets mark each communicative span (cf., e.g., '[. . .]T') and parentheses annotate embedded thematicity (cf., e.g., '[. . .]T(R)'). The annotators took into account the context (i.e., the previous sentence), but assumed an interpretation in which none of the elements is focalized or emphasized. The annotation was done by two groups of annotators (two in each group), who discussed in plenum their corresponding annotations to achieve a consensus and to refine the annotation guidelines.

For the validation of the IP pattern annotation procedure, the MTT-oriented annotation has been simplified to match Steedman's theme/rheme structures.

2.2. Speech recording stage (S2)

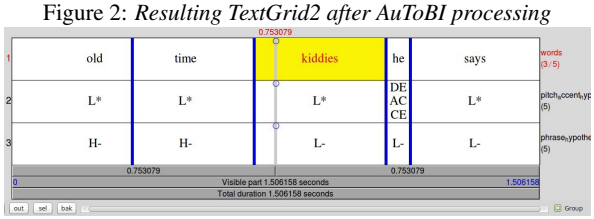
Within the speech recording stage, a subset of the corpus annotated in S1 with thematicity has been recorded. In our experiments, a non-expert native speaker of American English (not involved in the study) was instructed to read a selection of 109 sentences. The sentences contained varied information structure patterns, such that they were prosodically interesting for our study. The recording was done under professional conditions. The sentences were analyzed in order to create a reduction model from the AuToBI output to the IP level to be applied to the entire corpus.

[2]For details about the annotation criteria, see [13].

2.3. Automatic prosodic annotation stage (S3)

This stage consisted in segmenting audio files into words as required by AuToBI. This has been done to automatically process AuToBI's labeling task using Praat [14] and thus generating a TextGrid file for each audio file. Results were saved as TextGrid2 (see Figure 2), which has three interval tiers: the manually segmented word tier and two interval tiers generated automatically by AuToBI, one for the pitch accents and the second for the boundary tones.

Figure 2: *Resulting TextGrid2 after AuToBI processing*



2.4. AuToBI output adaptation stage (S4)

In spite of the fact that AuToBI meant a great step forward in the systematization of prosodic labeling, it has some major constraints for our descriptive approach, as has already been mentioned above.[3] Consequently, the information from AuToBI needs to be manipulated to meet our description requirements for intonational phrases within the information structure framework. For this purpose, we established a limited and manageable inventory of intonation patterns at the phrase level based upon the ToBI annotation convention [16]. We are labeling one main pitch accent (PA) and the boundary tone in each IP. Furthermore, while in the standard ToBI convention [17] four tiers of data are foreseen, namely a tone tier, an orthographic tier, a break tier and a miscellaneous tier, we are only making use of the tone tier, as reduction of detail is prioritized. The collection of patterns we currently use comprehends the items and their possible combinations summarized in Table 1.

Table 1: Patterns set by Pierrehumbert and Hirschberg [16].

pitch accents	L*, H*, L*+H, L+H*, H*+L, H+L*
boundary tones	L%, H%

This limited collection of twelve intonation patterns certainly does not cover all the possible natural tonal realizations of utterances, but it is expected to meet our initial requirements for a model to predict prosody events in speech synthesis applications. The integration of several layers of analysis is assumed to aid to solve the challenge of the prediction of prosody events in speech synthesis applications in that it caters for main pitch accents within the intonational phrase and relevant boundary tones at a clause level.

Our automatic adaptation stage can be envisaged as a loop of three steps over all sentences of the annotated corpus. The steps are: (1) Initial step, (2) Reduction step, and (3) Prerevision step.

[3] Some work has been done by Rosenberg [15] on the incorporation of intonational phrase boundaries into syntactic parsing for automatic summarization, but there is still a great deal of work to be done in this direction.

1. **Initial step.** This step consists in matching the output Textgrid from AuToBI to the sentence annotated in terms of theme/rheme. The result is a txt file (see Figure 3) that contains the following fields:

   - Id number of sentence
   - Chain of words
   - Communicative label
   - Chain of prosodic labels for those words

Figure 3: *Resulting txt matching AuToBI to thematicity labels*

```
Id.S.   Words                   AuToBI

0196    old time kiddies        R1      L*H-L*H-L*L-
0196    he says                 SP1     DEACCENTEDL-L*L-
0196    he                      T1(SP1) DEACCENTEDL-
0196    says                    R1(SP1) L*L-
```

2. **Reduction step.** The greatest part of the prosodic analysis is carried out during this step of the process. The strings of patterns from Step 2 are envisaged from the perspective of the intonational phrase in the pursuit of establishing not only the possible reduction models, but also the communicative and prosodic criteria to segment long utterances into smaller units. These units can help to draw a suitable intonational curve for speech synthesis purposes. As AuToBI does not predict bitonals, our reduction step seeks to predict possible bitonal PAs. The following automatic processing is performed on each pitch accent plus boundary tone (PABT) sequence:

   (a) Total deletion of deaccented items or word chains with a low BT (DL%). These intonation patterns match deaccented words which are disregarded in our IP characterization.

   (b) Substitution of deaccented items with a high BT (DH%) by a bitonal marker H+. High BTs in general may provide information on adjacent word stresses which are relevant in the detection of bitonals when they are followed by a main stress. A sequence of various H+ markers is reduced to a single H+ as it belongs to a sequence of deaccented words. Thus, the resulting single H+ matches a main stress and predicts a bitonal PA.

   (c) Word chains labeled as L*L% in a row can be disregarded for the IP contour definition. Three word-chains with such a label can be reduced to one L*L% IP label as only one word in such a chain will be more salient within the IP.

   (d) Initial L*H%L*L% has been reduced to L*+HL%. In this case, a high BT is turned into a bitonal.

   (e) 3-word combinations of L*H% and L*L% are turned to bitonals with either low or high BTs depending on the pattern chain. For instance, L*H% L*L% L*H% gives H+L*H%.

   The results from this label reduction process are saved into a txt file (see Figure 4) that contains the following fields:

   - Id number of sentence
   - Chain of words

- Communicative label
- Number of words
- Number of IPs
- Proposed ToBI label for each IP

Figure 4: *Resulting txt after reduction model processing*

Id.S.	Words	IS	N.W.	N.IP	PrePattern
0196	old time kiddies	R1	3	1	H+L*L%
0196	he says	SP1	2	1	L*L%
0196	he	T1(SP1)	1	0	0
0196	says	R1(SP1)	1	1	L*L%

3. **Pre-revision step.** After getting a proposed IP label, a Praat file needs to be created in order to revise all the material that has been automatically generated. Therefore, TextGrid3 file merges the existing tiers from TextGrid2 plus three more, namely:

   (a) clauses divided into intonational phrases and with their corresponding communicative labels,

   (b) same intonational phrases containing the proposed ToBI pattern, and

   (c) word divisions as in tier 1 for AuToBI input that will serve to place a pitch accent (PA) into the main stressed word within the IP and BT to be able to detect intermediate IP easily regardless pauses or silence dependency.

   See Figure 5 for illustration.

   Once the Textgrid3 file is generated, the manual process of revisor's validation of the proposed patterns takes place. The manual changes are saved as TextGrid4 (see Figure 6).

Figure 5: *Resulting TextGrid3 including processed tiers*

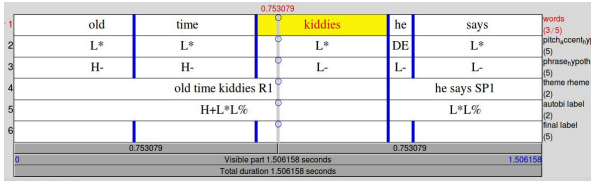


Figure 6: *Resulting TextGrid4 after manual revision*

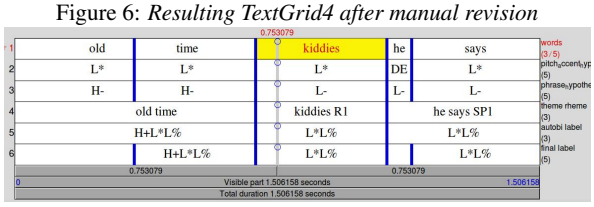
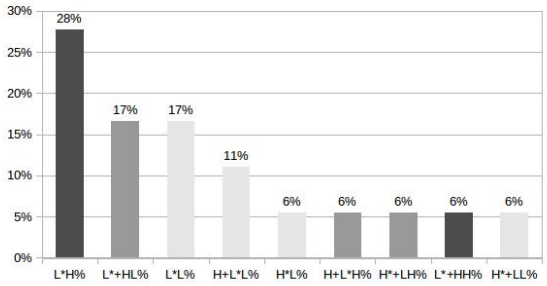


3. Validation stage (S5)

As mentioned above, the validation stage serves to assess the prosodic patterns obtained during the adaptation stage in order to evaluate the efficiency of our model. For this purpose, we first compared the results from our automatic reduction model at the intonational phrase level to a manual annotation. The comparison revealed that the model matches exactly the whole pattern in 58% of the total number of IPs. This includes number of IPs division and exact ToBI pattern assigned. There is a 18% of partially matched patterns (whose match corresponds in all cases to the BT). And the rest 24% of IPs does not match with the manual annotation.

Then, we compared the obtained prosodic patterns with those prognosticated by Steedman's [10] based on sentential theme/rheme structures. Figure 7 shows that themes tend to contain a rising intonation pattern as [10] claims, given that L*H%, L*+H H%, H*+L H% and H+L* H% (highlighted in dark gray) have a final rising intonation and L*+H L% contains a rising PA. These patterns add up to 63%, which proves that our model represents the general characterization made in theoretical approaches on this topic. Hence, the results can be regarded as reliable and we can conclude that apart from the obvious save in time in labeling effort, our reduction model is validated by existing theories on intonation applied to thematicity.

Figure 7: *Theme intonation patterns distribution (%)*



4. Conclusions

We presented a procedure for automatic prosodic pattern annotation that has been shown to be sufficiently reliable for experiments on the "semantics–syntax–intonation" language interface. In our validation, we have shown that our prosodic extraction is in concordance with Steedman's hypothesis for simple sentence structures. However, the great variety of intonation patterns that we found also proves that existing theories on thematicity characterization in prosodic terms, such as Steedman's [10], require a deeper insight from a qualitative perspective using real examples from different contexts, registers and speakers. For this reason, our procedure presented contributes, on the one hand, to the possibility of labeling large corpora with a substantial cut-off on manual revision efforts and minimizes, on the other hand, the risk of obtaining different labels as result of different annotators' subjective viewpoint, as long as all annotators are given a sistematic pattern and are asked to check whether there is an error with the initial output from AuToBI. Annotators can be trained to detect these errors and make more objective decisions when they spot an error than when they are labeling from scratch and therefore, have to make all decisions on their own.

Abstract

During automatic speech processing a number of problems appear, and among them there are such as speech variation and different kinds of speech disfluences. In this article an algorithm for automatic detection of the most frequent of them (filled pauses and sound lengthenings) based on the analysis of their acoustical parameters is presented. The method of formant analysis was used to detect voiced hesitation phenomena and a method of band-filtering was used to detect unvoiced hesitation phenomena. For the experiments on filled pauses and lengthenings detection a specially collected corpus of spontaneous Russian map-task and appointment-task dialogs was used. The accuracy of voiced filled pauses and lengthening detection was 82%. And accuracy of detection of unvoiced fricative lengthening was 66%.

Index Terms: speech disfluencies, filled pauses, lengthenings, speech corpus, automatic speech processing, automatic speech recognition.

1. Introduction

A number of factors such as speech variation and different kinds of speech disfluences has a bad influence on automatic speech processing. Speech disfluencies are any of various breaks or irregularities that occur within the flow of otherwise fluent speech. These are filled pauses, sound lengthenings, self-repairs, etc. Another problem close to speech disfluencies are speech artifacts such as cough, laugh or sighs. The occurrence of these phenomena may be caused by exterior influence as well as by failures during speech act planning [1]. Hesitations are breaks in phonation that are often filled with certain sounds. Filled pauses are those hesitations that are filled with certain sounds, and the nature of sound lenghtenings is also hesitational. Such phenomena are semantic lacunas and their appearance means that speaker needs an additional time to formulate the next piece of utterance [2]. In oral communication filled pauses and lengthenings may play a valuable role such as helping a speaker to hold a conversational turn or expressing the speaker's thinking process of formulating the upcoming utterance fragment. Self-repairs appear when speakers want to change partly or entirely some piece of their utterances, and may be online: when speaker changes a piece of utterance immediately, or retrospective: speaker changes it post factum.

These phenomena are an obstacle for processing of spontaneous speech as well as its transcriptions, because speech recognition systems are usually trained on the structured data without speech disfluencies, what decreases speech recognition accuracy and leads to inaccurate transcriptions [3,4].

Nowadays there are two main types of methods of dealing with speech disfluencies: methods that process them by means of only acoustic parameters analysis, such as fundamental frequency transition and spectral envelope deformation [5,6] and methods that process them by means of combined language and acoustic modeling [7,8].

There are lots of works devoted to speech disfluencies modeling within the systems of automatic speech recognition [5,7,9]. Also there are approaches that deal with speech disfluencies at the stage of signal preprocessing [10], as well as speech disfluencies removal using speech transcriptions [9,11].

Thus, in [10] an algorithm, which defines and eliminates filled pauses and repetitions from the speech signal, is proposed. For detection of boundaries of filled pauses the following characteristics were applied: duration, pitch, spectral and formant characteristics. For extraction and further elimination of repetitions the proposed algorithm used duration and frequency of the repeated segments as well as the Euclidian distance between the logarithms of the Linear Predictive Coding (LPC) spectra of each pair of the voiced sections around a long pause. Also the fact that repetitions are usually accompanied by a pause was taken into account.

In [12] authors describe a method for automatic detection of filled pauses. They propose a method that detects filled pauses and word lengthening on the basis of two acoustical features: small F0 transition and small spectral envelope deformation, which are estimated by identifying the most predominant harmonic structure in the input. The method has been implemented and tested on a Japanese spontaneous speech corpus consisting of 100 utterances by five men and five women (10 utterances per subject). Each utterance contained at least one filled pause. Experimental results for a Japanese spoken dialogue corpus showed that the real-time filled-pause-detection system yielded a recall rate of 84.9% and a precision rate of 91.5%.

In [13] authors focus on the identification of disfluent sequences and their distinct structural regions, based on acoustic and prosodic features. For the experiments a speech corpus of university lectures in European Portuguese “Lectra” was used. The corpus contains records from seven 1-semester courses, where most of the classes are 60-90 minutes long, and consist of spontaneous speech mostly, and its current version contains about 32h of manual orthographic transcripts. Several machine learning methods have been applied, and the best results were achieved using Classification and Regression Trees (CART). The set of features which were most informative for cross-region identification encompasses word duration ratios, word confidence score, silent ratios, pitch, and energy slopes. The performance achieved for detecting words inside of disfluent

sequences was about 91% precision and 37% recall, when filled pauses and fragments were used as a feature. Presented results confirm that knowledge about filled pauses and fragments has a strong impact on the performance. Without it, the performance decayed to 66% precision and 20% recall.

There are number of publications aimed to rise speech disfluencies recognition quality by means of additional knowledge sources such as different language models. In [7] three types of speech disfluencies are considered: repetition, revisions (content replacement), restarts (or false starts). A part of Switchboard-I as well as its transcription (human transcriptions and ASR output) was taken for research. Normalized word and pause duration, pitch, jitter (undesirable phase and/or random frequency deviation of the transmitted signal), spectral tilt, and the ratio of the time, in which the vocal folds are open to the total length of the glottal cycle, were taken as the prosodic features. Also three types of language models were used: (1) hidden-event word-based language model that describes joint appearance of the key words and speech disfluencies in spontaneous speech; (2) hidden-event POS-based language model that uses statistics on part-of-speech (POS) to capture syntactically generalized patterns, such as the tendency to repeat prepositions; (3) repetition pattern language model for detection of repetitions.

For the application of disfluences detecting methods based on language modeling a large corpus of transcriptions is needed while for rule-based approaches there is no need for such corpus. Also rule-based approaches have an advantage of not relying on lexical information from a speech recognizer. For this research we decided to test the effectiveness of rule-based approach for detecting filled pauses and lengthenings in Russian spontaneous speech.

This paper is organized as follows: in the Section 2 the methodology for corpus recording and the collected corpus description are given. Section 3 is devoted to description of the method of filled pauses and lengthenings detection. In Section 4 the experimental results of hesitations and sound lengthening are presented.

2. Corpus of Russian Spontaneous Speech

Nowadays, for studying speech disfluencies corpora with Rich Transcription [11] are used. As example such corpus as Czech Broadcast Conversation MDE Transcripts [14] may be cited. This corpus consists of transcripts with metadata of the files in Czech Broadcast Conversation Speech Corpus [15], and its annotation contains such phenomena as background noises, filled pauses, laugh, smacks, etc [16].

For our purposes a corpus of spontaneous Russian speech was collected based on the task methodology: map-tasks and appointment-task. Thus, we have recorded speech that is informal and unrehearsed, and it is also the result of direct dialogue communication, what makes it spontaneous [17]. For example, in Edinburgh and Glasgow the HCRC corpus was collected, which consists only of map-task dialogs [18], and half of the another corpus, corpus of German speech Kiel, consists of appointment tasks [19].

Map task dialogs in the collected corpus represent a description of a route from start to finish, basing on the maps. Pair of participants had a map which had various landmarks drawn on it. One participant also had a route marked on their map. And the task was to describe the route to the other participant, who had to draw this route onto their own map. After fulfilling this task participants switched their roles and dialogue continued. For our investigation several pairs of maps of varied difficulty were created. As the criterion of difficulty the number of unmatched landmarks was used. An example of difficult maps is shown on the Figure 1. For dialogs based on appointment task, a pair of participants tried to find a common free time for: a) telephone talk (at least 15 minutes), b) meeting (1 hour) based on their individual schedules. Participants could not see maps or schedules of each other. Due to maps and schedules structure they had to ask questions, interrupt and discuss the route or possible free time. This resulted in speech disfluencies and artifacts appearance.

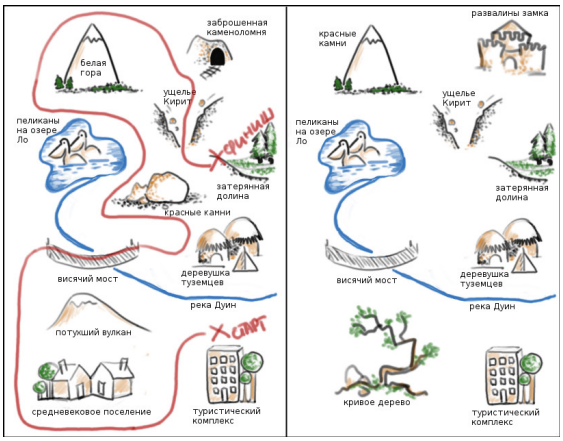

Figure 1: *An example of maps with the route (left) and without the route (right), used in map-task dialogs recording.*

The recorded corpus consists of 18 dialogs from 1.5 to 5 minutes. Recording was performed in the sound isolated room by means of two tablets PCs Samsung Galaxy Tab 2 with Smart Voice Recorder. Sample rate was 16kHz, bit rate - 256 Kbit/s. All the recordings were made in St. Petersburg in the end of 2012 - beginning of 2013. Participants were students: 6 women speakers and 6 men speakers from 17 to 23 years old with technical and humanitarian specialization.

Corpus was manually annotated in the Wave Assistant [18] on two levels: those disfluencies and artifacts that were characteristic for one speaker were marked on the first level, those that were characteristic for the other speaker - on the second level. During annotation 1042 phenomena such as filled pauses (for example pauses filled with [ ] and [ɐ] sounds), artifacts (as laugh, breath), self-repairs and false-starts as well as word-fillers were marked. The most frequent elements are shown on the Figure 2.

Figure 2: *A diagram of most frequent speech disfluencies and artifacts in the collected corpus, where ar.laugh - laugh, ar.brth – sighs and loud breath, h.a – hesitation [ɒ], h.e – hesitation [ə], i-i – lengthening of /i/, a-a – lengthening of /a/, "nu" and "vot": are common fillers in Russian.*

Sighs and loud breath, filled pauses [ ] and [m], self-rapairs and lengthening of sound /i/ appeared equally often in the speech of all 12 speakers. For speech of 11 speakers also lengthening of /a/ and filled pause [ɐ] were common. And almost everyone used such fillers as /vot/ ("there") and /nu/ ("well").

Due to the fact that certain disfluencies are communicatively significant and hardly can be distinguished from normal speech, on this stage of research we have confined ourselves to the most frequent elements of in speech disfluences – filled pauses and sound lengthenings.

3. Method of Filled Pauses and Lengthenings Detection

The basic idea of our method is to find acoustical features of filled pauses and sound lengthenings in speech signals by using spectrum analysis. Our method assumes that filled pauses and lengthenings contain a continuous voiced sound of an unvaried phoneme, due to this the neighboring instantaneous spectra are similar. For these phenomena such characteristics as unvaried value of pitch and duration of about 150-200ms are peculiar. This duration value is a reliable threshold for perception of speech pauses, because it is close to the value of mean syllable duration [21].

Taking into account only pitch change and duration it is possible to confuse sonorant sounds with filled pauses. For example, in such Russian word as "налево" /nalevo/ ("to the left") the pitch movement is almost horizontal as in filled pauses and lengthenings (Figure 3).

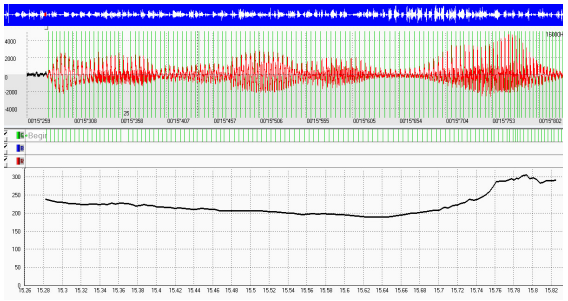

Figure 3: *A diagram of pitch movement for the word "налево" /nalevo/ ("to the left") with averaging interval of 50ms.*

As the measure of their similarity we have used a criterion of formant similarity between neighboring spectra. We also implemented the preliminary detection of lengthening of unvoiced fricatives.

In the following, we describe the main procedure of our method (Figure 4). First step was to calculate the Fourier transform to acquire a spectrogram with window length of 512 frames and step of 256 frames. This window length provides both reasonable spectral and temporal resolution.

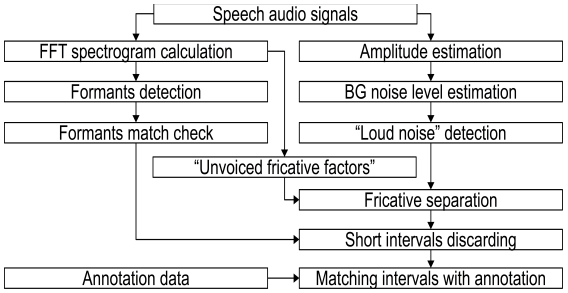

Figure 4: *Scheme of hesitations and breath detection method.*

The next stage was formants detection. First, spectrum was resampled to obtain exponential scale on frequency axis. This was done to acquire reasonable resolution in the middle- and high-frequency parts of the spectrum. Then we have searched for formants: the value of maximum and values of two surrounding samples were interpolated with quadratic curve and the position and value of the curve maximum was used as formant frequency and amplitude.

For formants match check we compared two neighboring spectra and estimated the coefficient of matching c for these two spectra (1). For every such pair of spectra the sum of formants' amplitudes multiplied by weight was estimated. Weight was calculated as a function of amplitude change and relative formant shift for every formant. Then this sum was divided by the sum of all amplitudes.

$$c = \frac{\sum_{match} A_n * F_{match}\left(A_n / A'_n, F_n / F'_n\right)}{\sum A_k} \quad (1)$$

where A_n, F_n - are amplitude and frequency in one neighboring spectrum and A'_n, F'_n - are amplitude and frequency in the other neighboring spectrum.

C reflects the sound invariableness in the current moment of time, if spectra are equal $c=1$, and if they are completely different, $c=0$. The diagram of *c* is shown on Figure 5 (the upper part). Those intervals where this function was above certain threshold for a long period of time are considered as filled pauses and lengthenings.

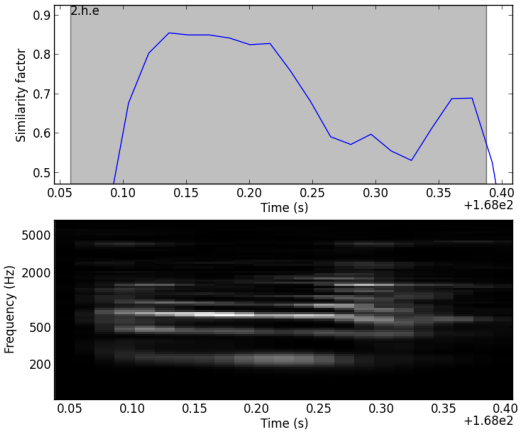

Figure 5: The diagram of s*imilarity function (above), with the gray background indicating mark in the annotation, and the resampled spectrogram (below) of the same signal part for filled pause /e/.*

To estimate an amplitude the signal was divided into overlapping frames, where the root mean square of samples in each frame is taken as the amplitude in correspondent moment of time.

To estimate a BG noise the signal was smoothed using the rectangular window with the length of 200ms, that is significantly less than characteristic length of silence intervals and greater than amplitude estimation window length. Minimum of this function was taken as background noise level.

The method based on the formant similarity described above doesn't perform well on the lengthenings of unvoiced fricatives. Due to the small amount of these elements (about only 1% of all annotated phenomena), almost all of them being sibilants lenghtenings, we relied on the fact that they are characterized by wide bands of certain frequencies ("fricative factors"). The situation of such bands for each unvoiced fricative sound is independent from the speaker. At this stage to detect unvoiced fricative lengthenings the following temporal series were computed: the ratio of the mean value of instantaneous spectrum samples in the band to the mean value of samples of the spectrum. Those intervals, where the series value exceeds a certain constant (more than 3), presumably contain the sound in question [22].

For fricatives separation the following actions were performed. For the found intervals values of "fricative factors" were examined by turns to detect among them those intervals that are corresponding to consonant lengthenings. The rest of the found elements were considered as breath.

Then the detected filled pause and lenghtening events were compared to the markup. For each event we looked for a mark that overlaped it, with the common part of these intervals being sufficiently large (the value of 0.4 was defined experimentally) (2):

$$L_{Ev\cup Mark} > 0.4\min\left(L_{Ev}, L_{Mark}\right) \qquad (2)$$

where the $L_{Ev\cup Mark}$ – is length of the common part, L_{Ev} – is the length of the event, and L_{Mark} – is the length of the mark. If the type of the mark matches the type of the event then the event was considered as match, otherwise it was considered as a false positive. All marks that were not matched during the events processing were treated as a false negative result.

4. Experimental Results

The filled pauses and sound lengthening algorithm based on the method described above was implemented and tested on a collected spontaneous Russian speech corpus. The training set consisted of 3 dialogs (4 speakers of different specialization) - two map-task and one appointment-task dialogue. The testing set was the other part of the corpus – 15 dialogs. The accuracy of voiced filled pauses and lengthenings detection was 82%. And accuracy of detection of unvoiced fricative lengthenings was 66%.

The main reasons for "misses" were the disorder of harmonic components in of hoarse voice and by laryngealized filled pauses and lengthening, the duration of which was not enough to overcome the threshold for correctly found elements. Another reason for misses was filled pauses consisting of two different sounds, such as /ae/. In such a case algorithm detected two lengthenings /a/ and /e/ ignoring the transition part, and both these lengthenings appeared to be too short to overcome the threshold. On the other hand, false alarms were mainly caused by lengthenings that were missing in the annotation and by noises and overlappings. For example the paper riffle sometimes is very similar to lengthening of a /s/ consonant and can be detected incorrectly.

5. Conclusions

This paper presents the method of filled pauses and sound lengthening detection by using the formant analysis. The experiments were based on the corpus of spontaneous Russian speech that was specially collected and manually annotated taking into account speech disfluencies and artifacts. The criterion of matching with the annotation marks was used as algorithm work estimation. The accuracy achieved for the voiced filled pauses and lengthenings detection was 82%. And the accuracy of the unvoiced fricative lengthening detection was 66%.

Further experiments will focus on more precise physical boundaries detection as well as on dealing with laryngealized sounds as well as on performing similar experiments with other Russian speech corpora within the other domain. Another stage of investigation will be devoted to context of filled pauses and lengthenings. This would help to detect more precisely their physical boundaries, that are of different nature, so there are such possible sounds as glottal stops in the beginning of filled pauses, transition parts between two sounds, etc. We also plan to apply our method to a Russian speech recognizer at a stage of signal preprocessing. Future work will also include an integration of the method with a speech dialogue system to make full use of the of filled pauses communicative functions.

Abstract

According to previous studies [1,6], acoustic and perceptual analysis can be considered useful clinical tools to investigate the speech characteristics of hearing impaired children (HIC). This study aimed at describing voice quality settings in speech samples from a HIC wearing cochlear implants. These samples were collected during speech therapy sessions in three moments: at the time the HIC was 5 years and 1 month old, and at 6 years and 1 month and at 7 years and 1 month. The perceptual analysis of the vocal quality was based on the Vocal Profile Analysis Scheme for Brazilian Portuguese (BP-VPAS - Camargo & Madureira, 2008). The recorded corpus was analyzed by means of the *ExpressionEvaluator script* (Barbosa, 2009) ran by *Praat* software v5.2.10. The measures, which were automatically extracted, comprised the fundamental frequency-f0, first f0 derivative, intensity, spectral slope and long-term mean spectrum. The correlations found between the acoustic and perceptual data are worth considering in rehabilitation programmes.

Index terms: Vocal quality; Auditory Perception; Acoustic Analysis; Cochlear Implant;

1. Introduction/Background:

This research focuses on the perception and production of voice quality settings and dynamic speech aspects [1-8] and it concerns the speech therapy and audiology settings since the analysis takes into account speech productions of a HIC and cochlear implant user (CI), collected during speech therapy sessions [6].

As indicated in a previous study [6], authors reinforce the demand for evaluating not only standardized speech tasks, but also semi-spontaneous speech data collected in the therapeutic environment.

Perceptual and acoustic analysis of voice quality settings, prosodic features and of temporal organization aspects are useful clinical tools to investigate the speech characteristics of HIC [5,6,8].

The description of vocal quality settings (supralaryngeal, laryngeal and tension) and voice dynamics related aspects such as pitch, loudness, continuity and rate can provide useful means for clinic evaluation and intervention on HIC and CI individuals .

Speech segmental characteristics may undergo changes under the influence of voice quality settings. These interactions between segmental and prosodic levels [7,8] must be considered in relation to the physiological, acoustic, auditory and cognitive mechanisms involved in the production and perception of speech [8-10,16].

The analysis of the perceptual and acoustic correlates of vocal quality and voice dynamics makes it possible to identify changes in speech production which demonstrate the oral language development in children who use CI. [21-23]. The application of the Vocal Profile Analysis Scheme for Brazilian Portuguese (BP-VPAS) [9], based on VPAS 2007, (Figure 1)[10], enabled the perceptive description of two kinds of prosodic aspects: vocal quality settings and voice dynamics elements.

The vocal quality settings are taken as the result from the combined actions of the larynx and the supralaryngeal vocal tract [10-16]. Furthermore, such description aims at revealing the long-term tendencies that characterize vocal quality settings, which can be regarded as products of the respiratory, laryngeal/phonatory, supralaryngeal/articulatory systems, as well as muscular tension conditions. For the voice dynamics evaluation the BP-VPAS, the model provides the possibility of evaluating pitch and loudness parameters, the use of pauses, speech rate and respiratory support.

Figure 1: Vocal Profile Analysis Scheme (VPAS) [13]

From the acoustic point of view, vocal quality and voice dynamics have been analyzed according to the following parameters: fundamental frequency (f0), first f0 derivate, intensity, spectral slope, and long-term average spectrum [2-17-20].

It is very difficult to analyze speech development in hearing impaired children due to methodological difficulties and the number of variables involved: degree of hearing loss; age at the beginning of amplification; involvement of the hearing impaired children's families especially at the beginning of the therapeutical care concerning the use of hearing aids and participation of the family in the hearing rehabilitation process; and changes in articulatory and phonatory patterns.

In the speech of children, the phonation system is oscillating and, due to the non-linear relationships between the elements, it can feature patterns of great variability. A model which allows the description of articulatory, phonatory and tense settings can be applied to evaluate changes in the adopted patterns that define the maturation of the mechanism.

The phonetic model [12] of voice quality settings description used to analyze the speech samples in this study does not make a distinction between normal and pathological speech. The focus is on the articulatory, laryngeal and tense settings which interact with the speech segments affecting their quality. In this way, the inherent quality of speech segments is modified. If, for example, an [i] is produced with a lip rounding setting of voice quality, its inherent characteristic of lip spreading will be modified. Since the vocal quality settings are described according to the principles of susceptibility to the speech segments, that is, an oral speech segment, for example, will be considered more susceptible to a nasalized voice quality setting than a nasal one, it follows that settings are defined and described in relation to key speech segments.

Considering the variability of speech patterns and the complex interactions between perception and production, a phonetic model [12] which provides the description of long term muscular adjustments related to the production of voice quality settings enables the analysis and comparison of interactions between prosody and segments.

The language acquisition process is very complex and descriptions of speech characteristics based on normal parameters are not helpful since speech characteristics are not stable. From the earliest babbling—especially in children with hearing impairment— babbling may show evidences of learning the relationships between motor gestures and acoustic characteristics.

This study aimed at describing voice quality settings in speech samples from a HIC who wears cochlear implants. These samples were collected during speech therapy sessions in three moments: at the time the HIC was 5 years and 1 month old and at 6 years and 1month and at 7 years and 1 month.

2. Methods

Speech samples comprised audio recordings from semi-spontaneous speech of a HI and user of CI child within the chronological age range of 5 years and 1 month and 7 years and 1 month (Table 1). The recording of the *corpus* took place in a therapeutic context, in a speech therapy room. The unit of analysis is long- term, recurring features throughout speech production. The analysis includes all long-term trends of speech production featuring a speaker in particular: the moments used speech samples analyzed are 5-15 seconds.

The instruments used to record the samples were a unidirectional *Le son* lapel microphone and a *Sony* MD digital recorder model MZ- R70. The edition, treatment, and sample analysis processes were carried out at the Acoustic Analysis and Cognition Integrated Laboratory (LIAAC) at PUC-SP. The recordings were digitalized at the sample frequency of 22050 Hz and 16 bits with the wav extension, using the Sound Forge software (version 7.0).

Table 1- *Subject characterization*

Subject	Hearing aids usage (chronological age: years; month)	IC –age at the time of surgery (chronological age: years; month)	Audio-recording sessions (chronological age/ auditory age: years; month)
Y.	0;7	2;7/ unilateral CI	Moment 1 (5;1/ 2;4), Moment 2 (6;1/ 3;4), Moment 3 (7;1/4;4)

The perceptual analysis was carried out with the use of the VPAS-PB [9,10] by two experienced judges.

The acoustic analysis was developed by using the *Expression Evaluator script* [17,19] running in the software *Praat*v5.2.10. The script generates f0 (median, interquartile semi-amplitude, 99,5% quartile and skewness), first f0 derivate (mean, standard deviation (SD) and skewness), as well as intensity (skewness), spectral slope (mean, SD and skewness) and LTAS (SD) measures [17,19].

The perceptual and acoustic results were statistically analyzed by means of XlStat software [16]. There were two elements under analysis: the perceptual judgments and acoustic measures results. Canonical correlation analysis between perceptual and acoustic data and the discriminant analysis of the acoustic correlates were performed taking into account the speech productions of the child at 5 years and 1 month, 6 years and 1 month and 7 years and 1 month.

It is important to highlight of methodological adequacy and consistency of the statistical analysis (canonical and discrimination analysis) adopted to consider the correlations between qualitative (perceptual evaluation of the settings) and quantitative (acoustic measures) in this study. This kind of analysis can be applied to semi-spontaneous and spontaneous speech excerpts and does not require the use of standardized speech samples

The issue of adopting relative measures instead of absolute measures allows correlation between perceptual evaluation and acoustic measures in the characterization of each speaker profile. This procedure does not require the labeling of vowel and consonantal segments, which may not be well delimited in certain children speech productions in the earlier stages of language development and in those productions considered altered for the age bracket. Even the speech of hearing children in the earlier stages of language development can not be described according to norm parameters.

This research was approved by the Ethics Committee at PUC-SP (#135/2009).

3. Results

The circular diagrams derived from the canonical correlation analysis between perceptual and acoustic data, considering moments 1, 2 and 3, are presented in Figures: 1, 2 and 3.

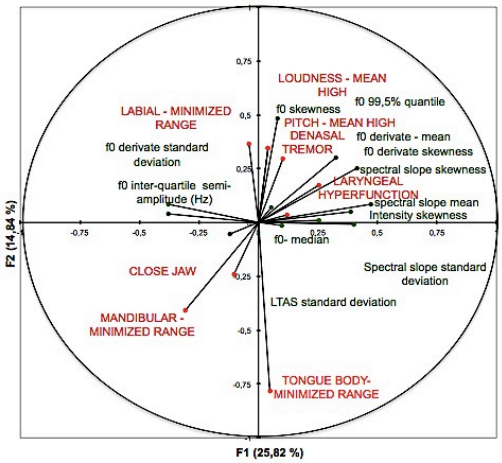

Figure 2: Circular diagrams from canonic correlation analysis: correlations between acoustic and perceptual data from a CI user in moment 1.

The correlations presented in Figure 2 comprised the most frequent vocal quality settings and voice dynamics parameters: f0-medianandusual *pitch* high (90,5%) and usual *loudness mean* high (90,5%,) f0-median associated with tremor (64,4%), f0-derivate skewness with labial minimized range (61%) and spectral slope - standard deviation associated with labial minimized range (50,5%).

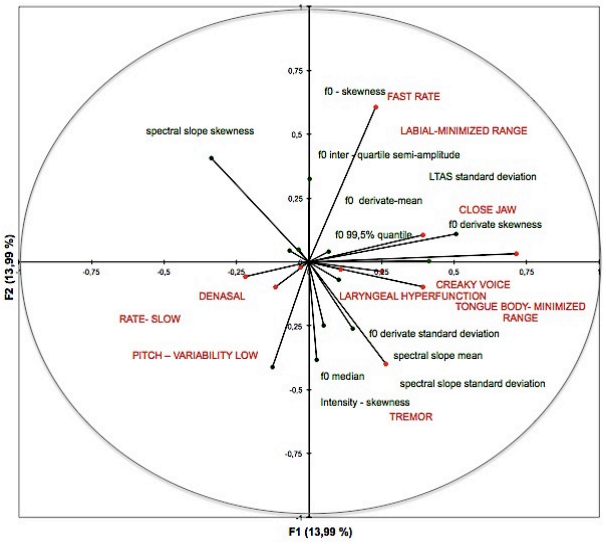

Figure 3: Circular diagrams from canonic correlation analysis: correlations between acoustic and perceptual data from a CI user in moment 2.

The correlations shown in Figure 3 concern the most frequent vocal quality settings and voice dynamics parameters: fast rate with f0-skewness (46,2%), creaky voice associated with f0-interquartile semi-amplitude (45,1%), slow rate with f0-interquartile semi-amplitude (41,5%) and tense larynx associated with intensity skewness(41,4%)

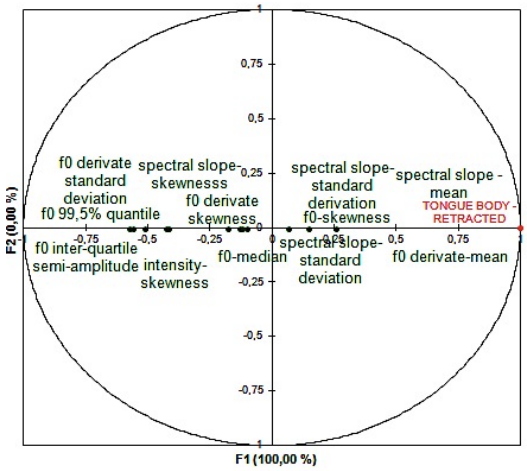

Figure 4: Circular diagrams from canonic correlation analysis: correlations between acoustic and perceptual data from a CI user in moment 3.

The correlations shown in Figure 4 revealed the most frequent vocal quality settings and voice dynamics parameters: f0-standard deviation derivative and minimized range of tongue body (93,9%) and harsh voice (93,9%) associated with falsetto and f0-median (91,3%).

4. Discussion and Conclusions

The results presented in terms of perceptual and acoustic data from a cochlear implant user during a period of speech therapy can be interpreted as being derived from mobilizations and adaptations of the articulators to achieve specific articulatory targets. Both language development issues and speech therapy strategies are factors which influence these speech maneuvers. These tendencies reveal the interaction between articulatory mechanisms and laryngeal (phonatory) events in language acquisition. In the articulatory domain, lingual, jaw and velopharyngeal settings were related to loudness, pitch and speech rate elements. In the phonatory domain, the tension (laryngeal hyperfunction) and laryngeal (harsh voice and whisper) settings groups were found to be very productive.

The association of laryngeal hyperfunction to high habitual pitch may be compatible with minimized range settings of jaw and tongue [22]. Such combinations are commonly described as yielding mechanisms for vocal tract and laryngeal hyperfunction, especially if conditions related to the developmental stages of the vocal apparatus are considered.

Taking into account the perceptual and acoustic data distribution in canonical correlation analysis (figures 3, 4 and 5), the interaction between some supralaryngeal mobilizations, especially tongue body and spectral slope and LTAS measures, is highlighted[10,14]. In the analyzed samples, these data can be interpreted as revealing some vocal loading in order to achieve some articulatory targets and, again, reinforce the complex interactions between supralaryngeal settings, voice dynamics elements and spectral measures in language acquisition for HI children [2,5-6, 15]

The findings also reinforce the complex interactions between pitch control and laryngeal (harsh voice and whisper) and muscular tension settings (laryngeal hyperfunction) [4, 6, 22-25], reflected in f0 acoustic measures. The values concerning habitual f0 at moment 1 (auditory age: 2y4m) were higher than those at moment 2 (auditory age: 3y4m), whereas at moment 3 (auditory age: 4y4m) these values increased 406,4 Hz. For this speaker, the influence of acoustic data of spectral slope and f0-skewness and intensity-skewness, in relation to laryngeal hyperfunction associated with aperiodicity are noteworthy. *Pitch* and *loudness* variability decreased. The phonetic literature refers to extreme and abrupt pitch variations not only for AASI users, but also for CI users [8,22,25,28]. Such findings indicate the influence of laryngeal hyperfunction and aperiodicity on pitch extension and variability and also reinforce the complex interactions of f0 control mechanisms in HIC, particularly in terms of the association of voice quality settings -vocal tract settings (minimized range – tongue, jaw and lip), laryngeal (tremor) and vocal tract hyperfunction. The findings concerning f0 variations in the listener population speech indicate that speech intelligibility and phonological discrimination can be affected if vocal aperiodicity characteristics are present. In relation to the vocal dynamics elements, the slow rate at moment 1 turned into a fast one at the moment 3, when the analysis detected a higher influence of the retracted tongue body setting of vocal quality. From the acoustic point of view, differentiation of evolutionary stages occurred mainly due to the distribution of f0 and spectral slope measures, which are supported by descriptions of perceptual basis. The measurements of median f0 increased over time (auditory age from 2y4m to 4y4m), as expected, because body and laryngeal development would be lowering. However, the retracted tongue body setting can change raised larynx setting and interfere with the characteristic vibration of the vocal folds. In addition, the resonance imbalances widely reported in the literature [1, 2, 6, 8, 15, 22, 23, 25, 26] may be related to vocal tract adjustments reported in this speaker (body of tongue, jaw and velopharyngeal mobility). The collected data likewise strengthen aspects of reduced movement of articulators. The collection revealed by the three

samples shows the evolution of meaningful maintenance vocal tract adjustments. The discriminant analysis of the findings using the VPAS-PB, in terms of moments of the recordings (moments 1, 2 and 3), revealed segregation of the variables at the rate of 74.16%. When individually analyzed, total segregation was higher for emission moment 3, with 100%, whereas moment 2 presented 75%, and moment 1, 66.67%. The most influential factors for this differentiation referred to the combinations of minimized range of jaw (grade 1), laryngeal hyperfunction (grade 1), decreased pitch variability (grade 1), and retracted tongue body (grade 1), represented by 80,18% combined with minimized range of tongue body (grade 2), jaw (grade 2) settings and the absence of laryngeal hyperfunction, at the rate of 19,82%. The discriminant analysis of the acoustic measures by *ExpressionEvaluator Script*, in terms of moments of the recordings (1, 2, and 3), revealed total segregation of the variables at 64.52%. Considering each moment in therapy, total segregation was higher for moment 2 emissions, by 80%, whereas moment 3 presented 72,22%, and 1 moment, 37.50%. The most influential factors for such differentiation referred to the combinations of f0-derivate SD, f0-mediana and interquartile (99,5%), represented by 88,21%, combined measures off0-semi-amplitude interquartile (11,79%). The f0 values-mean shows smoother variation at moments 1 and 2 than at the third moment, in which abrupt variations were found. In moment 3, f0-semi-amplitude interquartile arises - which reflects greater change compared to times 1 and 2. At moment 3, the f0 measure at 99.5% quartile showed higher values than at the other two moments. Similar characteristics in moments 2 and 3 were found, leading us to consider that a greater improvement took place between the first and second moments. The second and the third moments were characterized by more accurate productions of speech sounds. These aspects show the dynamic nature of speech and the complex interactions that take place between segmental and prosodic elements. At moment 3, a better delimitation of prosodic groups coincided with a period of gradual refinement of the ability in terms of articulatory productions [7]. It is worth pointing out that, besides the diagnosis and early intervention being important for the prognostics [3,4,21], specific rehabilitation procedures concerning the oral sensorial-motor system, voice and speech, seem to be crucial for a good verbal-oral language development and for the acoustic feedback [1,3,6]. Such information leads to the possibility to detail the articulatory maneuvers adopted by the children in developmental language process, and enhances the reliance of therapy, which indicates probable strategies in trying to attain the acoustic-articulatory targets in speech production. The findings reinforce some correlations between the acoustic and perceptual data, which are relevant to be considered in rehabilitation processes.

Structural and Prosodic Correlates of Prominence in Free Word Order Language Discourse

Tatiana Luchkina [1], *Jennifer S. Cole*[1]

[1] Department of Linguistics, University of Illinois at Urbana-Champaign, USA
luchkin1@illinois.edu, jscole@ling.illinois.edu

Abstract

Production and perception experiments with native speakers of Russian, a free word order language, show that prosody and change in word order are used to mark discourse-prominent constituents. Concurrent application of these cues to prominence is possible, as evident from distinctively higher f0 and intensity maxima, and duration values associated with ex-situ words, as well as their higher visibility in discourse. Distinctive acoustic-prosodic realization of ex-situ words may cue their relatively high informational load and discourse prominence, as well as (redundantly) signal that the word is left- or right- dislocated.

Index Terms: Information structure, prosodic prominence, word order

1. Introduction

Independently of the modality of presentation, human processing of discourse involves identifying the information structure status of discourse elements. Information structure, and the related notion of accessibility, have been offered a variety of interpretations in the linguistic and psychological literature [1,2,3]. One approach adopts a tripartite distinction of discourse entities into the most accessible (or given, active), least accessible (or novel, inactive) and inferable (semi-active) [4]. Discourse-novel entities are described as more prominent than the discourse-given ones. New information (also known as focus or rheme), is opposed to discourse-given information, (topic or theme) as categories of information structure (IS) and are differentiated with regards to their visibility in discourse or *discourse prominence* [5].

Prosody, morphology, and the structural organization of information provide different means of encoding the discourse status of a word [6,7]. The prosodic encoding of discourse-prominence is a well-studied, psychologically real property of discourse production and perception [8,9,10]. It involves perceptually salient changes in voice quality, duration and intensity, as well as changes in f0. The degree of discourse prominence or relative discourse accessibility expressed by prosodic means can be further affected by structural means, i.e., strategic positioning of the discourse-prominent word in a syntactic phrase or clause. Structural prominence is especially suited for the so-called free word order languages, where the syntactic function of a word is marked overtly by means of morphological case. In such languages, the ordering of sentential constituents can be used to encode their relative discourse prominence, and signal their information structure category.

2. Two routes to prominence

Cross-linguistic studies show that languages use *either* prosodic marking or constituent ordering to encode discourse prominence and IS. Based on a comparative study of Italian and Turkish (relatively free word order languages), and English (fixed word order language), Donati & Nespor [11] propose that languages with rigid word order allow prosodic marking of discourse information ('focus') at different locations in the sentence, while languages with flexible word order do it through word order, and, consequently, exhibit less variation in the location of prosodic prominence. This model, with dual routes for the encoding of discourse information, predicts that it will be relatively uncommon that a language uses both word order and prosodic marking simultaneously to signal novel or important information in discourse. With respect to this [11] suggested to categorize languages into prominence dislocating (e.g., English), i.e., those which utilize prosodic cues to mark prominence, and constituent dislocating (e.g., Turkish or Italian), i.e., those which primarily use word order, or structural cues.

Consider how discourse prominence is expressed in English. While rightmost accent placement is the default location of the prominent constituent in English (1), the phenomenon of metrical reversal or stress shift [12, 13] can displace phrasal prominence leftward to signal the IS marked category of contrastive focus (2):

(1) Joel bought a green PORSCHE.
(2) Joel bought a GREEN porsche.

Italian illustrates a different prominence marking strategy [11], where speakers may choose to move the discourse-prominent word to a syntactic location that is systematically associated with its IS category or discourse-prominent status. Thus, while SVO is the canonical word order in Italian (*Mario arrive* 'Mario arrives'), the reverse ordering of S and V confers prominence to the subject (*Arrivo Mario*).

This sort of overt movement is often said to be prosodically motivated, which means that a word undergoes overt movement in order to be associated with the main phrasal prominence position, where it is perceptually salient.

While the proposal by Donati & Nespor parsimoniously accounts for the cross-linguistic distribution of the two distinct prominence encoding mechanisms, structural and prosodic, this work draws attention to the growing body of empirical evidence that word order is an optional resource for encoding IS categories and discourse-prominence in free word order languages, along with prosodic means [14,15,16,17, among others]. Languages which are known to display IS-triggered movement (Spanish, Greek, Russian, Georgian, and Italian, among others) are also known to use prosodic means to mark prominence in-situ, i.e., on constituents that are discourse-prominent, but which have not been moved to a syntactically designated prominent position. For such languages, one interesting question is whether the concurrent application of structural and/or prosodic means is purposeful, i.e., used to encode different categories of information in discourse.

Luchkina and Cole [18] report a preliminary investigation of this issue for Russian, a highly free word order language which simultaneously exhibits structural and prosodic prominence as means of marking information that is novel or

particularly salient. The semantically neutral, default word order in Russian is SVO, and as in other free word order languages, in Russian, a word can appear in its canonical position (in-situ), fronted, or post-posed. The ordering of the constituents in a sentence marks IS and not grammatical function. In the following example from [18], continuations (a) and (b) are both possible for the sentence in (4), but are felicitous under different discourse conditions: given the context provided in (4), the word Ivan, critical to the understanding of who does the cooking, may be located in the rightmost position, where it is structurally prominent (as in b), or may occur pre-verbally as in (a) and receive (optional) prosodic prominence.

(4) Tri druga, Ivan, Petr, i Andrey, nahsli novjiy retsept pizzj.
Three friends, Ivan Petr and Andrey, found a new pizza recipe.
a. (Smotri!) IVAN gotovit pizzu.
(look) Ivan-SUBJ cooks pizza-OBJ

b. (Smotri!) Pizzu gotovit Ivan.
(look) pizza-OBJ cooks Ivan-SUBJ

Luchkina & Cole present an analysis of prominence ratings provided by linguistically naïve native speakers of Russian and find that salient acoustic-prosodic, as well as structural cues to discourse-prominence are used jointly in judgments of the prominence status of a word. The prominence ratings reported in [18] are based on the production of one (model) speaker, which raises the question of whether utterances produced by other Russian speakers would yield similar perceptual ratings.

In this paper we extend our earlier work and explore how prosody and word order function independently and in combination to mark IS in a free word order language like Russian. The proposed experimental design seeks to determine (1) whether in discourse, the sentential position of a word affects it perceived prominence; (2) and whether cross-application of prosodic and structural cues translates into a yet greater degree of discourse prominence.

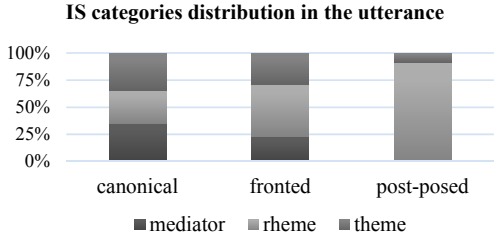
We test the hypothesis that in free word order discourse, an ex-situ sentential position acts as an independent cue to prominence, and if so, whether prominence may be further reinforced with acoustic-prosodic features associated with such position. To this end, we analyze word order and IS properties of two authentic Russian narratives for acoustic evidence of prosodic marking in relation to word order and IS. We (1) use the word-level prominence ratings obtained in a perceptual prominence rating task to gauge the native speakers' sensitivity to prosodic and structural means of encoding discourse-prominent information and (2) match the two classes of prominence correlates, structural and acoustic-prosodic, with the perceived prominence scores to test the ability of each of these sources of discourse-relevant information to predict the word IS category in the narratives chosen for this study. We analyze the experimental results with respect to the interaction between word order, prosodic marking, and perceived prominence.

3. Experiment 1: Production task

3.1. Materials

Both discourse samples used in this study come from two published narratives, which display a range of word order and prosodic features. With an average sentence length of 5.2 content words (SD=1.77, 230 content words), approximately 30% of the sentences in the narratives deviate from the canonical SVO order. Adopting the discourse annotation framework introduced in [3], the distribution of the following IS categories[1] was assessed: 'THEME' (word carrying discourse-given information, 2-12 mentions per narrative), 'RHEME' (words carrying discourse-new information, 1st mention in the narrative), 'MEDIATOR' (words carrying inferable information, 1st mention in the narrative), and 'CONNECTOR' (function words). The sentential position of each word in the narratives was marked as in-situ or ex-situ (specifically, 'fronted' or 'post-posed', relative to SVO order).

Figure 1: *Observed distribution of IS categories in the analyzed discourses*



The observed distribution of IS categories differed by sentential position (Pearson $\chi^2(6)=85.91$, $p<0.001$). Figure 1 illustrates that discourse-novel information is the most 'mobile' information category in the corpus, with more ex-situ locations than any other IS category, and clearly dominates the post-posed (utterance-final) position. Such non-random distribution of discourse information provides evidence that word order variability in the narratives under analysis may be indicative of IS category.

3.2. Acoustic-prosodic features pre-processing & production data overview

For the purposes of the perceived prominence rating task, both narratives were read orally by a female speaker of Russian (henceforth, the model speaker), age 27. Read productions from 14 speakers (ages 21-52, 8 females) were collected for the purposes of extended acoustic-prosodic analysis of the study materials. The acoustic-prosodic measures of f0 and intensity mean, minima, and maxima, f0 range, velocity, and excursion size, as well as vowel duration were taken from every syllable of each IS-coded content word in the corpus. Additionally, distance in milliseconds from the tonal center of gravity of each stressed vowel to the vowel midpoint was measured. All measurements were extracted automatically in Praat [20]. The values of max f0 and max intensity were taken from the center region of the vowel in order minimize the influence of the adjacent segments at the voice onsets and inter-segmental transitions. Each f0 output was transformed to semitone values relative to a fixed value of 100 Hz[2]. Prior to

[1] The IS category of each content word was annotated by one of the authors (TL) and another native Russian speaker. Inter-rater agreement (linearly weighted Kappa) between the annotators, across texts was satisfactory: $\varkappa=0.89$, SE=0.03, $\alpha=0.05$.

[2] The semitone scale was chosen to reduce male-female acoustic differences and ensure that +1 standard deviation constituted a perceptually equivalent interval as -1 standard deviation.

being submitted to regression analyses, all acoustic-prosodic measures were centered using mean-centered coding [21].
Extracted acoustic measures were examined as correlates of prosodic prominence, and analyzed for their relationship to the IS and sentential position of a word.
The model speaker's production data were subject to a preliminary analysis to determine how well cross-linguistically attested prosodic correlates of prominence (intensity and f0 maxima, and duration of the stressed vowel) can be predicted from the word's IS category and position in the utterance. A series of linear regression analyses each featuring one acoustic parameter of interest as the dependent variable revealed that both the ex-situ sentence position and IS category RHEME are reliably associated with greater intensity and f0 maxima, as well as longer duration of the stressed vowel (see Table1).

Table 1: *Significant predictors of vowel intensity, duration, and f0, with respect to the carrier word*[3]

(max)intensity	(max)f0	vowel duration
ex-situ (t=3.16, p<0.005)	ex-situ, fronted (t=6.36, p<0.001)	ex-situ (t=2.57, p=0.01)
RHEME (t=2.32, p=0.02	RHEME (t=2.84, p=0.005)	RHEME (t=2.94, p<0.01)

Significant patterns of co-variation were observed between some of the acoustic measures: e.g., a significant rise in max f0 was reliably associated with concurrent increases in intensity (t=24.77, p<0.001) and duration (t=5.35, p<0.001). Analysis of the model speaker's production data established that the acoustic parameters of f0, intensity, and duration contribute perceptual salience to the words carrying discourse-novel information and/or occurring ex-situ. Before we validate this finding with production data from multiple speakers, we test the psychological reality of the acoustic-prosodic and structural cues to prominence, i.e., gauge their ability to affect reader's or listener's perception of a word as prominent during discourse comprehension.

4. Experiment 2: Prominence rating task

Structural and acoustic-prosodic cues to prominence were determined in reading and auditory comprehension tasks performed by linguistically naïve native speakers of Russian (N=49 (reading modality), N=27 (auditory modality)). The task included thirty-nine clause-size excerpts from the narratives. Each clause, or target segment, was presented along with the preceding context. The mode of presentation of the target sentence was either written text or audio recording of the model speaker's production. Respondents read the entire portion of the text preceding the target segment, read or listened to the target segment and identified discourse-prominent word(s) in the target segment by associating them with one level of the binary feature "+/- prominent". Following [22], no formal definition of prominence was given. Participants were instructed to mark only those words that 'were the focus of their attention' in the utterance, based on the preceding context. Any number of content words could be marked as prominent.

4.1. Results

Assessing consistency of the responses: Responses to the prominence rating task were assessed for intra- and inter-rater agreement. The kappa coefficients assessing consistency of the intra-rater rating behavior fall within the range 32.4 – 88.1 (mean=70.4, SE=2.21) and translate into moderate to very high agreement. The inter-rater agreement coefficients translate into fair, though highly significant agreement levels: Fleiss' kappa=0.26 (p<0.001) for the written and 0.36 (p<0.001) for the auditory modality.
Overall picture of the perceptual prominence ratings: Following [9], each word in the narratives was assigned two discourse prominence scores (one per test modality). Prominence scores were obtained by dividing the total number of times a word was chosen as salient by the total number of participants who responded to the relevant test question. Additionally, a global prominence score was computed for each word to represent its perceived prominence across the presentation modalities. In order to gauge the respondents' sensitivity to word order changes in the narratives, a two-way analysis of variance assessed prominence of the IS categories represented in the corpus under (a) canonical and (b) non-canonical word order. With the global prominence score used as the dependent variable, the ANOVA crossed the factors IS and Word Order (see Table 2). Results revealed no significant main effect of Word Order (F=0.137, p>0.05), a significant main effect of IS (F=47.82, p<0.001) and a significant interaction between these two factors (F=3.36, p<0.01).

Figure 2: *Global perceived prominence scores (y-axis) of the 4 IS categories (x-axis) as determined by the combined results of the silent reading and listening prominence rating tasks.*

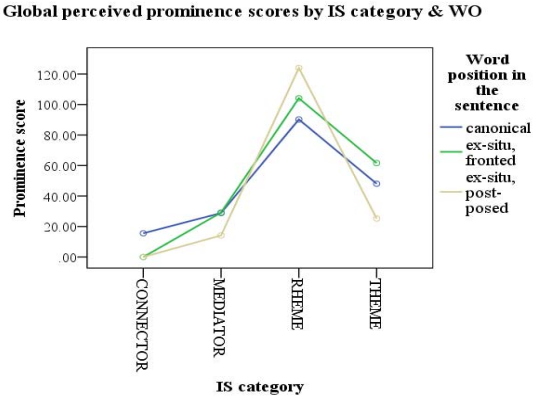


Figure 2 illustrates that IS categories with highest prominence ratings, THEME (discourse-given information, mean prominence score =49.6, SE=6.0) and RHEME (discourse-novel information, mean prominence score =106.0, SE=3.5), demonstrate a meaningful dissociation in the prominence scores as a function of the word position in the sentence. Pairwise comparisons reveal that both *in-situ* (canonical) and *fronted words* carrying *discourse-given* information are viewed as significantly more discourse-prominent than those post-posed relative to their canonical position (mean

[3] Factors '*speaker*' and '*word*' (not shown in Table1) were included in the model as random effects.

difference=22.83, p=0.05 for in-situ words, and mean difference=36.4, p<0.05 for fronted words). The dissociation goes the opposite way for the ex-situ words carrying *discourse-new* information (RHEME): *post-posed* discourse-novel words receive significantly higher discourse prominence scores than those appearing the in-situ or fronted, relative to their canonical position (mean difference=33.7, p<0.001 for in-situ words, and mean difference= 19.9, p=0.05 for fronted words).

Correlates of perceived prominence: Modality-specific prominence scores were modelled with linear regression analyses. Predictors for auditory prominence perception were extracted from the recording of the model speaker's reading performance and included the acoustic-prosodic measures of standardized f0 and intensity maxima, f0 range and excursion size, and vowel duration taken from the stressed syllable of each IS-coded content word.

In silent reading of the Russian corpus, words located in ex-situ position, specifically, post-posed (t=7.17, p<0.001) or fronted (t=5.78, p<0.001), relative to the canonical position, as well as words carrying discourse-novel information (t=2.69, p<0.01) were associated with higher prominence scores.

In the auditory modality, these factors were complemented with acoustic predictors duration (t=2.23, p<0.05), intensity (t=2.27, p=0.05), and f0 range (t=2.78, p<0.01).

4.2. Introducing production data from multiple speakers

While results of the auditory prominence rating task present compelling evidence for structural and prosodic prominence being utilized by the listeners during discourse comprehension, they hinge on the reading performance of the model speaker. To test whether the perceived prominence scores from the auditory modality are consistent with the IS properties of the narratives encoded via word order and multi-speaker prosody, acoustic-prosodic measurements of the model speaker's reading performance were augmented with those from 14 speakers (who did not participate in the prominence rating task). A multinomial logistic mixed effects regression was fit to the data to model the IS category of a word (discourse-given or THEME, discourse-novel or RHEME, inferable or MEDIATOR) using its auditory modality prominence score, sentence position, and the acoustic measures for that word extracted from the productions of the 15 speakers[4]. Results of the logistic regression analysis confirm that structural and prosodic correlates of discourse prominence successfully predict the IS category of content words. Specifically, discourse-novel information, which is the IS category that received the highest perceived prominence scores (z=6.69, p<0.001), bears a reliable association with ex-situ sentential positions (z=1.77, p=0.08 for fronted RHEMEs; z=1.97, p<0.5 for post-posed RHEMEs) and distinctive acoustic-prosodic realization. The latter is supported by a number of parameters from oral productions by 15 Russian speakers, including f0 range (z=1.99, p<0.05) and maxima (z=3.23, p=0.001), lower mean f0 values (z=-3.18, p=0.001), as well as greater duration (z=2.10, p<0.05) and mean intensity (z=2.28, p<0.05) associated with the stressed vowel of RHEMEs. *Discourse-inferable* words (MEDIATOR), on the other hand, are characterized by lower perceived prominence scores (z=-4,84, p<0.001) and smaller duration (z=-4.30, p<0.001) and mean f0 values (z=-2.12, p<0.05).

[4] The regression model included two random effects, *segment* and *speaker*. Each level of the variable *segment* corresponds to one unique vowel from which the acoustic-prosodic measurements were extracted.

5. Discussion

The goal of this work is to parameterize perceived prominence in a free word order language like Russian and understand which factors guide naïve readers' or listeners' perception of a word as prominent in a discourse or narrative. To this end, we offer an empirical test of whether variation in word order, along with the more established acoustic-prosodic ways of marking discourse-prominent information, can serve as a means of encoding the information status of a word and, by doing so, mediate its perceived prominence.

Analyses of the production and perceptual prominence ratings data presented in this work successfully capture the close interrelatedness of the prosodic and structural cues to prominence in the corpus of two published narratives. Results demonstrate that independent of the modality of presentation, words that carry discourse-novel information are perceived as more prominent.

In a free word order language such as Russian, information status is encoded via two routes, prosodic and structural. In the auditory modality, listeners treat the acoustic-prosodic realization of a word as a cue to its discourse status. This is evident from the finding that distinctive f0 qualities, greater intensity and vowel duration reliably trigger perception of a word as prominent. About 30% of the utterances in the mini corpus deviate from canonical word order, which means that words carrying novel or given information may occur ex-situ, i.e., be fronted or post-posed, relative to the canonical SVO position. Results of the prominence rating task show that apart from the acoustic effects of prosody, an ex-situ position of a word also contributes to its perception as prominent.

Analysis of the syntactic and acoustic-prosodic characteristics of perceived prominence reveals that Russian allows cross-application of different cues to prominence within the same utterance. Ex-situ positions are associated with (1) a higher prominence score and (2) in the auditory modality, distinctive perceptual qualities. Such distinctive acoustic-prosodic realization of non-canonically positioned words may not only cue their relatively high informational load and discourse prominence, but, in a language that exhibits focus fronting and right-edge dislocation for IS purposes [16,25], may also (redundantly) signal that the word is left- or right- dislocated.

6. Conclusion

This study contributes to the understanding of discourse-prominence in a free word order language. Results of the production and perception experiments performed by linguistically naïve native speakers of Russian reveal that concurrent application of prosodic and structural cues does not preclude either cue class from being perceived as a signal to information that calls for special attention in discourse. Further work is necessary to determine whether cross-application of prominence cues is characteristic of all vs. select categories of discourse-prominent information and whether its effect is additive, i.e., leading to a word being associated with a yet greater degree of perceived prominence.

Abstract

In both tone and intonation systems, segmental context is known to influence production and perception of target F0 contours in various ways. Many languages, for example, prefer to realize critical F0 events during maximally sonorous intervals, either by varying the timing of pitch movements, or by virtue of distributional limitations on certain contour types. Current analytic practice, by contrast, routinely ignores segmental backdrop when estimating the perceptual efficacy of putative cues, such as F0 turning points, to tone scaling and timing patterns. Results of the perception study presented here argue that pitch accent scaling is best modeled using a weighted average of F0 sampled over a defined region of interest, and that individual sample weights are determined in part by the sonority of the segments from which they are taken. That is, samples from lower sonority segments contribute less to integrated scaling percepts than those from higher sonority segments. This model, called TCoG-F(requency), accounts for crosslinguistic tonal timing and distribution patterns in the literature, and underscores the danger of analyzing tonal phenomena completely apart from the segments that express them.

Index Terms: Intonation, Pitch perception, tone scaling, tonal timing, sonority, Tonal Center of Gravity.

1. Introduction

Since the dawn of the autosegmental era in tonal and intonational phonology [10, 19, 4, 22], we have grown accustomed to thinking of linguistic pitch specifications as existing apart from, or parallel to, the segmental skeleton of the spoken utterance. Specifications on the so-called tonal tier must then be associated, according to the dictates of the grammar, with appropriate Tone-Bearing Units in order to be realized phonetically. At the same time, however, it is well known that both perception and production of F0 can be influenced significantly by the segmental contexts in which contours are realized. For example, 'microprosodic' effects on the F0 contour stem from, e.g., voicing differences in syllable-initial consonants, differences in vowel height between otherwise comparable syllables, etc., and experimentalists routinely control for such effects [15, 17, 26].

Less widely appreciated, however, are the ramifications of a commonly-remarked tendency for languages to avoid realizing critical portions of F0 contours within lower-sonority regions of the segmental string. This tendency manifests itself in various ways: On the one hand, intonational phonologists have observed what appear to be systematic alterations to tonal timing patterns in order to ensure optimal expression of F0 contours in a given segmental context. For example, in a variety of languages, accentual High F0 targets occur relatively earlier in closed syllables than in open, and in syllables closed by obstruents than in those closed by sonorants [5, 18, 23, 24, 25]. On the other hand, languages can impose categorical distributional restrictions on the association of certain tone patterns with particular kinds of segment hosts. For example, cross-linguistically, contour tones tend to be restricted to syllables with longer, higher-sonority rhymes [11, 28, 29].

The latter pattern, typically observed in languages with lexical tone contrasts, has been explained as resulting from the comparatively greater salience of the percept of pitch during segments that are higher in intensity and richer in harmonic structure [8, 29]. Under this scenario, languages deploy their fullest array of tonal contrasts only in contexts where these contrasts are most likely to be accurately perceived. This explanation could account for the first cases mentioned above as well: If F0 peaks associated with intonational High pitch accents occur relatively earlier in closed syllables than in open, for example, we might attribute this to speakers' desire to realize critical pitch information (i.e. the bulk of elevated F0) within a more sonorous portion of the syllable (i.e. the nucleus rather than the coda).[1]

Against this backdrop of general awareness of the influence of segmental context on tone perception and production, there is also a somewhat paradoxical countervailing tendency to assume that putative tonal targets such as F0 turning points are of equal perceptual value regardless of the nature of their host segments. According to this practice, linguistically meaningful pitch accent scaling patterns are equated phonetically with measured F0 maxima, regardless of where in the segmental string those maxima fall; similarly, the temporal location of F0 turning points is estimated according to the visual salience of 'corners' in the F0 track, regardless of whether those corners fall in regions of the signal with high or low auditory salience. In an analogous vein, the subjective continuity of intonation contours, even through regions where F0 is heavily disrupted by intervals of voicelessness, has led some to assume that listeners have an ability to effectively 'restore' missing F0 intervals to the signal via interpolation, or extrapolation based on existing trajectories [12, 13, 21]. Accordingly, F0 stylization algorithms such as the Fujisaki model, MOMEL, or Tilt [9, 14, 27] create continuous F0 tracks based on gappy originals, in some cases even locating critical F0 target points within such 'filled in' intervals, when the shape of the interpolated pitch curve suggests it. It is the tension between this tendency, on the one hand, and the literature on avoidance of low-

[1] Another explanation that has been offered for these altered timing patterns is based on House's Spectral Stability Hypothesis [16, 7, 24], whereby pitch movements are more readily perceived as such when they are realized during regions of spectral stability. For reasons of space, we will not treat this hypothesis further here, other than to note that it relates less obviously to the distributional restrictions on lexical tones noted above.

sonority segmental hosts on the other, that inspired the experiments described in this paper.

A first step toward resolving these issues was taken recently by [1], who demonstrate that, at least for perceived F0 target scaling, the "perceptual completion" approach cannot be correct.[2] In that study, subjects made judgments regarding the scaling of synthetic English High pitch accents (L+H*) realized either as clear peak- and plateau-shaped F0 contours extending over fully voiced segmental intervals (e.g., in a context like '*DAY' might fit*), or as analogous contours in which the region corresponding to the nuclear pitch accent contained 'missing' or inferable peaks/plateaux (i.e. mirror-image rises and falls separated by the closures and releases of voiceless stops, as in a context like *'DATE' might fit*). Rather than either extrapolating or interpolating F0 across such voiceless intervals in a way that would register systematically on scaling judgments, subjects were seen to behave as though the missing intervals were absent altogether, ignoring the gaps, and judging relative pitch accent scaling exclusively on the basis of the F0 values actually present in the signal.

While that study gives an indication of how listeners treat F0 gaps created by voiceless stops, it remains unclear what listeners do with intervals in which F0 is in fact present, but with lower-amplitude or spectral impoverishment. In the current study we use similar investigative techniques to those of (1), applied specifically to the perception of measurable F0 over lower-sonority intervals. We hypothesize that vowel vs. silence are in fact two ends of a continuum of possible F0 carriers with differing degrees of salience, along which higher sonority segments such as liquids or nasals give way gradually to lower sonority ones, such as voiced fricatives or stops. We predict that these sonority-based differences in the robustness of perceived pitch will be manifested in listeners' scaling judgments. We situate the results of this study in a model of tone scaling perception we call TCoG-F (Tonal Center of Gravity in the Frequency dimension), where the perceived scaling of an F0 event (e.g., the elevated F0 associated with a High pitch accent) is modeled as a weighted average of F0 measured over a particular region of interest. In the calculation of this average, F0 samples taken from more sonorous regions are accorded heavier weights, and are thus predicted to extend relatively greater influence over perceived scaling.

2. Methods

The reasoning behind the current design is as follows: Consider a set of utterances, such as those depicted in Figure 1, bearing rise-fall-rise intonation contours, with plateau-shaped L+H* nuclear pitch accents on the first word of the sentence (*'X' might fit*, uttered perhaps in the context of the solution to a crossword puzzle clue), where F0 rises through the nuclear vowel, remains high and level through the coda nasal, and falls thereafter, before rising at the end to signal something like tentativeness. In all three examples, the syllable rhymes (and their constituent nuclei and codas in a. and c.) are identical in duration, as are the relevant segments of F0 contour. What differs is only the sonority of the portion of the syllable rhyme bearing the high, level portion of the accentual plateau for the three target words *Dane*, *day* and *Dave*. Assuming, as hypothesized above, that the perceived scaling of this pitch accent involves averaging over F0 samples taken during the entire rhyme of the accented syllable, we expect first that the perceived scaling of all three of these words will end up lower than the maximum F0 realized during the plateau-portion of the contour. However, to the extent that the perceptual contribution of any given F0 sample is weighted by a factor representing the sonority of the segment bearing it, we expect the perceived scaling of the pitch accents in these three utterances to differ from one another as well. Since the highest portion of the pitch accent in *day* (i.e. the plateau) occurs in a region of greater sonority than the analogous portion of the pitch accent in *Dane*, the high F0 samples for *day* will contribute more to the resulting average, so that *day* will sound higher to listeners than *Dane,* despite identical F0. Correspondingly, owing to the lower sonority of this region in *Dave,* we predict the pitch accent in 1c to sound lower than those in a and b, again despite the lack of difference in objective F0.

To test these predictions, we designed a set of experimental stimuli similar to those used by [1] but differing in several critical ways. As just described, all stimuli were instances of the English words *day, Dane,* and *Dave,* realized in the target position of the frame sentence *X might fit*. All target stimuli were realized with rise-fall-rise intonation contours (ToBI L+H* L-H%), with the nuclear pitch accent on the first word. However, F0 for these base utterances was resynthesized to create contours of two basic types: plateau-shaped pitch accents and sharp-peak-shaped pitch accents, in effect extrapolating the preceding rise and following fall to a single higher intersection point instead of a plateau. These are both depicted in Figure 1, and their deployment in our task is detailed in Section 2.2 below.

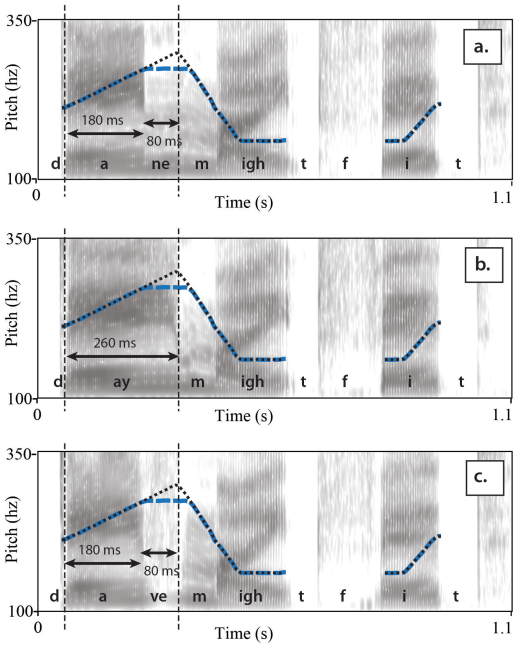

Figure 1: *Spectrograms with superimposed pitch tracks for plateaux (blue dashed lines) and peaks (black dotted lines) for* Dane *(a),* day *(b) and* Dave *(c).*

[2] At least in the most literal sense. It is still possible that non-F0 cues within voiceless regions contribute either to the 'subjective continuity' of the pitch contour, or to the perception of 'prominence' (a linguistic dimension sometimes cued in part by the higher-than/lower-than relations that underly linguistic pitch distinctions [20]. At the same time, is worth noting the extent to which relative pitch and prominence relations vary orthogonally (as in the expression of lexical tone contrasts, or the difference between downstepped and non-downstepped nuclear pitch accents).

2.1. Stimulus Creation

Target phrases were created from two sets of base recordings, one produced by a male native English speaker, the other by a female, and then resynthesized using Praat [3]. Synthesized segment durations for the female speaker, given in Fig. 1, were based on mean values over multiple utterances. For peaks, F0 rises were identical in duration (260 ms) and scaling (212-300 Hz, a 6 st rise) for this speaker for all stimulus types, and were followed by a 140 ms fall to 160 Hz. Plateau stimuli had a rise of the same slope as the peaks, but truncated after 180 ms (212-273 Hz), followed by a 101 ms plateau (at 273 Hz), and a 119 ms fall to 160 Hz (the same slope as in the peak stimuli, but starting from the end of the plateau). Duration and F0 values for stimuli based on the male speaker were comparable, though different in quantitative detail.

2.2. Experimental task

Our primary question pertains to the perceived relative scaling of nuclear L+H* pitch accents realized on syllables with differing rhyme types. However, to avoid the potential for confounds inherent in the direct pairwise comparison of syllables with differing segmental content, the relative scaling of these contours was investigated indirectly. That is, the bulk of experimental trials consisted of the pairing of a given target item (i.e. a target utterance with *day, Dane, or Dave,* with either a peak- or plateau-shaped pitch accent) with one out of a continuum of standard reference contours. These reference contours were segmentally identical to the target item, but F0 throughout the accented syllable was held steady at one of 7 levels, the highest at 300 Hz, descending thereafter in .5 semitone increments (Figure 2). After the fall from the accented syllable, F0 was identical for target items and standards.

If we assume that corresponding level standards sound identical in scaling regardless of syllable type, since sonority-related weighting variation cannot change perceived pitch for a flat-F0 contour, then any effects of F0 weighting differences on tokens with changing F0 should be manifest in subjects' perception of the relative scaling of target items and their respective level standards. (E.g., *day* might sound equal in pitch to its standard level 5, while *Dave* might reach only level 4.)

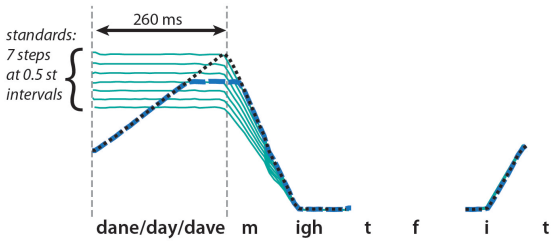

Figure 2: *Pitch tracks for standards (teal solid), plateaux (blue dashed) and peaks (black dotted).*

The task itself was 2AFC: 77 native speakers of American English were presented with pairs of contours (a target item and a level standard), and decided which contour's target word reached a higher pitch. After 6 consecutive correct responses in an initial block comparing standards separated by ≥ 3 steps, the experiment began, with each test item (2 accent shapes X 3 word types) compared to its continuum of 7 standards (2 reps of standards 1, 2 & 7, and 3 reps of standards 3, 4, 5, & 6 = 18) in 2 orders, for a total of 216 trials. Additionally, there were two more trial types interspersed. The first was represented by 36 trials pairing two level standards separated by either 2 or 3 continuum steps for *day* target types (18 comparisons x 2 orders). These trials served as a baseline measure of participants' accuracy in discriminating pitch levels. The final trial type involved 18 pairings consisting of each sharp-peak-shaped version of a given syllable type with its plateau-shaped counterpart (3 reps X 2 orders X 3 word types). These trials served as an additional test of the hypothesis that the phenomena under investigation here are in fact the result of lowered perceptual salience of F0 samples taken from utterance intervals of lesser sonority. In all such pairings, as with the level vs. level comparisons, there is in fact a "correct" answer: The sharp peak version of the pitch accent should sound higher than its plateau-shaped counterpart because it is, in fact, by any measure, higher.[3] On the other hand, since the entirety of the region of F0 difference between peaks and plateaux fell within the region of sonority difference across word types, if our hypothesis is correct, the scaling difference between the two should be relatively easy to detect for *day,* but progressively harder in the lower sonority rhymes of *Dane-* and *Dave*-type stimuli. All trial types were mixed together, and all 270 experimental trials were presented in random order, with breaks after every 50 trials. (See Figure 3 for a schematic summary of the 4 trial types.)

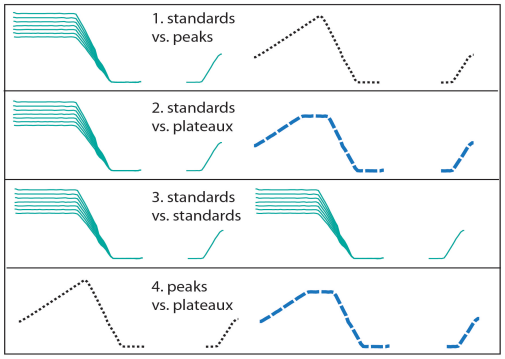

Figure 3: *Schematic showing the 4 types of experimental trials.*

2.3. Results and analysis

Data from 62 participants is included in the analysis. (Of 77 total, 15 of whom did not reach criterion for inclusion based on discrimination of level standards.) Fig. 4 displays results, pooled across subjects. Lines represent the percentage of trials in which *day, Dane,* or *Dave* was judged higher than each of its 7 level standards. Comparing target types, the percentage of 'higher-than' judgments for *Dave* clearly declines earlier in the continuum of level standards than does that of *Dane,* which in turn declines earlier than *day*. We infer from this that *day* sounds higher to listeners than *Dane,* and that *Dave* sounds lower. This is confirmed by a mixed-effects logistic regression analysis, using both standard level and target-syllable type, as well as accent shape (peak vs. plateau) as fixed factors, and participant as a random factor. The resulting model (N = 12,971, log-likelihood = -5573) shows a main effect of standard level (Est. = -0.934 (SE = 0.017), Wald Z = -55.73, p

[3] Mean F0 for the accentual high region, however measured and weighted, was higher for peaks than for plateaux.

< .001), and of word type, with *day* differing in a positive direction from *Dane* (Est. = 0.256, (*SE* = 0.079), Wald *Z* = 3.24, *p* = .001), and *Dave* differing from *Dane* in a negative direction (Est. = -0.504 (*SE* = 0.08), Wald *Z* = -6.29, *p* < .001). Importantly, in addition to a main effect of accent shape, with plateaux differing in a negative direction from peaks (Est. = -0.941 (*SE* = 0.082), Wald *Z* = -11.35, *p* < .001), there was also a significant interaction between accent shape and word type: the peak-plateau difference was less salient for *Dave* than for *Dane* (Est. = 0.276 (*SE* = 0.118), Wald *Z* = 2.34, *p* < .05) (*day* did not differ significantly from *Dane* in this respect).

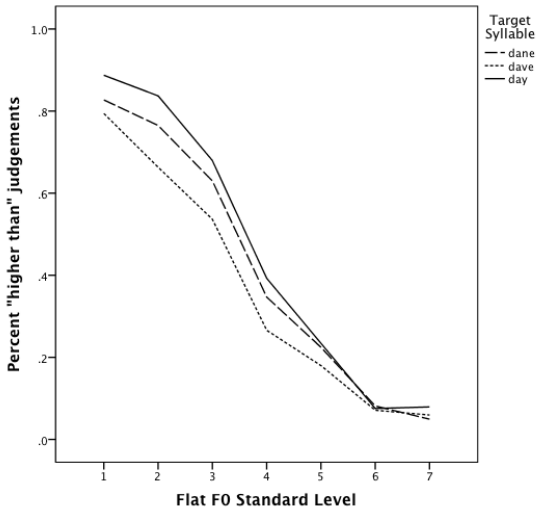

Figure 4: *Percent 'Higher-than' judgments for the three syllable types, as a function of the level standard against which they were compared.*

These results strongly bear out the predictions of the TCoG-F hypothesis detailed above. *Day* tokens sounded higher than *Dane,* which sounded higher than *Dave.* Critical in understanding this primary result is the significant interaction between accent shape and word type. The fact that the perceived scaling difference between peaks and plateaux was less pronounced when realized over the voiced fricative in *Dave* than in the nasal coda of *Dane* suggests that pitch percepts stemming from the former region are indeed less robust than those originating in the latter.

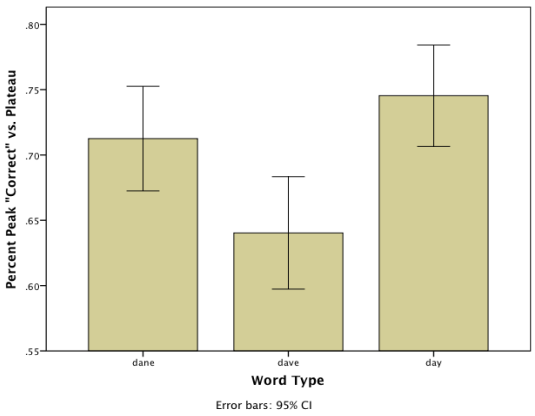

Figure 5: *Percent of peak vs. plateau trials in which peaks were correctly judged to sound higher than plateaux, for three target syllable types.*

This same conclusion is supported by trials in which subjects compared peak-shaped versions of a contour directly with their plateau analogues (Figure 5). Listener judgments of these comparisons were most accurate (i.e. listeners heard peaks as higher) for *day,* less so for *Dane*, and were least accurate for *Dave.* Another mixed-effects logistic regression (with word type as a fixed effect and participant as a random effect, *N* = 1462, log-likelihood = -849.4) shows that, while the *day-Dane* distinction was non-significant (Est. = 0.187 (*SE* = 0.15), Wald *Z* = 1.248, *p* = .21), the distinction between *Dave* and *Dane* was significant in the predicted direction (Est. = -0.358 (*SE* = 0.144), Wald *Z* = -2.494, *p* = .012). This lowered accuracy for scaling judgments where the sole difference between the two F0 contours lies within the lower sonority region of the coda is, again, just what TCoG-F would predict: Lower F0 sample weights during the crucial interval understate the objective difference between the two contours and make judgments more error-prone.

It is also worth noting that the connection between this result and the earlier one is a first glance not obvious: on the face of it, the fact that *Dave* trials sounded systematically lower than *Dane* or *day* to our listeners when paired with level standards bears no logical connection to the degree of accuracy listeners might exhibit when comparing one kind of *Dave, Dane,* or *day* contour to another in paired scaling judgments. The connection between the two results becomes clear only through the lens of TCoG-F.

3. Conclusions

While from a phonological point of view, the advent of autosegmentalism brought with it a great deal of progress and innovation, in the domain of phonetic realization, there remains a persistent danger that the core autosegmental insight, the separation of tonal and segmental phenomena onto distinct representational "tiers", may at times be taken too literally. The findings described here suggest that listeners' perception of F0 in speech signals is influenced by the nature of the consonant and vowel segments over which the F0 pattern occurs, even when voicing continues through those segments; that is, F0 values in regions controlled by more-sonorous segments (like vowels and nasals) are weighted more heavily than F0 values in regions controlled by less-sonorous segments (like voiced fricatives). This means that models based on a straightforward mapping between values of F0 peaks and valleys on the one hand, and perceived intonational targets, on the other, will need to be modified to take account of the influence of host segments. Taken together with earlier findings demonstrating the role of F0 contour shape on perceived tonal target alignment [2], these results support a model of intonation processing based on the Tonal Center of Gravity in both the time and frequency domains. We suggest furthermore that perceptual registration of individual cues in the speech signal is only the first step in the process of integrating multiple cues to form a single linguistically-relevant auditory percept. Future work will test this hypothesis in languages other than American English.

Abstract

We examined the phonetics and phonology of intonation of infant-directed speech (IDS) and non-IDS in story-reading in two typologically-divergent languages, English and Bengali. In addition to finding an increase in f0 range and variability in IDS, replicating previous work on IDS prosody, we found novel evidence that f0 manipulations in IDS are constrained by intonational phonology. Speakers in both languages used an increased proportion of tonal elements with higher tonal targets and more turning points in IDS, within the language-specific intonational grammar. The tonal elements showing increased use in IDS also were associated with marking topic and focus. Thus, phonetic changes in IDS may in part be induced by speakers' choices of phonological tonal elements, which in turn may be connected with choices about marking discourse structure.

Index Terms: infant-directed speech, intonational phonology, speech style, information structure, Bengali, English

1. Introduction and background

It has long been noted that gradient phonetic variation in prosodic elements such as pitch, rhythm, and duration can carry information about interpersonal interaction and emotional state, cf. [1] for a review. However, work in intonational phonology ([1], [2], i.a.) has shown that prosodic variation is also structured according to the language-specific phonological grammar, which generates well-formed tunes constructed over discrete phonological categories, conveying linguistic meanings such as contrastive focus ([3], i.a.).

A classic example of gradient prosodic manipulation occurs in the speech style of infant-directed speech (IDS) or "motherese": relative to adult-directed speech, IDS has been shown to exhibit higher mean fundamental frequency (f0), higher maximum f0, an expanded pitch range, greater f0 variability, and shorter utterances across a variety of languages ([4], [5], [6], i.a.). With almost no exception, work on IDS prosody has exclusively involved phonetic description of pitch manipulations as described above. Moreover, these gradient phonetic manipulations have been described as serving attentional and emotional functions. For instance, high pitch and increased pitch variability such as bell- and sinusoidal-shaped pitch modulations have been suggested to maintain infant attention and elicit positive emotional rapport ([7], [8], [9], [10], [11], [12], [13]).

Without attention to intonational phonology, phonetic characterizations of IDS prosody leave open the possibility of pitch variation in IDS wholly motivated by attentional and emotional considerations, e.g. with sinusoidal ups and downs over a wide pitch range, irrespective of constraints of phonological grammar. To date, very little in the literature suggests otherwise, with the exception of three studies that explored phonological constraints on pitch variation in IDS. In the tone languages Thai [6] and Mandarin [14], it has been found that f0 cues to lexical tonal identity are preserved in IDS. Only one study thus far ([15]) addresses intonational phonological constraints on IDS; pitch range expansion in Japanese was shown to be restricted to boundary tones, a sub-component of the intonational grammar where pitch is not lexically contrastive. In all three cases, the pitch manipulations ascribed to IDS did not interfere with lexically-contrastive aspects of pitch; the current study extends this recent work to two languages that have no lexical contrasts in pitch but that nevertheless manipulate pitch linguistically as intonation.

Our study investigates the hypothesis that pitch variability in IDS can be constrained by intonational phonological grammar in English and Bengali, languages with typologically divergent prosodic systems. We compared how parents of infants and young children read a story standardized across the languages in adult-directed speech (ADS) vs. IDS. We annotated the readings with intonational transcriptions based on intonational models of lab speech-style ADS in the two languages.

While [15] examined how pitch variation changes in Japanese IDS are conditioned on particular tonal elements, our study examines how pitch variation changes in IDS are realized via *changes in the choice of tonal elements within intonational grammar*. Moreover, our phonological analysis of IDS intonation allows us to examine how prosodic choices in IDS may reflect attention to conveying linguistic meaning and structure, in addition to regulating attention and emotional rapport. To preview our results: based on comparing the distribution of discrete tonal elements within the two speech styles, we found that in both languages, IDS showed an increase in tonal elements with high tonal targets and multiple turning points. These distributional changes occurred within the constraints of each language's intonational grammar. Moreover, these changes also resulted in an increase in the use of tonal elements used to mark aspects of discourse structure.

1.1. English intonation and transcription

The most widely known model of the intonation of American English (henceforth, simply "English") is often referred to as MAE_ToBI, from the Mainstream American English Tones and Break Indices transcription system devised to annotate the intonation of this variety ([1], [2], [3]). In MAE_ToBI, pitch accents are borne by the primary stressed syllable of prominent words, where stress is contrastive and thus must encode lexical information. The pitch accent inventory includes default H* (high) and L* (low) tones as well as rising L+H* (early rise) and L*+H (late rise) tones and one falling H+!H* tone. The choice is related to attitude, focus status, and tonal environment ([3], [16], [17]). The choice of pitch accent is somewhat variable, although certain tune–meaning relationships have been proposed in the literature: L+H* and

L*+H often convey focus ([3]). Boundary tones occur at the right edge of Intonation Phrases (IPs) and intermediate phrases (ip). The IP boundary tone inventory includes L-L% (low falling), H-H% (high rising), L-H% (low rising), H-L% (high level), and !H-L% (downstepped high level), the choice of which conveys sentence type, finality, etc. ([3]).

1.2. Bengali intonation and transcription

The intonational phonological model of Bangladeshi Standard Bengali (henceforth, simply "Bengali") presented here is based on that of [18], [19]. The pitch accent inventory of Bengali includes default L* (low), H* (high), L*+H (rising), as well as f-marked (focus-marking) versions of the latter two, fH* (extra high) and L*+fH (rise to extra high), the choice of which conveys speaker attitude, focus status/type, and tonal environment ([18], [19]). Focus-marking tones are easily distinguished by their unique tonal interactions not seen in other pitch accents (i.e. violation of downtrend, immunity from overriding, triggering of post-focal tone compression); these phonetic and phonological criteria were used in the current study to identify focus-marking tones.

Each pitch accent projects a small prosodic unit called the Accentual Phrase (AP), which is marked on the right edge by a tone of the opposite target of the pitch accent: Ha (high target) and La (low target). These phrases group into ips, marked by sharp final contours: H- (sharp final rise) and L- (sharp final fall). As in English, ips group into IPs, marked by boundary tones that covey sentence type, information structure, and finality ([18], [19]). H% (high rising) and HL% (high falling) can serve as topicalizers, and both LH% (low rising) and HLH% (high dipping) can serve as markers of non-finality.

1.3. Comparison of English and Bengali intonation

Noteworthy similarities and differences between Bengali and English intonation are in (a) pitch contour regularity, (b) focus realization, and (c) boundary tone complexity.

One of the most clearly noticeable differences between English and Bengali is the regular repeating patterns seen in the Bengali pitch contour and the general lack of such regularity in English. This is largely an effect of the restricted pitch accent and AP boundary tone distribution of Bengali. While a content word in English is fairly free to bear any of five basic pitch accents (H*, L*, L+H*, L*+H, H+!H*) or none, Bengali content words almost always bear L* followed by a Ha, except in very specific cases: H* followed by La conveys surprise or sarcasm, and L*+H is only a secondary option phrase-finally, and the two f-marked pitch accents (fH*, L*+fH) are only used to convey narrow focus.

In both languages, focus is realized via pitch accent choice and post-focal tone compression (i.e. deaccenting). In Bengali, an f-marked tone (fH*, L*+fH) marks the focused word. These are sharply distinct from the non-focused pitch accent L*, and can even be distinguished from H* and L*+H as the latter two obey downtrend and do not trigger post-focal compression, unlike f-marked tones. In English, the focused element can bear L+H* and L*+H rather than H* in declaratives [3]. The distinction between tones associated with and without focus in Bengali is clearer than in English, where H* and L+H* appear to have overlapping allophonic variation [20], although they are functionally distinct [21].

Lastly, Bengali and English differ in the complexity of their boundary tones. While Bengali has three levels of tonally-marked prosodic structure (i.e. AP, ip, IP), English has only two (i.e. ip, IP). Bengali APs and ips typically end in a single underlying tone, but the ip tones L- and H- both inherently incorporate a sharp phrase-final rise or fall in pitch. English ip tones L- and H- do not have this sharp phrase-final rise or fall, and are instead realized as "phrase accents", i.e. generally low or generally high pitch across the phrase-final stretch. The five Bengali IP tones are very complex, including one, two, or three tonal targets (e.g. HLH%), all of them involving large changes in pitch. The five English IP tones, on the other hand, can have only one or two tonal targets (e.g. L-H%), and two of them involve a stretch of flat pitch (H-L%, !H-L%), which is at best rare in Bengali.

2. Methods

2.1. Data collection

The speech of nine (5 male, 5 female) native speakers of English and ten (5 male, 5 female) native speakers of Bengali was recorded in a quiet room in Los Angeles. Subjects were paid $5 for their participation, which typically took 20 min. To help ensure that subjects were comfortable and familiar with the IDS task, only parents were recruited. The English speakers had infants of 4.4±0.7 months of age at the time of recording, while there was no specific cutoff for the age of the Bengali speakers' children due to subject pool limitations. However, all Bengali subjects lived with their (grand)children <10 yrs of age, and six subjects were teachers at a Bengali-language weekend school for children.

Subjects were recorded while reading the "North Wind and Sun" fable, the Bengali version of which was taken from [22]. Storytelling was used as a context appropriate for both IDS and non-IDS default read speech. The particular text was chosen for comparison with other work on speech rhythm using the same text, as part of a larger study. Using translations of the same text across both languages ensured that the recordings from the two languages would not be affected by different semantic/pragmatic features triggered by reading different stories. Furthermore, unlike studies that examine spontaneous IDS, the current study kept the text constant to minimize changes in semantics, morphosyntax, and the underlying segments across conditions. This way we could observe how speakers' prosodic choices might change, given the same morphosyntactic and discourse structure.

Multiple recordings were made using a Shure SM10A head-mounted microphone plugged into a laptop computer via a preamplifier. The first of the two conditions was default reading ("non-IDS"), in which subjects were asked to "read at a comfortable pace". This task direction was designed to be comparable with other studies of speech rhythm using lab speech, as part of a larger study. The second condition was simulated infant-directed reading ("IDS"), in which the subject was asked to read the same passage as if speaking to their 4-5 month-old infant. (Bengali speakers were asked to imagine their child at that age.). This is an age range where IDS has fewer single-word utterances, is less dominated by soothing/comforting affect, and is intensely used for rapport and attention ([9], [6]). Thus, it is an age range where paralinguistic demands play a large role in driving prosodic

manipulations in IDS. Childlike illustrations and plush toys were used to help further encourage this register.[1]

2.2. Data analysis

For each condition, the three clearest repetitions with minimal or no disfluencies were analyzed, giving 2 conditions x 3 repetitions = 6 recordings per speaker. Text grids were generated in Praat ([23]) to allow annotation in MAE_ToBI tone labels ([24]) for English and B-ToBI tone labels ([18], [19]) for Bengali, by a transcriber trained in each system.

Both acoustic-phonetic measurements and categorical phonological measurements were taken during each sound file. These include: pitch range, tonal inventory, total number of pitch accents and boundary tones, and the frequency of use of each type of pitch accent and boundary tone. Currently, the results presented reflect the whole Bengali data set, but annotations for the English data set are incomplete and preliminary results presented here reflect one repetition from each speech style for each speaker. For the Bengali data, a random sample of the data has also been transcribed by a second transcriber to check for intertranscriber reliability.

Transcribers in both languages were trained only on non-IDS speech materials from outside of the current study, and were encouraged to propose new tones or take note of new tonal interactions when approaching the IDS and non-IDS recordings from the current study. This was done to discourage transcribers from forcing aspects of the non-IDS intonational phonological grammar onto what could hypothetically be a completely different grammar in IDS. All tones transcribed in IDS were also found in the non-IDS recordings in this study, including two tones in Bengali that had not yet been identified in previous work (and were not found in the training files): L+H*, M%.

To analyze changes between the distribution of pitch accent and boundary tone types between styles, proportions of each tone type were calculated, aggregated across repetitions. Separate mixed effects logistic models were built for individual tonal elements, with the proportion of an individual tonal element as the dependent variable, speech style and speaker sex as fixed effects, and random effects by speaker (cf. [25] for advantages of logistic models for proportional data). Results reported as significant were significant with Bonferroni corrections for multiple comparisons.

3. Results

3.1. Phonetic changes in IDS: both languages

F0 data was extracted at 10ms intervals from the recorded files using RAPT ([26]). Mean, minimum, and maximum f0 (in Hz), as well as f0 range and change in f0 variability were calculated over each phrase and averaged across phrases for each speaker, following [5]. Paired t-tests indicated significant increases in IDS for mean f0, maximum f0, f0 range, and f0 variability, all with $p < 0.01$, but no change in minimum f0, for both languages. These results are consistent with previous studies of IDS in many languages, supporting the validity of properties of the simulated IDS recorded here as bearing on properties of IDS in general.

3.2. Phonological changes in IDS: Bengali

While the number of pitch accents significantly decreased by 7% in IDS ($t(9)=3.1$, $p=0.01$), the proportion of focus-marking pitch accents significantly increased. Proportions of pitch accents between speech styles are shown below in Figure 1. The proportion of fH* accents significantly increased from an average of 0.9% across speakers to 5.0% in IDS ($\beta_{IDS} = 2.1$, $p = 2e\text{-}6$). The proportion of L*+fH accents significantly increased from 1.9% to 4.1%, with a larger increase for females ($\beta_{IDS \text{ nested in } SEX} = 1.0$, $p = 0.007$). The proportion of (default) L* accents significantly decreased, while the proportion of (non-default) H* accents significantly increased.

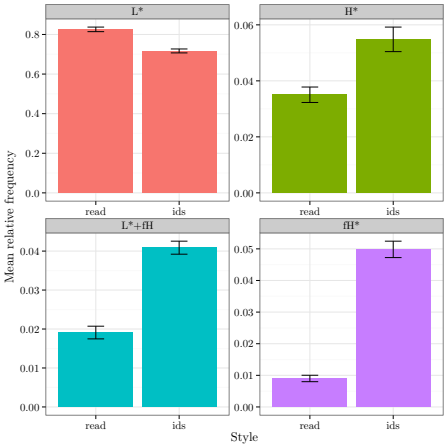

Fig. 1: Change in relative frequency of pitch accents between speech styles, averaged over speakers. Error bars show ±1SE.

In addition, the number of IPs significantly increased by 49% in IDS ($t(9)=5.5$, $p=3.8e\text{-}4$) and the number of ips by 21% ($t(9)=-3.5$, $p=0.006$), while the number of APs significantly decreased by 10% in IDS ($t(9)=-3.5$, $p=6.5e\text{-}3$). Among the AP tone types, there was no significant change in the proportion of La tones, but the proportion of Ha tones significantly decreased in IDS ($\beta_{IDS} = -0.64$, $p = 7e\text{-}8$), while the proportion of fHa tones significantly increased ($\beta_{IDS} = 0.79$, $p = 2e\text{-}8$). Changes in the proportion of IP tone types are shown in Figure 2. The proportion of HLH% tones significantly increased from an average of 8% to 17% in IDS ($\beta_{IDS} = 0.80$, $p = 1.9e\text{-}5$), as did the proportion of HL% tones, from an average of 2% to 7% ($\beta_{IDS} = 1.2$, $p = 3.1e\text{-}4$). In contrast, the proportion of L% and LH% tones significantly decreased ($\beta_{IDS} = -0.31$, $p = 7.2e\text{-}3$. $\beta_{IDS} = -0.58$, $p = 3.9e\text{-}6$).

3.3. Phonological changes in IDS: English

While the number of pitch accents did not significantly change between speech styles, ($t(8)=-1.8$, $p=0.11$), there was a significant increase in IDS in the proportion of rising pitch accents of L*+H from 0.7% to 4.9% on average across speakers, and of L+H* from 2.8% to 10.3% on average (L*+H: $\beta_{IDS} = 1.9$, $p = 0.003$; L+H*: $\beta_{IDS} = 1.44$, $p = 4.17e\text{-}5$). There was a concomitant insignificant trend for decreases in IDS in the proportion of L* and H* accents. In addition, speakers produced a significantly higher average of 32% more

[1] In pilot work when an infant was in the room, the infant would often fuss and cry, disturbing the audio recording, causing disfluencies in the subject's speech, and interrupting him/her at unpredictable intervals. As the study of intonational phonology in IDS is in its beginning stages, we decided to abstract away from these disturbances for the time being.

ips and 35% more IPs in IDS (ip: t(8) = 3.4, p = 0.01, IP: t(8) = 4.8, p = 0.001). There were no significant changes in the proportion of different boundary tone sequences, and the majority of boundary tone sequences were L-L% (85%).

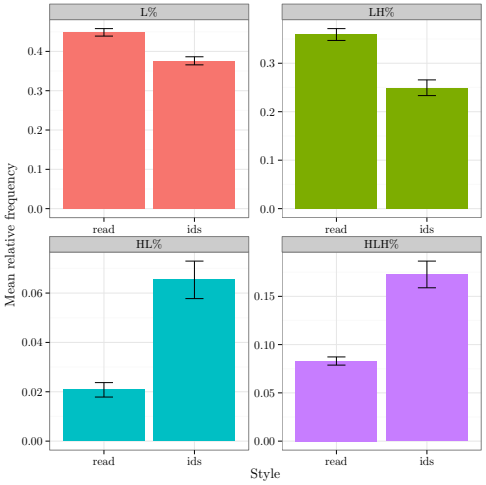

Figure 2: Change in relative frequency of IP tones between speech styles averaged over speakers. Error bars show ±1SE.

3.4. Summary of results

To summarize, both languages showed an overall acoustic-phonetic expansion of the pitch range and overall increase in f0 variability. Both languages also had phonological changes in intonation: increases in the use of non-default pitch accents (despite the lack of increase in pitch accents overall), increases in the number of ips and IPs, and for Bengali, increases in the use of some complex boundary tones.

4. Discussion

We found that IDS prosody in a storytelling context was characterized by gradient phonetic changes as well as changes in the choice of discrete tonal elements within the language-specific intonational grammar.

The overall expansion of f0 range, higher f0 maxima and increased f0 variability in IDS was realized within the constraints of the language-specific grammar. First, we found that pitch variation in IDS could be understood using phonological models of intonation: all tones we found in IDS were also found in non-IDS. Second, changes in the choice of tonal elements in IDS were changes that could induce the gradient phonetic changes of higher f0 maxima and increased f0 variability. Both languages showed an increase in pitch accents with higher tonal targets and more turning points in IDS (L+H* and L*+H in English; H*, fH* and L*+fH in Bengali); Bengali also had an increase in use of an AP tone with a higher tonal target, fHa. In addition, both languages showed increases in the number of higher-level boundary tones. Higher-level boundary tones such as IP tones are realized in an expanded pitch range relative to lower-level boundary tones. Moreover, in Bengali, the inventory of IP tones includes complex contours not available for lower-level boundary tones; indeed, there was a decrease in default L% tones but an increase in HL% and HLH% tones in IDS. Thus, while non-IDS in Bengali was characterized by a series of predictable contours built with L*, Ha, and L%, IDS replaced these with H*/fH* and complex boundary tones.

In addition, the change in choice of tonal elements in IDS appears to not only be influenced by the pitch patterns they induce, but also by their tone-meaning mappings. Almost all the pitch accents with increased use in IDS in both languages are ones associated with focus, and Bengali also showed an increase in use of the focus-marking fHa AP tone and the topicalization marker HL%. The lack of an increase in the number of pitch accents in both languages can also be understood as a consequence of focus-marking within intonational grammar: preliminary analyses suggest that the increased use of focus-marking pitch accents in both English and Bengali in IDS limited the increase in the number of pitch accents overall since the use of focus-marking pitch accents causes post-focal tonal compression and deaccenting in both Bengali and English. Preliminary inspection also suggests that speakers were not deploying tones associated with focus- and topic-marking in IDS in a manner divorced from the discourse structure, which is what one might expect if these tones were chosen simply due to the pitch patterns they induce. For instance, L+H* accents in English did not appear on pronouns, which were discourse-given. Thus, we speculate that the phonetic pitch changes in IDS may be in part a consequence of increased marking of discourse structure in IDS, as suggested in [10].

5. Conclusions

In this study, we examined changes in patterns of pitch variation in English and Bengali when speakers read a story in a non-infant directed style and an infant-directed style. We found that in both languages, there was an increase in f0 range via raising of f0 maxima as well as increased f0 variability in IDS, replicating previous cross-linguistic phonetic work on IDS prosody. In addition, we performed phonological analyses of intonation in the two speech styles, which revealed that the phonetic pitch manipulations in IDS we observed were constrained by language-specific intonational grammar. We observed that IDS and non-IDS intonation could be modeled with the same underlying tonal elements, but that the distribution of use of these elements differed between styles. In IDS, speakers increased the proportion of tonal elements with high tonal targets and more turning points, which induce higher f0 maxima and greater f0 variability. Thus, the phonetic changes in pitch in IDS may have been in part a consequence of speakers' choice of phonological tonal elements. Moreover, tonal elements with increased use in IDS were also associated with marking focus and topic in previous work. Preliminary analyses suggest that these tonal elements were not placed arbitrarily, but in ways consistent with them being used to mark discourse structure. Thus, phonetic changes in pitch in storytelling IDS may also be in part due to increased marking of discourse structure. In further work, we are continuing to analyze the role of discourse and syntactic structure in the prosodic choices made by the speakers, and we are performing phonetic analyses of f0 assessing the contribution of different tonal elements to increasing f0 range and variability.

Abstract

Prosody (as the melody of speech) is an important component of human social interactions. More specifically, linguistic prosody conveys meaning of speech through syllable, word, or sentence level stress and intonation. In the modern neuroimaging era the hemispheric representation of sentence intonation is widely investigated. Most of these studies suggest bilateral activations predominantly in the perisylvian language areas and in the subdominant homologues. However, there are some inconsistencies about the hemispheric representation and lateralization of linguistic prosody. These inconsistencies could be due to the lack of attention on the language lateralization of the subjects. The present study aims to investigate the hemispheric representation and lateralization of linguistic prosody with a sentence intonation task in two groups of left handed subjects with typical and atypical language lateralization. Functional MRI was used to test the assumption that - according to the functional lateralization hypothesis - the representation of sentence intonation is predominantly lateralized within the language dominant hemisphere and the lateralization of sentence intonation is associated with language lateralization in both groups.

Left handers were examined to create two groups of subjects with typical and atypical language lateralization. In all, 32 healthy subjects were evaluated with a standard verbal fluency task with fMRI in order to assess functional hemispheric language lateralization. In our final investigation the atypical group consisted of 8 subjects with right hemispheric language dominance (LI<-0.2) and the typical group also consisted of 8 subjects with left hemispheric language dominance (LI>0.2).

Sentence intonation task was utilized to test linguistic prosody skills with fMRI. 49 pairs of sentences (18 pairs of neutral-neutral sentences, 10 pairs of interrogative-interrogative sentences, and 1 pair of interrogative-neutral sentence) were presented with an event-related design. Sentences were matched in terms of syntactic structure, semantic complexity and length and all were affectively neutral. In the fMRI data analysis interrogative pairs were compared to neutral pairs.

One of the main findings of our study is that subjects with typical language lateralization activated the middle temporal gyrus (MTG) on the right side. The activation of the MTG in the right hemisphere is classically associated with the encoding of prosodic information. Furthermore, both groups recruited the frontal and temporal language areas predominantly in the language-dominant hemisphere. Moreover, between-group comparison showed significantly stronger activations in subjects with typical language lateralization only in left sided language areas: pars triangularis of the inferior frontal gyrus, the superior frontal gyrus and the inferior parietal lobule.

This finding is in accordance with the functional lateralization hypothesis of prosody, and suggests a correlation between linguistic prosody lateralization and language lateralization.

Index Terms: sentence intonation, language lateralization, left-handers, fMRI

Introduction

Prosody is an important component of everyday discourse and thus, of social interaction. It conveys different pieces of linguistic information at the word and sentence level (also known as linguistic prosody), and expresses information about the speaker's emotional state (called emotional prosody) [1,2]. More specifically, linguistic prosody conveys meaning through syllable, word, or sentence level stress and intonation. Currently, there are four general hypotheses about the hemispheric localization of speech prosody. (1) Acoustic lateralization hypothesis posits that both linguistic and emotional prosody are processed in the right hemisphere through the extraction of suprasegmental information [3]. (2) Functional lateralization hypothesis proposes that linguistic prosody, like word stress, sentence focus and sentence modus, engages neural mechanisms in the left hemisphere, while emotional prosodic information (such as emotions and personality) are encoded in the right hemisphere [2,4]. (3) Several findings claim that the lateralization of speech prosody and the division of labor of the two hemispheres depend on different acoustic cues, such as temporal vs. spectral cues, high frequency vs. low frequency cues and rapidly changing vs. slowly changing acoustic cues [5,6]. (4) However, some clinical studies posit that prosody processing is not lateralized at all, but is rather subserved by subcortical regions [7,8].

Relatively few fMRI studies have been published that specifically focus on prosody based language processing [6,9,10,11] and hence, there are still some inconsistencies about the hemispheric representation and lateralization of subjects. Most of these fMRI studies suggest bilateral

activations predominantly in the perisylvian language areas and in the subdominant homologues. The mentioned inconsistencies could be due to the fact that these studies did not take into consideration the language lateralization of the examined subjects.

The present study aims to investigate the hemispheric representation and lateralization of linguistic prosody with a sentence intonation task in two groups of left-handed subjects with typical and atypical language lateralization. Functional MRI was used to test the assumption – held by the functional lateralization hypothesis - that the representation of sentence intonation is predominantly lateralized within the language dominant hemisphere and thus the lateralization of sentence intonation is associated with language lateralization in both groups.

Methods

2.1. Verbal fluency task

Left-handers were examined to create two groups of subjects with typical and atypical language lateralization. In the modern neuroimaging era it is believed that among left handers the incidence of atypical language lateralization is higher (15-30%) than in right handers (4-6%) [12], hence, in the present study, 32 healthy, left-handed subjects were evaluated with a standard verbal fluency task with fMRI in order to assess functional hemispheric language lateralization. The paradigm included seven cycles of 30-second-long rests alternating with 30-second-long internal word generation tasks. During the active conditions, the subjects were asked to silently generate different words starting with a particular letter. During the rest periods, the subjects were instructed to stop the active task and relax. In our final investigation the atypical group consisted of 8 subjects with right hemispheric language dominance (LI (lateralization index)<-0.2), while the typical group, also formed by 8 subjects, was characterized by left hemispheric language dominance (LI>0.2).

2.2. Linguistic prosody task:

A sentence intonation task was utilized to test linguistic prosody skills with fMRI. 33 pairs of sentences (see examples) were presented by a professional actress with an appropriate intonation: 18 pairs of neutral-neutral sentences, 10 pairs of interrogative-interrogative sentences, and 5 pairs of interrogative-neutral sentences. As we can see in the examples below, in Hungarian each sentence pair was based on the same syntactic structure with either the same (interrogative-interrogative pairs and neutral-neutral pairs) or different (neutral-interrogative pairs) intonation. (The neutral-interrogative pairs were not used for contrasts in the fMRI analysis, they were used to keep subjects' attention during the paradigm instead). In other words, in one sentence pair, neutral and interrogative sentences were syntactically exactly the same, only sentence intonation differentiated the semantic meaning. Since Hungarian uses variations in pitch to signal different sentence intonations, the syntactic form of questions and statements are identical, and there is no transformation from one to another as in English. (In this study, neutral sentences with monotonic intonation could be statements from a syntactic viewpoint, only intonation differentiates them from questions.) It is important to note that in Hungarian the fundamental frequency of interrogative sentences appears to start high and generally move upward through the duration of the sentence. Besides, the fundamental frequency of the used neutral sentences of monotonous intonation in our design starts much lower and stays flat through the whole sentence. Also, sentences were strictly matched in terms of syntactic structure, semantic complexity and length, which is important from a methodological point of view, in order to make sure, that the neutral and interrogative sentences differ only in prosody. All of the pairs were presented in a randomized order, which was the same across subjects. We used an event-related design. Between sentence pairs an inter-trial interval of 4-6 s (jittered) was used. Participants were asked to press an answer button when the two sentences sounded different, e.g.in the case of neutral-interrogative sentence pairs. As mentioned earlier, the neutral-interrogative pairs were not used for contrast in the fMRI analysis, they were only used to keep subjects' attention focused during the paradigm.

2.3. Functional data analysis

Functional data sets were analyzed using FSL 4.1.3. In the fMRI data analysis of the linguistic prosody task the question "Where is the response to the interrogative sentences greater than the response to the neutral sentences?" was asked by defining contrast of regressors: interrogative pairs compared to neutral pairs (interrogative>neutral). Since we hypothesized that the neutral and the interrogative sentences differ only in sentence intonation, analyzing the above mentioned contrast shows neural circuitry underlying pitch perception associated with sentence intonation. LIs were calculated using the LI toolbox available as part of the SPM8. Because most areas of the frontal cortex are activated during verbal fluency task, language lateralization analysis was focused on the frontal lobe. Language dominance was classified as left hemispheric (LI>0.2), bilateral (-0.2≤LI≤0.2) or right-sided (LI<-0.2).

2.4. Examples

Neutral-neutral pair:

János a könyvtárban tanul./John is studying in the library.
János a könyvtárban tanul./John is studying in the library.
Interrogative-interrogative pair:

Péter a konyhába megy?/Is Péter going to the kitchen?
Péter a konyhába megy?/Is Péter going to the kitchen?
Neutral-interrogative pair:

Mária a szobában sír./Mary is crying in the room.
Mária a szobában sír?/Is Mary crying in the room?*
*In the original Hungarian examples no structural change signals sentence type, only prosody and intonation distinguishes declarative and interrogative sentences.

Discussion

As far as we know, this is the first fMRI study investigating the relationship of hemispheric representation and functional lateralization of sentence intonation with both atypical and typical language lateralization in a preliminary sample of healthy, left-handed subjects. During the sequential analysis of fMRI data, we found that the two groups had markedly distinct neural activation patterns. The 'atypical group' (AG) – in the interrogative versus neutral sentence contrast – recruited language related brain areas only in the right hemisphere, such as the posterior division of the right middle temporal cortex and the right anterior paracingulate gyrus. On the other hand the 'typical group' (TG) activated language related areas mainly in the left hemisphere, such as the left frontal operculum reaching the left middle temporal gyrus, the left superior temporal gyrus, the left inferior parietal lobule and the pars triangularis of the left inferior frontal gyrus. Moreover, the left superior frontal gyrus, the left gyrus lingualis, the left thalamus was also recruited by the TG. Even more, the TG activated brain regions in the right hemisphere as well, such as the posterior division of the middle temporal gyrus and the insula. Between-group comparison showed significantly stronger activations in subjects with typical language lateralization than in subjects with atypical language

lateralization only in left sided language areas: the pars triangularis of the inferior frontal gyrus, the superior frontal gyrus and the inferior parietal lobule. This finding is consistent with our previous data [13], which found that a reduced microstructural integrity of the left hemisphere was associated with atypical language lateralization.

Results in the sentence intonation processing task revealed activations mostly in the dominant hemisphere in both groups. Interestingly, the AG showed a much poorer activation pattern than the TG. Considering the AG poorer activation pattern, we can speculate that this finding may potentially be the result of a neurodevelopmental disorder behind atypical language lateralization [14,15]. In contrast, the typical group recruited a more widespread brain activation network including language areas in the dominant hemisphere and also in the right (subdominant) middle temporal gyrus - which is classically associated with the encoding of prosodic information - and in the right insula.

Like most of the higher-order cognitive functions, it is very likely that linguistic prosody is processed within a neural network mainly in the frontal, temporal and parietal cortex [6,9,2,11]. Our fMRI data demonstrate that during the sentence intonation task the TG recruited the fronto-temporo-parietal activation network predominantly in the language-dominant hemisphere. This predominantly dominant hemispheric activation pattern is supposedly due to the processing of the modality (i.e. the semantic meaning) of the interrogative sentences. This finding is in line with the functional lateralization hypothesis which proposes that linguistic prosody is processed within the language-dominant hemisphere. Besides, for the processing of non-linguistic acoustic signals subdominant temporal activations were also observed in the TG.

Conclusions

Our finding is in harmony with the functional lateralization hypothesis, since we have found that the representation of sentence intonation is predominantly lateralized within the language-dominant hemisphere in both investigated groups.

Abstract

In this study, we examine how 3-, 4-, and 5-year-old Catalan-acquiring children are able to make use of audio (intonational) and visual (facial gesture) modalities in the comprehension of speaker disbelief, as well as the role of the child's developing Theory of Mind. Our results suggest that in this case, facial gesture provides children with scaffolding for linguistic meaning, and that explicit belief-reasoning also helps children to infer speaker disbelief. We discuss the implications of these findings for the study of intonational development.

Index Terms: intonational development, multimodal comprehension, acquisition, prosodic meaning

1. Introduction

When inferring meaning, adults may rely on different modalities (auditory and/or visual) in different ways. [1] showed, for example, that when incredulity or *disbelief* meaning is marked through intonation and facial gesture in polar questions, Catalan listeners rely more on the visual modality than Dutch listeners, since Dutch encodes incredulity intonationally in a way that is quite different from other types of questions. Children, then, must learn to make use of both the audio and visual modalities to guide them to meaning. Often times the information from the visual modality *reinforces* the message from the audio modality. [2] found that when preschoolers and kindergartners were faced with the task of comprehending a syntactically complex message, reinforcing gestures facilitated comprehension for preschoolers, but not for kindergartners. They suggested that reinforcing gestures serve as "scaffolding", by guiding the child toward the intended meaning of the utterance. They also pointed out that when a message is conveyed through two modalities (e.g. audio + visual), younger children might disregard one channel altogether for working memory reasons. Older children, on the other hand, are more capable of integrating both modalities. While [2] investigated manual gestures, to our knowledge no studies have investigated the reinforcing nature of facial gestures with respect to speech comprehension in children.

One limitation in the literature is the precision with which the audio modality is described, especially with respect to the prosodic cues that guide listeners to meaning, and that children learn to attend to. Most recently, [3] refer to children's understanding of "emotional cues in the voice", but describe their materials as neutral versus "affectively inflected stimuli" with no acoustic characterization of the prosodic differences between the different emotions. Such descriptions do not allow us to understand the types of prosodic cues that children learn to attend to. Recent work has applied the Autosegmental Metrical framework [4,5] in order to investigate children's comprehension of the intonational aspect of the audio modality. [6] showed that 4-, 5- and 6-year-old children performed at above-chance levels in a linguistic comprehension task where children had to identify a "disbelieving" speaker based on differences in the ¡H* L% and L* HL% nuclear configurations in Puerto Rican Spanish [7]. 6-year-olds, however, significantly outperformed the 4- and 5-year-olds. Therefore, in the absence of visual information, children used linguistic information to perceive belief-state meaning. Linguistic meaning associated with belief states is of particular interest since it involves Theory of Mind (ToM) reasoning [8]. That is, in order to fully comprehend linguistic forms that encode information about speaker and hearer belief states, children must have some ability to "mind-read", i.e. infer the belief states of others. One measure of ToM in children is the false belief task [9, 10]. In recent work assessing ToM and emotion understanding, [11] pointed out that awareness of false belief is needed to understand the human state of surprise since one needs to recognize that something must have contradicted the beliefs of a speaker. They compared children's (ages 3-5) scores on a facial expression task where the child had to select a target label about how a person in a picture felt, based on his/her facial expression. They used a battery of ToM tasks, and found a relationship between belief-based emotion labeling such as surprise, and ToM. The children found the false belief tasks in their study easier than labeling facial gestures of surprise or fear. They claim that children exhibit the ability to pass explicit false belief tasks before they are able to label belief-based facial gestures.

In this study we sought to understand the role that facial gestures might play in children's belief state comprehension, specifically how they use audio, visual or audiovisual cues in the comprehension of a speaker's state of *disbelief.* If facial gesture provides scaffolding to linguistic meaning, there should be an ordered path of acquisition - children should be more successful at comprehending disbelief meaning from facial gesture cues than they are for audio cues. Audiovisual cues could, on the one hand, be more useful than audio only cues because of the presence of the facial gesture, but might also be more difficult since the child must integrate the two modalities. Thus it is possible that children use different strategies for the audiovisual condition. When no visual information is available at all (i.e. audio-only modality), we hypothesize that comprehension of belief states should be more difficult for younger children. If children do not have access to the "scaffolding" they use for meaning, they might simply not have access to the meaning. Further, we hypothesize that children with explicit false belief reasoning should be more successful at the task, regardless of the condition. We tested these hypotheses using the tasks outlined below.

2. Methods

2.1.Participants

Seventy-seven Central Catalan-speaking children participated in the experiment, which consisted of two tasks: a ToM false belief task and a comprehension task. The age range was between 34 and 75 months (M = 53.6 mo.). For the comprehension task, there were three conditions, with a between subjects design: Audio Only (AO), Visual Only (VO) and Audiovisual (AV). A total of twenty-six children received the AO condition: one 2-year-old (35 mo.), six 3-year-olds (range 40-44 mo., M=41 mo.), ten 4-year-olds (range 49-59 months, M=53.5 mo.), six 5-year-olds (range 62-68 mo., M=64 mo.) and three 6-year-olds (range 73-75 mo., M=74 mo.). Twenty-three children received the VO condition: two 2-year-olds (both 34 mo.), six 3-year-olds (range 36-47 mo., M=41.5 mo.), six 4-year-olds (range 52-58 mo., M=54.7 mo.), nine 5-year-olds (range 60-71 mo., M=68 mo.) and two 6-year-olds (range 74-75 mo., M=74.5 mo.). Finally, twenty-eight children received the AV condition: one 2-year-old (34 mo.), eight 3-year-olds (range 37-47 mo., M=41.8 mo.), seven 4-year-olds (range 48-59 mo., M=47.8 mo.), eleven 5-year-olds (range 60-71 mo., M=65.4 mo.) and one six-year-old (72 mo.). The participants were all students at Catalan public elementary schools where Catalan was the primary language of instruction.

2.2.Materials

2.2.1. False belief task

The false belief task was an adaptation of the Sally Ann task [8], a classic ToM task. The materials for this task consisted of a short video (0:54) featuring two puppets. At the beginning of the video a princess puppet appears with a ball, announcing that she will leave her ball in one of two containers in front of her. She leaves the ball in one of the containers and subsequently states that she will leave for school. The princess then leaves for school, disappearing from the video. While the princess is gone, a lion puppet appears. The lion takes the ball out of the container and transfers it into the other container in the scene, covering it so that the ball cannot be seen. The lion laughs in a sneaky way and leaves. The princess puppet then appears, announcing that she has returned from school.

2.2.2. Comprehension task

For all three conditions mentioned above, the materials consisted of a Powerpoint presentation containing AO, VO or AV materials. The premise of the task was such that the child had to decide which member from a set of twins did not believe his or her friend about an animal that the friend claimed to have seen while on vacation. Thus, for each slide (which constituted one trial), participants saw four images: the two twins (upper left and lower left in Fig. 1), the twins' friend (lower right) and an image of the animal the friend claimed to have seen (upper right). The images seen in the upper left and lower left regions of Figure 1 were either a female child or a male child, depending on the block of presentation (2 blocks per participant).

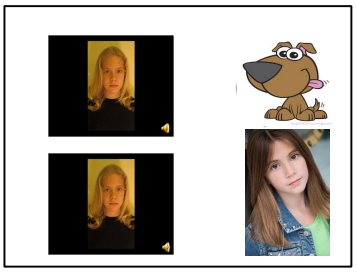

Figure 1. *Slide from AO condition (neutral faces) depicting the two twins (left panels), their friend (lower right panel) and the animal the friend claimed to have seen (upper right panel)*

2.2.2.1. Stimuli

The stimuli for the AV condition were created first. Two child actors, a female (11 years old) and a male (13 years old) were video recorded producing two types of echo questions: neutral echo questions and disbelief echo questions. While there can be variation in terms of the specific pitch contour that might appear for these contexts, the actors produced two different contours labeled L+¡H* L% (neutral echo question) and L* H% (echo question with disbelief marking) in the Cat_ToBI system [12]. (1) and (2) show examples of neutral versus disbelief echo questions:

(1) A and B are talking about what time to leave in the morning in a noisy restaurant. B strains to hear what A has said.

A: I think we should be on the road by eleven.

B: **Eleven**?

(2) B knows A has been a vegetarian for the last ten years.

A: I had the best filet mignon last night. It was cooked to perfection.

B: **Filet mignon!?!** When did you start eating meat?

In (1) B simply repeats an element from A's prior turn and does not convey any type of attitudinal information towards the proposition. In (2) B produces an echo question that repeats linguistic information from the prior discourse, and at the same time expresses her belief state about the propositional content – that she can't believe it.

The intonation contours used for the neutral vs. disbelief echo questions are presented in Figures 2 and 3. Each stimulus was phonetically analyzed in Praat to confirm that the appropriate contour was produced by the actors.

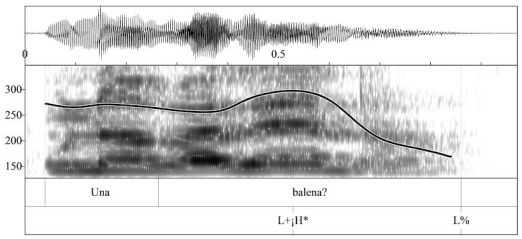

Figure 2: *Pitch track, spectrogram and waveform for the neutral echo question* ***Una balena?*** *'A whale?'*

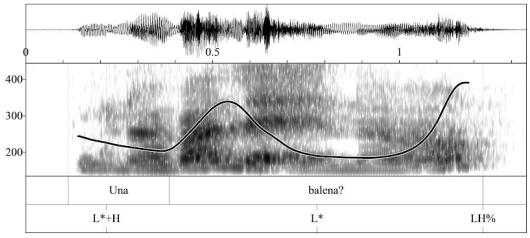

Figure 3: *Pitch track, spectrogram and waveform for the disbelief echo question* ***Una balena?!*** *'A whale?!*

For the AO condition, the audio was extracted from the original AV videos. For the VO condition, the audio was removed so that only the visual information was available. Figures 4 and 5 show typical facial gestures that were presented for the AV and VO stimuli: brow raising and eye-widening for the neutral echo questions, and brow furrowing accompanied with a backwards movement of the head for the disbelief echo questions. Children that received the AO condition saw two identical neutral faces (as shown in Figure 1) presented as screenshots (as in Figure 1).

Figure 4: *Screenshots of facial expressions for neutral echo (left panel) and disbelieving echo (right panel)*

2.3 Procedure

The experimenter was a female native speaker of Central Catalan (the second author of this paper). First, the children were given the ToM task. The experimenter was seated with the child in a quiet room in the child's school. The child was told to watch a video presented on a laptop computer and listen carefully to what the characters said, because afterwards s/he would have to answer some questions. After watching the video, the child was asked two questions: 1.) *On buscarà la pilota, la nena?* 'Where will the girl look for the ball?'; and secondly 2.) *On és la pilota, en realitat?* 'Where is the ball really?' 1.) was considered correct if the child responded that the girl would look for the ball in the container where she left it. 2.) was considered correct if the child said that the ball was in the container where it was moved to.

After the child finished the false belief task, s/he was administered the comprehension task for either the AO, VO or AV condition. This was done with a between subjects design, such that each child saw only one of the three conditions. Like the false belief video, the Powerpoint was presented on a laptop computer. At the beginning of the task each child received familiarization trials. S/he was told that there was a set of twins, and their friend Marta (lower right hand panel in Figure 1). Marta was telling the twins about what she saw when she was on vacation. The children were also told that there would always be a twin that did not believe what Marta said, and that they would have to decide which twin that was based on how the twins reacted to Marta. For instance, the experimenter told the child that Marta was telling the twins that she saw a whale – *La Marta els explica que va veure una balena* 'Marta tells them that she saw a whale'. The experimenter then showed the child a reaction from each twin, one on top, and the other below. For each test trial, one twin produced a neutral echo question and the other produced a disbelief question. The children that received the AV condition saw one of the twins producing the facial gesture for a neutral echo question with the L+¡H* H% intonation contour. The other twin produced the facial gesture for the disbelieving echo question with the L* H% intonation contour. For the AO condition children saw still images and heard only the audio stimuli. For the VO condition the children saw the videos but without audio. After each twin spoke (or gestured as in the case of VO), the experimenter asked *Quin/a bessó/na no es creu la Marta, el/la de dalt o el/la de baix? Assenyala'l/-la.* 'Which twin does not believe Marta, the one on top or the one below? Point to him/her.' The child then pointed to the twin s/he thought did not believe Marta. The answer was marked correct by the experimenter if the child picked the twin that produced brow furrowing/backwards movement of head along with the L* H% for the AV condition, and the one that picked the relevant component of these for the AO (L* H%) and VO (brow furrowing/backwards head movement) conditions. Each participant received two blocks of stimuli. Children were either exposed to the female actor in Block 1, and the male actor in Block 2, or vice versa. They received four familiarization trials in Block 1, and two more in Block 2 in order to familiarize them to the new actor. For the familiarization trials, the neutral versus disbelief distinction in meaning of the test trials was maintained, but it was expressed lexically rather than intonationally (*Ah, que bé, que veiessis un gos*. 'Oh, that's nice that you saw a dog.' produced with a positive nodding head movement and *No m'ho crec, que veiessis un gos.* 'I don't believe that you saw a dog.' with a negative head shaking movement). Trials of this type were also used as fillers throughout the experiment. Therefore across the two blocks there were four filler trials in order to reorient the child were they to forget the intended meanings. For each actor, the child received six test trials and two fillers, for a total of twelve test trials and four fillers per child.

3. Analysis and Results

Two separate analyses were performed in order to account for performance on the two tasks described above. We first sought to test our predictions about children's performance for the three conditions. A total of 924 trials were analyzed. We first ran a set of mixed-effects logistic regression model in R [12] with CONDITION (three levels: AO, AV, VO), AGE (3, 4, 5[1]) and THEORY OF MIND (two levels: pass vs. not pass) as fixed effects and PARTICIPANT as a random effect. The dependent variable was CORRECT RESPONSE (correct vs. incorrect). Models were compared using ANOVAs. The best-fit model included CONDITION and AGE, but not THEORY OF MIND (pass or fail[2]). No interactions were included in the best-fit model. AGE was selected as a significant predictor of CORRECT

[1] The older 2-year-olds mentioned in 2.1 were included in the category "Age 3" and younger 6-year-olds were categorized as "Age 5".

[2] We did not include the second ToM question in the pass vs. fail decision, since all ages were shown to be at ceiling for this question.

RESPONSE. 4-year-olds performed significantly better than 3-year-olds (Estimate=1.35 vs. .38, $p<0.05$, SE=.38, z=-2.56) and 5-year-olds performed significantly better than 4-year-olds (Estimate = 2.70 vs. 1.35, $p<0.01$, SE=0.42, z=3.24). In order to investigate further any differences between conditions, a simple regression analysis was then performed. This analysis revealed differences for conditions. The slopes for the AO condition ($p<0.01$, r=0.70) and the AV condition ($p<0.01$, r=0.65) were both significant, while the slope for VO was not significant (p=0.09, r=0.39).

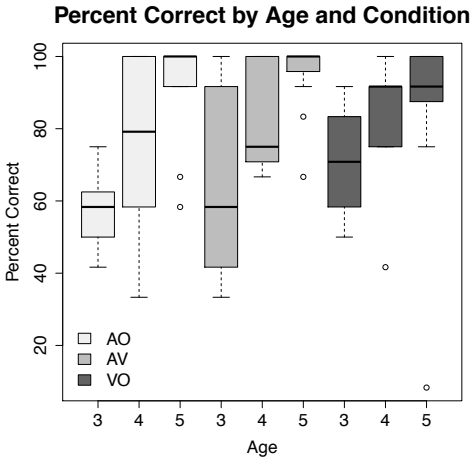

Figure 5: *Percent correct by Age for AO, AV & VO*

The fact that the slope for VO was not significant is evident if we inspect the boxplots in Figure 5, where less change between age groups is apparent for the VO condition when compared to the AO and AV conditions. Also evident in Figure 5 is the fact that the youngest children perform the worst on the AO task. 4-year-olds are better, but with a great deal of variability, suggesting that acquisition is still in progress. By Age 5, children are no longer struggling and show very little variability. A great deal of variability is observed for younger children that received the AV condition, especially for 3-year-olds. This could reflect the fact that even though children had gestural information available to reinforce the disbelief meaning in the AV condition, it may have been difficult to integrate the two cues. It is also possible that they ignored one modality because of working memory, which could have helped or hindered them depending on which one it was. Interestingly, 5-year-olds show more variability for the VO condition than for any other condition. This is perhaps because as children get older, they learn that facial cues do not always reinforce linguistic meaning.

With respect to ToM performance, Table 1 shows a general tendency observed. Across ages, children that pass the Sally Ann task tend to be more successful at the comprehension task, regardless of the condition.

Table 1. *% correct trials on linguistic comprehension task based on performance on Sally Ann task.*

Condition	Pass SA	Fail SA
AO	80	68
AV	89	73
VO	89	74

T-tests revealed that both the pass and fail groups performed at above-chance levels for all conditions. We conclude, then, based on the tendency observed in Table 1, that while explicit false belief reasoning (i.e. success on the Sally Ann task) may be helpful to children for the comprehension task, it is not a prerequisite for successful performance.

4. Discussion and Conclusions

In this experiment, each age group differed significantly from the next, showing that in general, children are making great strides in their comprehension of disbelief between the ages of 3 and 5. The simple regression analysis confirms our hypothesis that children might be better at inferring disbelief through the visual modality (significant slopes for AO and AV conditions but not VO). Inspection of the boxplot in Figure 5 reveals very different patterns for the three age groups across conditions. The amount of variability found for 3-year-olds depends on the condition. The 3-year-olds performed worst on the AO condition, but with less variability than 3-year-olds that received the AV condition, where the most variability for this age group is found. This suggests that combining the audio and visual modalities may help some children, but hinder others. The variability observed for 4-year-olds in the AO task, however, could be explained by a 'transition' stage of acquisition between the 3- and 5-year-olds. Four-year-olds are still in the process of abandoning the stage during which they rely on visual scaffolding, and are moving towards full acquisition of the linguistic meaning. For this reason, less variability is found for the 4-year-olds that received the AV condition when compared to 3-year-olds for that condition. Finally, 5-year-olds no longer require scaffolding from the visual modality, and do not seem to be thrown off by the presence of two modalities in the AV condition (there is very little variability). With respect to how explicit false belief reasoning might help children with our task, our results reveal a tendency for children that pass the Sally Ann task to perform better on the comprehension task. But across ages, those that failed the Sally Ann task still perform at above-chance levels, indicating that success on the Sally Ann task is not a prerequisite for success on the comprehension task. These results should be interpreted with caution, since our task tested *explicit* false belief judgments. Younger children may exhibit *implicit* knowledge of false belief [8]. It is obvious that some kind of mind-reading ability (i.e. ToM) must be present for children to perceive their interlocutor's state of disbelief, and this study shows that the modality through which this belief state is communicated matters. In linguistic theory, gesture is often thought to be peripheral to the study of speech. We argue that gesture is a critical component of the study of intonational development that should not be ignored.

Abstract

We experimentally investigated the pragmatics of two melodies commonly used with Greek *wh*-questions, L*H L-!H%, described as the default, and LH* L-L% considered less frequent and polite. We tested two hypotheses: (a) the !H%-ending melody is associated with information-seeking questions, while the L%-ending melody is pragmatically more flexible and thus appropriate also for non-information-seeking *wh*-questions expressing bias; (b) the !H%-ending melody, being more polite, is more appropriate for female talkers, all else being equal. In Experiment 1, comprehenders rated !H-ending and L%-ending versions of the same questions for politeness and appropriateness for the context in which they were heard (which favored either information-seeking or "biased" *wh*-questions). In Experiment 2, comprehenders heard the same questions and chose between two follow-up responses, one providing information, the other addressing the bias of the wh-question. Comprehenders rated !H%-ending questions more appropriate than L%-ending questions and judged the !H%-ending questions of female talkers more polite. They also chose information-providing answers more frequently after !H%- than L%-ending questions, but the preference was higher for female talkers and depended on comprehender gender. The results argue in favor of a compositional view of intonational meaning which depends not only on the tune but also on *context*, broadly construed.
Index Terms: *wh*-questions, intonation, pragmatics, gender

1. Introduction

We present data from two perception experiments on the intonational pragmatics of Greek *wh*-questions to argue that intonation requires, in addition to a description of its phonetic realization, a phonological representation which must take into consideration differences in meaning in tandem with differences in form. These results, in combination with the production study of [1] show that a phonological analysis is required to explain variation in the realization of intonation as well as differences in meaning and pragmatic interpretation.

In Greek *wh*-questions, the *wh*-word is utterance initial; thus the questions are marked both morphologically and syntactically as such, e.g., [pos se ˈlene] *what's your name?* (*lit.* how you.acc call.3pl). In addition to the morphosyntactic information, *wh*-questions are marked by the use of a particular melody (this melody can be used with other constructions as well [2]; a discussion of these cases is beyond the scope of this paper). In addition to this default melody, *wh*-questions can sometimes be uttered with another melody and a different pragmatic interpretation ([1], [2], [3], [4]). Past reports on these differences, combined with our own assessment as native speakers, constitute the background of our experiments, which probe the pragmatic interpretation of the *wh*-questions when used with these two melodies.

1.1. Melodies of Greek wh-questions

Illustrations of the melody used by default with *wh*-questions are presented in Figure 1 below (based on [1]). A comparison between the two panels of Figure 1 shows that there is variation in the realization of the melody. In Figure 1a, which shows a short question, F0 starts high, reaching a peak on the stressed vowel of the *wh*-word [pu] "where," after which it quickly dips before a final small rise. Figure 1b shows a longer question, in which F0 starts low, has a late peak that occurs on the syllable *following* the *wh*-word [apo ˈpu] "from where"), and shows a rather extensive low F0 stretch before the final rise. Despite the obvious phonetic differences, these two contours are recognized by native speakers as instances of the same melody. Further, the variation illustrated in Figure 1 is systematic: it depends on the length of the question, the length of the *wh*-word itself, and the position of the stressed syllables with respect to each other and the utterance edges [1]. The representation L*H L-!H% ([1], [3]), abstracts away from phonetic detail and allows us to predict systematic differences in realization, including those illustrated in Figure 1.

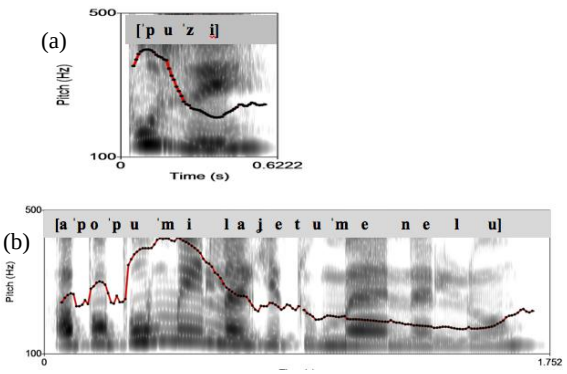

Figure 1: *Spectrograms and F0 contours of wh-questions: In panel (a), [ˈpu ˈzi] "where does he live?"; in panel (b), [apo ˈpu ˈmilaje tu ˈmenelu] "from where was she speaking to Menelos?". For details see text.*

Although the description above covers the typical realization of contours used with *wh*-questions in Greek and their phonological analysis, certain issues remain unresolved. First, as noted, Greek uses an additional melody with *wh*-questions. This has been analyzed as L*H L-L%, a melody similar to L*H L-!H% but ending at the bottom of the speaker's range, rather than with a final rise ([1], [3]). The fact that the two contours can be elicited under the same conditions, [1], puts into question the posited phonological difference between !H% and L%; !H% could represent simply a return to a default mid-level pitch rather than a meaningful difference (cf. [6]). If so, then the difference between !H% and

L% is one of phonetic realization and as such it need not be included in the phonological representation.

As a first step in addressing this issue, we conducted an exploratory production study in which two female and two male native speakers of Greek produced sixteen questions in two types of contexts which, based on our assessment as native speakers, should lead to the use of either the !H%- or the L%-ending melody; the contexts were similar to those presented in (1a) and (1b) below.

Both our male and our female speakers produced distinct melodies in response to the different contexts suggesting that the two melodies convey different pragmatic meaning and therefore, that they are phonologically distinct. Acoustic analysis of these data indicates that the melodies differ systematically not only in the way they end but also in the pitch accent associated with the *wh*-word. The !H%-ending melody has an accent best represented as L*H ([1], [7]), as it starts with a marked rise (Figure 2, filled symbols, solid lines), while the L%-ending melody has an accent best represented as LH* ([3], [4], [8]), which typically starts with a peak (as its L tone is truncated when the *wh*-word is short (Figure 2, unfilled symbols, broken lines). These results support previous descriptions ([1], [3]) about a systematic difference in the way the melodies end but also establish differences in regards to the pitch accent on the *wh*-word (cf. [4]).

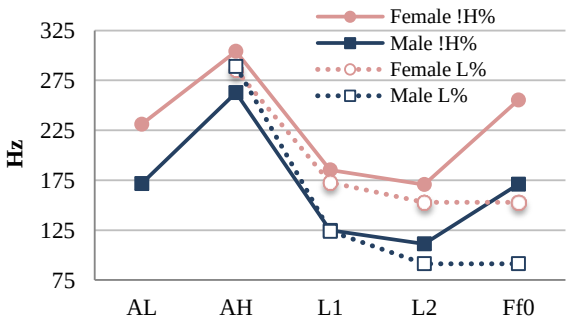

Figure 2: *Average F0 values (in Hz) of the stimuli used in the two experiments, separated by gender and melody; AL = F0 onset; AH = accentual peak; L1, L2 = beginning and end of low-F0 stretch respectively; Ff0 = final F0 value in melody. Note that L2 in the L%-ending contours is added for clarity.*

Here we investigate the differences in meaning associated with these differences in realization by means of two perception experiments conceived on the basis of the production data briefly discussed above and the following observations by [1] and [3]. According to [3], L*H L-L% sounds less polite or less "involved" than L*H L-!H%, as if the speaker does not care for an answer; [1] note that the L%-ending tune was rare in their data (accounting for only 8% of tokens) and most instances were elicited from male talkers.

Based on the above, our hypotheses regarding the two melodies were as follows. First, the !H%-ending melody is the default melody for *wh*-questions and therefore the most appropriate when questions serve their primary function of seeking information. Second, the L%-ending melody is appropriate for both information-seeking and non-information seeking questions. Non-information-seeking questions can serve various functions; e.g. [4] discusses rhetorical questions and notes they are produced with the L%-ending melody. Here we investigated questions indicating questioner bias for a specific answer (cf. [9]); such questions serve as an indirect way of making a statement. We hypothesized that !H%-ending questions would be deemed inappropriate in this context, while L%-ending questions would be highly preferred. Finally, we hypothesized that the L%-ending melody, being less polite, would not be as appropriate for female as for male talkers, especially in requests for information [3].

2. Exp. 1: Appropriateness and politeness

In Experiment 1 comprehenders rated LH* L-L% and L*H L-!H% versions of six *wh*-questions for their appropriateness and politeness in a given context.

2.1. Participants

Eighty-nine comperhenders took part in the experiment. They provided information about their linguistic background and history on the basis of which 13 were not considered for further analysis as they turned out to be either bilingual or have a history of speech or hearing disorders. Two more comprehenders were excluded as they failed to respond to more than 20% of the trials. Results reported here are based on 74 comprehenders, 56 female and 18 male. They were all monolingual native speakers of Greek studying at the University of Ioannina, and ranged in age from 18 to 22 years.

2.2. Stimuli

The stimuli were six pairs of Greek *wh*-questions, one !H%- and one L%-ending version per pair. The questions were selected from our corpus of 128 questions discussed in section 1.1. and were evenly divided among the four speakers of that corpus. The six pairs of questions were chosen on the basis of their naturalness. The total number of stimuli was 48 questions (6 *wh*-questions × 2 melodies × 4 speakers).

We constructed two contexts for each question, so that each context in a pair would most likely lead to a different response: an information-seeking question, as in (1a) or a biased question as in (1b). Specifically, a question following a context such as (1b) would be interpreted in Greek as an attempt by the speaker not to seek information but, rather, to elicit addressee acquiescence to an indirect point (which reflects the questioner's bias for a particular answer). In our example, this indirect point is recognition on the part of the addressee that going to Syntagma would be difficult, if not impossible, under the circumstances. The contexts were read by a different native speaker of Greek. Contexts and questions were crossed for a total of 96 trials (48 melodies × 2 contexts) so that each question was heard after (a) a context that made asking for information a plausible action or (b) a context that did not necessitate an information-seeking action.

(1a) Context: *Lena, who is visiting Athens for the first time, stops a passerby for directions:*
Question: ['pos θa 'pao sto 'sidaɣma]
'How will I get to Syntagma?'

(1b) Context: *A protest march in Syntagma is scheduled for the time Kostas has an interview there; as they listen to the news, Kostas says to his wife:*
Question: ['pos θa 'pao sto 'sidaɣma]
'How will I get to Syntagma?'

We expected that !H-ending questions would be rated more appropriate after contexts like (1a), while L%-ending questions would be rated more appropriate after contexts like

(1b). In addition we expected that in information-seeking contexts !H%-ending questions would be rated more polite than L%-ending questions, and that melody would interact with talker gender so that !H-ending melodies would be rated more polite if the talker was female.

2.3. Procedures

The comprehenders heard each context followed by a question over loudspeakers in a classroom at the University of Ioannina and filled in hard copy response sheets. They were tasked with rating how appropriate and polite each question was in the context that preceded it, using a 1-7 rating scale. The timeline of each trial is presented in Figure 3.

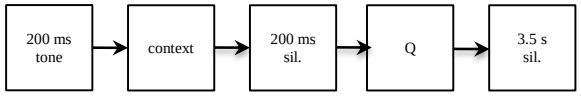

Figure 3: *Timeline of a trial in Experiment 1.*

2.4. Results

Ordinal logit regression showed that comprehenders judged questions more appropriate when they were preceded by a context that made information-seeking a plausible action [Wald = 219.6, $p < 0.0001$; Figure 4a]. They also rated !H%-ending questions more appropriate than L%-ending ones [Wald = 155, $p < 0.0001$; Figure 4b].

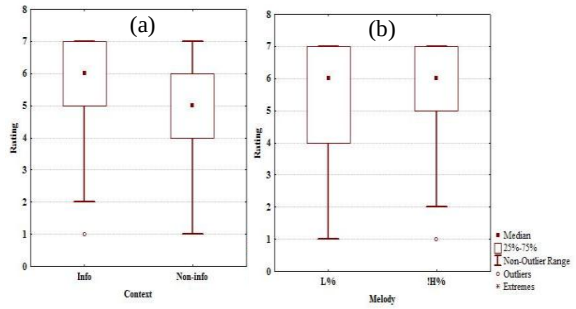

Figure 4: *Appropriateness ratings as a function of context (left) and melody (right).*

Regarding politeness, results showed an interaction between melody and talker gender [Wald = 15.5, $p < 0.0001$]. Melody did not affect the rating of questions uttered by male talkers, but it did affect questions by female talkers: their questions were judged more polite when !H%-ending (Figure 5).

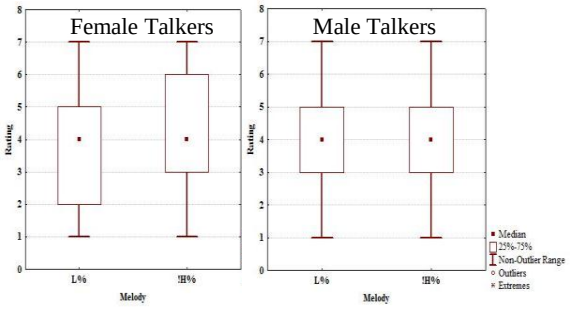

Figure 5: *Politeness ratings as a function of melody, separately for female (left) and male (right) talkers.*

Post-hoc analysis also showed that both appropriateness and politeness were affected by *comprehender* gender, with females giving overall lower politeness ratings than males [Wald = 35.5, $p < 0.0001$] but higher appropriateness ratings [Wald = 52.2, $p < 0.0001$].

3. Experiment 2: Pragmatic interpretation

3.1. Participants and stimuli

A different set of 79 comprehenders took part in Experiment 2. The data of six of them were discarded for the same reasons as before. The results reported here are based on 73 comprehenders (55 female and 18 males) with the same demographics as in Experiment 1. The same !H%- and L%-ending versions of the six questions used in Experiment 1 were also used here.

3.2. Procedures

The questions were presented aurally out of context under the same conditions as in Experiment 1. The comprehenders' task was to choose one of two possible responses to each question, presented to them in hard copy response sheets: (i) an information-providing response or (ii) a response that agreed with the bias implied by the question. There was a total of 48 trials (6 *wh*-questions × 2 melodies × 4 speakers).

The setup is illustrated in (2): comprehenders heard a question like "how will I get to Syntagma?" (stimulus) and had to choose between two possible responses (counterbalanced across trials): Response A which provides information and Response B, which concurs with an implicit bias attributed to the questioner. The timeline of a trial is presented in Figure 6.

(2) Stimulus: ['pos θa 'pao sto 'sidaɣma]
'How will I get to Syntagma?'
Response A: *You will take line 3 and get off at (stop) Syntagma.*
Response B: *You're right, you can't go. There'll be mayhem.*

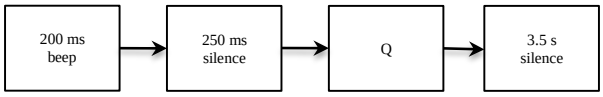

Figure 6: *Timeline of a trial in Experiment 2.*

It was expected that the comprehenders would be more likely to interpret !H%-ending questions as information-seeking and thus choose an information-providing response, such as Response A in (2). On the other hand, L%-ending questions would be more likely interpreted as indicating the questioner's bias, rather than seeking information. Thus comprehenders would be more likely to select the answer that did not provide information but concurred with this bias, such as Response B in (2).

3.3. Results

Logit regression showed that comprehenders preferred information-providing responses to responses concurring with (the questioner's implied) bias when questions were !H%-ending [Wald = 49.1, $p < 0.0001$]. The preference was stronger for female than male talkers [Wald = 7.6, $p < 0.01$]. Panels (a) and (b) of Figure 7 illustrate these two points respectively.

Post-hoc analysis showed an additional effect of comprehender gender [Wald = 6.9, $p < 0.01$], indicating that among comprehenders females chose information providing responses less often than males (Figure 7c). Post-hoc investigation of the interaction between comprehender and talker gender [Wald = 4.7, $p < 0.05$], illustrated in Figure 8 further indicates that the difference between male and female comprehenders was due to the fact that female comprehenders chose information providing responses less often when the talkers were male; i.e., they more frequently interpreted male than female stimuli as more likely to indicate bias rather than be genuine requests for information.

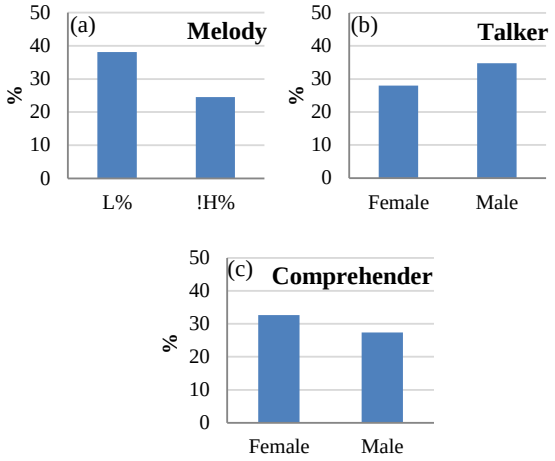

Figure 7: *Percentages of bias concurring responses as a function of melody (panel a), talker gender (panel b) and comprehender gender (panel c).*

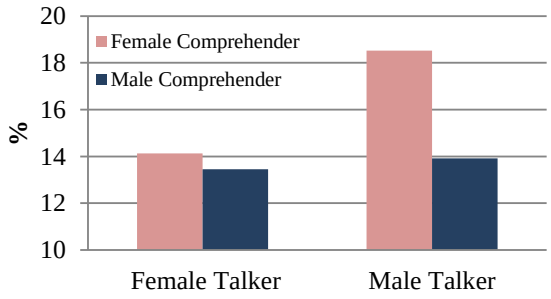

Figure 8: *Percentages of bias concurring responses as a function of comprehender and talker gender.*

4. Discussion

Our results confirmed that the two boundary tones cannot be seen as "allophonic" as each one leads to a different evaluation of the questions, in terms of their politeness and appropriateness as responses, as well as to a different interpretation of their pragmatic intent. In addition, our data showed that the assumption held in the literature, [1], [3], that the accent of the two melodies is the same must be incorrect, at least for the questions used in our experiments. Overall then, our results support the view that we are dealing with two different melodies, L*H L-!H% and LH* L-L% (cf. [4]).

Here we offer a preliminary compositional pragmatic analysis of the two melodies, which is based on attributing different pragmatic interpretations to the two melodic components that vary between the two tunes: the pitch accent (L*H or LH*) and the boundary tone (!H% or L%). Each of these components contributes to the pragmatic interpretation of the whole question.

Specifically, we maintain that the two melodies differ in givenness and completeness status: the L*H L-!H% melody is composed of a pitch accent which marks new information in Greek ([7]), and a boundary tone which marks the utterance as incomplete thereby inviting an answer ([1]; cf. [10]). The LH* L-L% melody is composed of a pitch accent typically used to mark contrastive focus in Greek: it conveys that the accented item (and not some alternative) should be believed (cf. [8]) and marks the remainder of the utterance as given. The L% boundary tone marks the utterance as complete ([1]; cf. [10]). The result of combining these components, L*H with !H% and LH* with L%, is that while the former questions are interpreted as requiring an answer, the latter need not function as such. This in turn explains why the L*H L-!H% melody is restricted to questions proper, while the LH* L-L% melody can be used more widely.

The results are also of interest from the point of view of processing and the value of experimental research in intonational pragmatics. First, our experiments showed that the comprehenders preferred taking *wh*-questions at face value, i.e. interpreting them as requests for information. This is not surprising given that, as noted, *wh*-questions in Greek are morphosyntactically marked as such. It is significant however that this preference was modulated by melodic changes which shifted responses towards alternative interpretations without concomitant morphosyntactic changes. Crucially, both talker and comprehender gender played a part in the interpretation and evaluation of questions, with female comprehenders in Experiment 2 being more likely to interpret stimuli from male talkers as statements than as questions (as compared to how they treated the stimuli from female talkers). This suggests that intonational pragmatics does not depend only on the interaction of melody with semantics and linguistic context, as is often maintained, but can be affected by additional factors, such as talker and addressee gender. Thus focusing exclusively on speaker intent when examining intonational pragmatics may be unnecessarily constricting, since, clearly, all participants in a conversation play an active part in constructing intonational meaning.

5. Conclusion

The results confirmed L*H L-!H% as the default melody for Greek *wh*-questions, supporting our hypothesis about a difference in the pragmatic interpretation of the L*H L-!H% and LH* L-L% melodies that string-identical Greek *wh*-questions are uttered with. Since these interpretations were available to comprehenders out of context and despite the presence of a fronted *wh*-word clearly marking the stimuli as *wh*-questions, our findings suggest that intonation can win over conflicting morphosyntactic information. Evidence was also found that both talker and comprehender gender must be factored into the pragmatic analysis, in addition to melody, semantics and linguistic context. These results strongly suggest that acknowledging comprehender expectations about the social use of melodies is crucial for fully understanding intonational pragmatics. Finally our results show that closer attention is due to the systematic differences in meaning that relate to melodic variation.

Temporal stability of long-term measures of fundamental frequency

Pablo Arantes[1], *Anders Eriksson*[2]

Abstract

We investigated long-term mean, median and base value of F0 to estimate how long it takes their variability to stabilize. Change point analysis was used to locate stabilization points. In one experiment, stabilization points were calculated in recordings of the same text spoken in 26 languages. Average stabilization points are 5 seconds for base value and 10 seconds for mean and median. Variance after the stabilization point was reduced around 40 times for mean and median and more than 100 times for the base value. In another experiment, four speakers read two different texts each. Stabilization points for the same speaker across the texts do not exactly coincide as would be ideally expected. Average change point dislocation is 2.5 seconds for the base value, 3.4 for the median and 9.5 for the mean. After stabilization, individual differences in the three measures obtained from the two texts are 2% on average. Present results show that stabilization points in long-term measures of F0 occur earlier than suggested in the previous literature.

Index Terms: fundamental frequency, long term measurements, forensic phonetics

1. Introduction

The study of statistical measures of location or preferred value of the voice fundamental frequency (F_0) of an individual has at least two applications. The first one is the development of F_0 contour normalization procedures [1][2][3], that are used to factor out the most common value of a particular speaker so that variation due to linguistic components of the contour becomes more evident. In the other important usage, knowledge of preferred F_0 value of individual speakers is often relevant to speaker comparison in forensic case work (see [4] and references therein), speech technology applications [5] and the development of security systems that require user authentication by voice, for instance (see [6] for a recent survey of the field).

When it comes to the estimation of preferred F_0 value, important issues are (i) what long-term statistical measures are better suited to do it and (ii) how long should a speech sample be in order to the estimated value be representative of an individual's speech? Regarding the choice of estimator, the literature mostly cites the mean and standard deviation (for an overview of the subject see [4]). Given that long-term F_0 distributions are usually skewed towards higher values, it seems advisable to compare the mean to alternative measures that make no assumptions regarding normal distribution of sample values. To fill this gap, we propose to compare the mean to two other measures, the median and the base value. The base value can be conceived as a neutral and speaker-specific value of F_0 below which maintaining phonation becomes difficult and to which speakers return to after excursions of linguistic or expressive value (see [7] for a detailed explanation and section 2.4 for the definition implemented in this study). Both the base value and the median are quantile-based measures that are robust to the presence of skewness or extreme values in the F_0 sample, although the median does not share all of base value's properties.

Regarding the appropriate minimum length of speech sample required for long-term mean to stabilize, the literature shows no definite consensus. Eriksson [4] makes reference to five different estimates, ranging from 14 seconds to two minutes. There is also no agreed upon objective way of estimating when a long-term measure has reached a stable point, most researchers resorting to visual inspection of trajectories of cumulative mean. In this study we explore a statistical technique called change point analysis as a way to objectively compare the performance of the three measures studied here.

2. Materials and Methods

2.1. Language effect

To study the possible effect of language on the variability of measure of location of F_0, a set of recordings of speakers of 25 languages reading the "The North Wind and the Sun" passage were analyzed. The recordings are publicly available on the website of the International Phonetic Association (IPA). One recording of a Brazilian Portuguese speaker reading the same text was included in the sample. Sixteen speakers are male. The sample includes languages of eight linguistic families: Afro-Asiatic, Sino-Tibetan, Indo-European, Uralic, Niger-Congo, Altaic, Tai-Kadai and Turkic.

2.2. Text effect

To test the possible effect of the text being read on the time it takes the long term measures of F_0 to stabilize, recordings of four speakers reading two different texts were analyzed.

The texts are the "North Wind and the Sun" passage translated to Brazilian Portuguese and a passage of "A Menina do Narizinho Arrebitado" by Brazilian writer Monteiro Lobato. The first is coded text 1 and the second text 2. Text 2 is phonetically balanced in the sense of having all Brazilian Portuguese (BP) phonemes, while in translating and adapting the "North Wind and the Sun" passage to BP the goal was to be faithful to the semantic content and not to make sure all the phonemes in the language were being used.

The recordings are by two male and two female speakers of two Brazilian states, São Paulo and Minas Gerais. Speakers from São Paulo and Minas Gerais are referred to by the sp1 and sp2 labels, respectively, followed by -f or -m to indicate if it is a female or male speaker.

2.3. Acoustical analysis

F_0 contours for every recording analyzed were extracted with the help of a Praat script that implements a heuristic suggested by Hirst [8] that tries to minimize extraction errors such as octave or fifth jumps by optimizing floor and ceiling values passed to Praat's auto-correlation F0 extraction algorithm[1]. Remaining errors were hand-corrected. Further processing of F_0 contours to obtain cumulative measures of location was done by a second Praat script written specifically for this purpose.

2.4. Measures of location

The following statistical measures of location were investigated:

- Arithmetic mean
- Median (50th-quantile of the sample F_0 values)
- Base value (7th-quantile of the sample F_0 values)[2]

All measures were taken cumulatively from the first voiced frame up to the last in non-overlapping steps of 200 ms. All F_0 values within each 200 ms interval are included in the computation of the measures. The number of F_0 samples contained in each 200 ms step depends on the floor parameter provided to Praat's F_0 extraction algorithm. In the IPA languages sample, the average minimum value for male speakers was 70 Hz and 120 Hz for female speakers, which gives us 20 values for male speakers and 32 for female speakers each 200 ms.

In the IPA languages sample, the median duration of recordings was 38 seconds with values ranging from 25 seconds (Galician) to 66 seconds (Thai). In the text effect experiment, recordings of text 1 have an average duration of 32 seconds and recordings of text 2 have an average duration of 41.3 seconds.

Mean and median values are usually close, but base value, by definition, is smaller than both. Since here we are more interested in how their variability changes over time and not specially in their absolute values, a normalization procedure was applied so that the three time series can be seen in the $[0, 1]$ interval. This was done by means of formula 1, where f_i is the i^{th} raw F_0 value in a given contour and $f_{\min}$ and $f_{\max}$ are respectively the minimum and maximum values in the contour:

$$(f_i - f_{\min})/(f_{\max} - f_{\min}) \quad (1)$$

The normalized values were used for visualization purposes only. The statistical analysis were carried out on the raw values (in Hz) of the cumulative measures.

2.5. Statistical analysis

Our main interest is to determine how long it takes for the time series defined by the cumulative measures of location of F_0 studied here to have its variability reduced to what could be considered a stable value. In most of the literature on the subject, what we are calling the stabilization point has been determined by visual inspection of the time series of cumulative measure of location. Although the visual inspection can be useful, it would be important to develop a less subjective and more automatic way of determining stabilization points.

A statistical technique called change point detection analysis was used to attain a greater level of objectivity in determining stabilization points. This technique estimates the point in time at which underlying statistical properties (mean, variance or both) of a time series change. A function of the R package changepoint [9] was used in the analysis to find a point that divides the time series in in two parts having different variances and tests the hypothesis that the two values are significantly different. We searched for single variance change points in cumulative mean, median and base value time series. Since distribution of cumulative mean, median and base value are highly skewed, an algorithm that does not assume that the values in the time series follow a normal distribution was used.

3. Results and discussion

3.1. Language effect

Figure 1 shows temporal evolution of cumulative normalized measures of location. Wide-range fluctuations in the three estimators are a general trend across languages, specially at the first seconds of the recordings. As estimators' values are computed over longer stretches of time, the range of fluctuations gets increasingly smaller, but with notable differences between the languages: in some cases, variability quickly drops (e.g, Arabic, German, Galician, Hungarian, Slovene and Swedish) whereas, in other cases, the reduction seems to be more gradual (e.g., Brazilian Portuguese, Catalan, French, Irish and Korean). For all languages, with the possible exception of Turkish, the cumulative value of the three estimators tend to reach a stable value at some point, usually within the first fourth of the recording duration.

Table 1 lists the temporal location of change points for the 26 languages investigated as determined by the change point analysis described in section 2.5 as well as ratio of variance before and after the change point. Figure 2 shows a box plot of change points broken down by typical measure type.

One of the main findings is that change points in this sample seem to happen in the low range of values suggested in most of the previous literature on the subject or even earlier than that (see section 1). The other main finding is that the base line tends to stabilize a little earlier (5 seconds) then mean and median (about 10 seconds). The base value change points are also less variable (median absolute deviation of 2.2) than mean and median (MAD of 6.2 and 7.6 respectively). Inspection of variance reduction factors in Table 1 suggests that in fact the points identified by the change point analysis can be considered stabilization points. Base value also has a superior performance in terms of variance reduction: base line has an average reduction factor of 120 and the mean and the median an average factor of 48.

3.2. Text effect

Figure 3 shows cumulative values of long-term measures of typical F_0 for four speakers reading two different texts. Table 2 lists change points in the three measures as well as variance reduction factors.

For a given long-term estimator, the change point and the estimator value for a given speaker would ideally be the same, regardless of the text being read. Strictly speaking, that was not the case for the four speakers in our sample: average absolute difference between change point for text 1 and text 2 is 4.9 seconds, with a minimum of 0.4 and a maximum of 21.1 seconds. 75% of the differences are under 6 seconds. Considering

[2] In [7], the authors say that the base value can "as a rule of thumb, be expected to be about 1.5 σ below his average F_0". To Define the base value in terms of a quantile is for all practical purposes equivalent to the definition based on standard deviation, assuming F_0 values are normally distributed.

Table 1: *Change point locations (in seconds) in the mean, median and base value time series for the 26 languages investigated. Ratio of variance before and after change point are shown in parentheses.*

language	mean	median	base value
Amharic	11 (44)	16.2 (137)	4.8 (69)

Hindi	10 (112)	16.4 (322)	10 (84)
Hungarian	2.4 (194)	3.8 (171)	4 (217)
Igbo	7.8 (19)	8.8 (2)	21 (222)
Irish	14.4 (7)	12.6 (17)	15 (10)
Japanese	6 (183)	11.6 (58)	0.4 (1772)
Korean	21.4 (18)	21.6 (13)	1 (3)
Persian	20.6 (27)	20.6 (21)	4.6 (3)
European Portuguese	11 (116)	6.4 (81)	5.8 (219)
Sindhi	15 (66)	15.4 (44)	6.4 (172)
Slovene	9 (141)	14.8 (21)	0.8 (232)
Swedish	6.2 (108)	2.8 (504)	15.4 (271)
Thai	22.2 (23)	24.4 (52)	27.6 (137)
Turkish	20 (11)	3.2 (3)	4.6 (16)

that the standard deviation of change point location on the IPA language sample is 6 seconds, the differences in change point location between text 1 and text 2 are less then what would be expected when comparing samples of different languages. A comparison of the differences between the raw values (in Hz) of the cumulative mean, median and base value of text 1 and text 2 at the time of change point shows that on average the difference is 2%, with a range going from 0 to 9%, the four speakers polled. 90% of the differences are under 4%, i.e., less than one semitone. These data indicate there is an effect due to text whose magnitude is slightly smaller than that due to language.

None of the texts yielded overall earlier change points or greater variance reduction factors. The only exception to that is the long-term median of text 2, whose change points are earlier than those of text 1 for all four speakers. It's not clear if the behavior of the median can be attributed to the fact that text 2 is phonetically balanced and why only the median should be affected by this particular feature of text 2.

4. Conclusions

We set out to compare three long-term measures of typical value for F_0, namely the mean, median and base value, in two respects: how long it takes for each measure to achieve a more or less stable level of variability and how much they are affected by language and text.

Our results indicate that long-term measures tend to stabilize at most 30 seconds after the begining of a recording of read speech, with median times around 10 seconds. Of the three measures, the base value seems to yield the earliest and less variable change points, confirming earlier findings suggesting its robustness against factors such as variation in speaker emotional state, vocal effort and channel quality.

Table 2: *Change point (seconds) in the mean, median and base value for the four speakers and the two texts. Ratio of variance before and after change point are shown in parentheses.*

speaker	text	mean	median	base value
sp1-f	1	9.8 (18)	9.6 (21)	9.6 (6)
sp1-f	2	15.2 (28)	5.2 (13)	5.6 (83)
sp1-m	1	10.2 (92)	10.2 (58)	6.2 (33)
sp1-m	2	4.8 (22)	4.8 (42)	5.2 (7)
sp2-f	1	7.2 (11)	7.2 (4)	9.4 (9)
sp2-f	2	28.2 (8)	5.6 (6)	9.8 (39)
sp2-m	1	10.4 (33)	10.8 (33)	5.2 (41)
sp2-m	2	24 (20)	8 (14)	13.8 (39)

The results also show that both language and the specific text being read seem to cause variability in stabilization points. The base value is less affected by the language effect than the mean and median measures. The text effect is slightly smaller than the language effect and the three measures seem to be equally affected by it.

In order to increase the accuracy of the results obtained in the present study, in follow-up studies we are going to increase the number of speakers in the languages investigated and the length of the recordings. Two promising avenues of investigation worth exploring are the effects of different speaking styles (reading vs. spontaneous speech, for instance) and non-contemporaneous recordings on the temporal stability of long-term measures.

Abstract

Speech perception depends on the ability to rapidly accommodate considerable variability in speech rate. We present results from two eye-tracking experiments indicating that listeners use context speech rate to generate, maintain, and update probabilistic hypotheses about the timing and number of constituents in upcoming speech. Participants heard utterances containing polysyllabic nouns preceded by indefinite articles and followed by [s]-initial words (e.g. *...saw a raccoon slowly...*). We altered the speech rate of the indefinite article and of the [s] with respect to surrounding context, manipulating the likelihood that the item would be perceived as singular (*a raccoon*) vs. plural (*raccoons*). Shorter indefinite articles elicited higher proportions of fixations to plural target pictures than longer articles both before and after the processing of [s], demonstrating that listeners made rapid use of prosodic cues to the presence or absence of the article. Importantly, fixations were also influenced by the duration of [s] relative to context speech rate. These findings suggest that listeners maintain and update provisional speech-rate hypotheses across multiple morphophonemic units. We interpret these results with respect to probabilistic approaches to spoken language understanding.

Index Terms: perception of prosody, speech rate, expectations, eye movements, language comprehension

1. Introduction

The realization of prosodic information in speech, such as pitch accents, speech tempo, and other intonational features, is highly variable (e.g. [1], [2], [3]). This variability poses numerous challenges for spoken language processing. For example, the realization of temporal speech cues like voice onset time depends on an individual's overall speech rate. Comprehension therefore crucially depends on the ability of listeners to interpret prosodic cues and rate-dependent speech cues with respect to surrounding context (e.g. [4], [5], [6]). A comprehensive understanding of the role of prosody in spoken language comprehension requires an explanation of how listeners accommodate contextual information during real-time processing.

In this paper we explore a possible explanation for how listeners interpret prosody in context based on emerging *data-explanation* approaches to perception and cognition. Data-explanation approaches posit a central role for *generative processes* within perceptual systems that give rise to probabilistic expectations about incoming sensory input based on high-level representations and contextual information (e.g. [7], [8]). During speech perception, we hypothesize that listeners continuously make and update inferences about the source of the speech signal (i.e. the communicative intention of the speaker) by comparing internally generated probabilistic expectations about the acoustic realization of the speech signal to the actual speech signal as it unfolds. This provides a potential explanatory framework for the integration of multiple distinct and temporally distributed constraints during spoken language processing [9]. Particularly compelling from this perspective are so-called *distal prosody* effects [10], [11]. For example, manipulating pitch and timing patterns across utterance material several syllables before a temporarily ambiguous word (e.g. *panda*, which can initially be interpreted as *pan*) influences the time course of lexical competition, even when the prosodic characteristics of the target word itself are unaltered [12], [13]. These findings suggest that listeners develop expectations based on prosodic patterns in speech that extend across a relatively wide window.

The data-explanation framework provides a potential explanation for how expectations based on preceding prosody are mapped onto the acoustic-phonetic properties of the unfolding speech signal. It also makes the prediction that listeners continuously update their provisional hypotheses about the source of the speech signal on the basis of additional downstream information. The present study investigates this prediction by capitalizing on effects of context speech rate on the number of words that are perceived within a stretch of speech [11]. Compressing the speech rate of portions of an utterance surrounding a highly coarticulated word (e.g. the underlined segments surrounding the determiner "a" in *The Smiths wouldn't buy a Butterball...*) reduces the likelihood that listeners report hearing this word. Likewise, when the word in question is not present in the signal (e.g. *buy Butterball...*), slowing down the segments surrounding its potential location makes listeners more likely to perceive the word within the slow portion of speech.

In the present study, we investigate whether and how listeners maintain and update provisional prosodic percepts based on downstream cues, by manipulating the relative speech rate of multiple temporally-distributed cues to the plurality of a noun phrase – the presence or absence of the indefinite determiner *a* before the noun and of the plural marker *–s* following the noun. Our experiments use the *visual world paradigm* to examine listeners' eye movements to pictures depicting singular and plural versions of the target noun phrase, providing an index of the time course of interpretation [14], [15]. The goals of this work were to determine (a) whether and how listeners combine multiple temporally distributed prosodic cues to the plurality of a referring expression; and (b) whether the time course of prosodic cue integration is consistent with the hypothesis that listeners rapidly update their previous prosodic expectations and provisional percepts in light of downstream information.

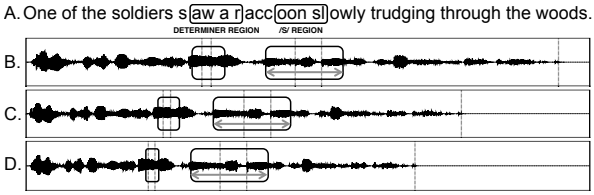

Figure 1: *Illustration of the distal /s/ speech rate manipulation in Experiment 1: (a) Example stimulus sentence; (b) 86% determiner, 95% distal /s/; (c) 86% determiner, 75% distal /s/; (d) 86% determiner, 65% distal /s/. Boxes indicate the position and duration of determiner and /s/ regions, respectively.*

2. Experiment 1

2.1. Methods

2.1.1. Participants

We recruited 36 students from the University of Rochester to participate in Experiment 1. All participants were native speakers of American English and had normal hearing and normal or corrected-to-normal visual acuity.

2.1.2. Materials

The stimuli were 54 grammatical declarative sentences containing a highly imageable singular noun phrase (e.g. *a raccoon*) followed by a word starting with an /s/ (e.g. Fig. 1a). Recordings of these sentences were elicited from 12 speakers. These speakers also recorded 81 filler items whose target nouns were equally likely to be singular or plural and whose number was unambiguous (e.g. *those bathrobes*). We selected one token of each item for use in the experiment, consisting of 4-5 critical item tokens and 6-7 filler item tokens from each speaker. Critical item tokens were selected such that they had a relatively high degree of coarticulation on the indefinite determiner "a" and continuous articulation of the target word and the following /s/, such that the presence or absence of the plural marker *–s* was not clearly signaled.

Stimuli were manipulated in two ways (Fig. 1b-d). First, the speech rate of the region consisting of the determiner and the segments immediately surrounding it (*determiner region*) was compressed to 92%, 86%, or 78% of its original rate. Then, we compressed the speech rate of utterance context preceding and following the segments surrounding the /s/ following the target word (*/s/ region*), such that it was 95%, 75%, or 65% of its original rate. The absolute physical duration of the /s/ region remained the same across conditions, but its speech rate relative to surrounding context increased with successive levels of context speech rate compression. Levels of each manipulation were selected based on norming data. The global speech rate of filler items was manipulated such that equal numbers of items were compressed to 95%, 75%, or 65% of their original rate.

2.1.3. Procedure

On each trial, participants were presented with a computer screen containing a four-picture visual display. The display contained singular and plural versions of the target word and of a distractor picture. Each participant heard a single version of each item over Sennheiser HD 570 headphones after 500 ms of display preview. Their task was to click on the picture that they heard referred to in each sentence. Eye movements were recorded using a head-mounted SR Research EyeLink II system sampling at 250 Hz, with drift correction procedures performed following every fifth trial.

Two lists were created by pseudo-randomizing trial order and rotating picture positions 180 degrees. An additional set of two lists was created by reversing the order of these lists. An equal number of critical items in each list were assigned to each of the nine pairings of determiner condition and distal speech rate condition. The assignment of items to conditions was counterbalanced across participants. All lists started with six filler items to ensure that participants were familiar with the task prior to encountering critical items.

2.1.4. Analyses

Response choices and fixations were analyzed separately. Data from trials on which the participant incorrectly selected one of the two distractor pictures (less than 0.5% of trials) were excluded. Selections of singular vs. plural target pictures were analyzed using multilevel logistic regression. Proportions of fixations to singular and plural target pictures on each trial were averaged across two windows of interest: (a) an *early window* 400 ms in duration (the mean duration of the target word), starting 200 ms before and ending 200 ms after the onset of the /s/; and (b) a *late window* between 200–1000 ms following the onset of the /s/. Both windows were selected to take into account a 200 ms delay for programming and executing fixations. Mean proportions of fixations to the plural target picture were divided by the mean propotion of fixations to both target pictures to calculate a *plural target advantage ratio* across each window for each trial, which was transformed using the empirical logit function [16], [17]. Plural target advantage ratios were analyzed using linear regression. The significance of predictors in the linear regression models was estimated by assuming convergence of the t distribution with the z distribution [18]. Models were computed using the *lme4* package in R (version 2.15.0) [19], [20]. All regression models had determiner speech rate, distal speech rate, and their interactions as fixed effects, and full random effects structure except as noted due to lack of convergence [21]. Factors were contrast coded with the least rate-manipulated level set as the reference level (i.e. 92% determiner, 95% distal /s/). Model comparison procedures were used to remove fixed effects that did not contribute significantly to model fit according to the likelihood ratio test [18].

2.2. Predictions

We predicted that compressing determiner speech rate would result in increased selections of plural target pictures and higher plural target advantage ratios in both the early and late windows, replicating early effects of relative speech rate on spoken language processing observed in previous work [22]. Importantly, we predicted that compressing speech rate of material distal to the /s/ (effectively slowing down the speech rate of /s/ relative to surrounding context) would also result in increased plural target picture choices and proportions of fixations to plural target pictures following the onset of /s/.

2.3. Results and discussion

2.3.1. Picture choices

Participants' response choices were consistent with our predictions (Fig. 2). The multilevel logistic regression model of response choices confirmed that participants were more likely to select plural target pictures when the determiner had a faster

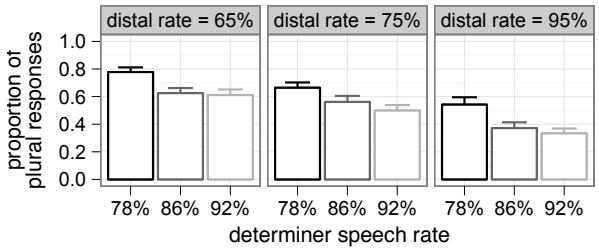

Figure 2: *Proportions of plural responses in Experiment 1.*

speech rate (66% plural responses for the most compressed determiner compared to 48% for the least compressed determiner; β=1.42, z=5.76, $p<.0001$). The distal /s/ manipulation also had the predicted effect. Participants were most likely to choose plural target pictures when the /s/ was surrounded by the most compressed speech, and therefore had a slower speech rate with respect to the utterance context (67% plural responses). They were least likely to choose plural target pictures when the /s/ was surrounded by the least compressed speech (42% plural responses; β=1.89, z=7.96, $p<.0001$).

2.3.2. Proportions of fixations

Figure 3 shows fixations to plural and singular target pictures over time with respect to the onset of the /s/. Analysis of plural target advantage ratios across this window revealed early effects of determiner speech rate on fixation proportions (Fig. 3, top). More compressed determiners were associated with more looks to plural target pictures and fewer looks to singular target pictures, compared to less compressed determiners (β=0.11, t=1.92, p_{est}=.055). This finding replicates early effects of speech rate on determiner perception previously observed in related work and suggests that effects of speech rate manipulation on the perception of short words have a locus in perceptual expectations [22]. Effects of determiner speech rate persisted into the late analysis window (β=.13, t=3.97, $p_{est}<.0001$).

The distal /s/ speech rate manipulation also exhibited the predicted effects within the late analysis window, during and following the processing of the /s/ (Fig. 3, bottom)[1]. Plural target advantage ratios were highest when the /s/ was surrounded by the most compressed speech, and therefore had a slower speech rate than the utterance context, than when the /s/ was surrounded by relatively slow speech (β=.17, t=3.61, $p_{est}<.0005$).

These results suggest that determiner perception is influenced by prosodic information influencing whether the /s/ multiple syllables downstream is perceived as containing the plural morpheme *–s*. However, it is also possible that these effects are instead attributable to the absolute duration of the determiner. The determiner is compressed first as part of the determiner region manipulation, and then as part of the distal /s/ speech rate manipulation (which involves compressing all material distal to /s/, including the determiner). The absolute duration of the determiner therefore covaries with the relative speech rate of the /s/. For example, in the 86% determiner speech rate condition, the absolute duration of the determiner is in fact 82% of its initial duration in the slowest distal speech rate condition and 56% in the fastest (cf. Fig. 1b-d). It is therefore possible that apparent effects of the speech rate of /s/ relative to surrounding context could instead have resulted from effects of distal speech rate compression on the absolute duration of the determiner. These possibilities cannot be distinguished on the basis of the time course data, because of the overall effects of speech rate compression on fixations prior to the onset of the target noun phrase.

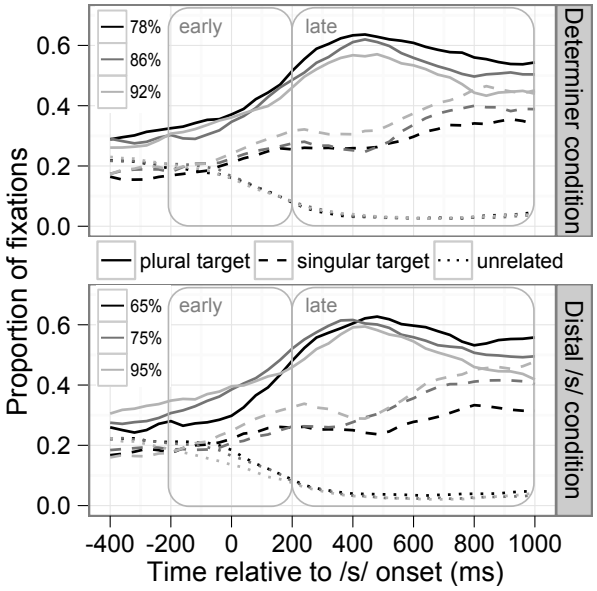

Figure 3: *Proportions of fixations in Experiment 1, by determiner (top) and distal /s/ (bottom) conditions. Superimposed shapes depict early and late analysis windows.*

To address this potential confound, we conducted a second visual world experiment in which we manipulated the speech rate of the /s/ by slowing down the /s/ region itself, rather than by compressing surrounding context. This proximal /s/ speech rate manipulation had no effect on the absolute duration of the determiner. Thus, if the effects that we observed in Experiment 1 were merely attributable to effects of the distal speech rate manipulation on the absolute duration of the determiner, we would not expect to observe effects of the proximal /s/ speech rate manipulation on picture choices or fixations to singular or plural pictures. If, however, the effects found in Experiment 1 were due to the speech rate of the /s/ relative to surrounding context, we would expect to see effects of the proximal /s/ manipulation that are similar to those that we observed in Experiment 1.

3. Experiment 2

3.1. Methods

Participants were 36 University of Rochester students meeting the same criteria as for Experiment 1. In addition, the experi-

[1] We also found marginally significant effects of the distal /s/ speech rate manipulation on fixations within the early window (i.e. before the processing of the /s/; β=.10, t=1.74, p_{est}=.082). Post-hoc analyses revealed that the logit-transformed sum of fixations to both target pictures differed as a function of distal speech rate condition (β=-0.17, t=-3.89, $p_{est}<.0005$). Increased compression of the utterance context was associated with lower proportions of fixations to target pictures within the early analysis window, because the analysis window was time-locked to the onset of the /s/. It is therefore likely that these effects of distal /s/ speech rate manipulation on pre-/s/ fixations are merely attributable to information about the target word becoming available at different times and different rates. Importantly, because the baseline effects observed in the early analysis window were in the opposite direction of the predicted effects of distal speech rate following the onset of the /s/, they did not complicate interpretation of effects in the later analysis window.

ment setup, stimulus lists, data collection, and analysis procedures were the same as in Experiment 1.

We used the recordings from Experiment 1 to create the stimuli for Experiment 2. The determiner manipulation was the same as in Experiment 1. However, instead of manipulating the relative speech rate of /s/ by compressing the speech rate of material surrounding the /s/ region, we instead manipulated the /s/ region directly by slowing its speech rate to 110%, 150%, or 170% of its original rate. Following this proximal /s/ speech rate manipulation, all critical and filler items were globally compressed to 85% of their original duration, to maintain similarity with Experiment 1 in terms of global stimulus characteristics and overall experiment duration.

3.2. Results and discussion

3.2.1. Picture choices

The multilevel logistic regression model of response choices. Participants again selected plural target pictures more frequently when the determiner region had a faster speech rate (65% in the fastest condition compared to 46% in the slowest condition; β=1.43, z=6.86, $p<.0001$). Crucially, the speech rate of /s/ also influenced response choices in the predicted direction, such that participants were more likely to select plural pictures when the /s/ region had a slower speech rate (62% plural responses in the slowest condition compared to 43% in the fastest condition; β=1.48, z=8.76, $p<.0001$). This suggests that the effects of the speech rate of /s/ relative to surrounding context influenced listeners' judgments in both experiments, rather than simply the absolute duration of the determiner.

3.2.2. Proportions of fixations

The multilevel linear regression of plural target advantage ratios in the early analysis window indicated no significant effects of determiner or /s/ speech rate manipulation. The determiner manipulation used in these experiments was subtle relative to manipulations used in previous related work, in which early effects of determiner speech rate were reliably observed (Brown et al., 2012). Previous work also used a multi-word target expression, providing a larger window of analysis with more statistical power. Although the manipulation we used in the present experiments elicited robust effects in response choices and in overall fixation behavior, it is possible that it was nevertheless too subtle to elicit large enough effects to be reliably observed immediately after the processing of the determiner, even though numerical trends in the predicted direction emerged within this window. In addition, other factors such as a lack of variation in the global speech rate of filler items may have contributed to subtle differences in time course and/or magnitude of effects across experiments.

Crucially, however, analysis of plural target advantage ratios during the late analysis window revealed significant effects of not only determiner but also /s/ speech rate. As predicted, more compressed determiners were associated with higher plural target advantage ratios (i.e. more fixations to plural pictures and fewer to singular pictures; β=.28, t=5.80, $p_{est}<.0001$). In addition, plural target advantage ratios were higher when the speech rate across the /s/ region was the slowest (β=.21, t=4.33, $p_{est}<.0001$). This finding, together with the significant effect of /s/ speech rate on picture choices, indicates that the effects of Experiment 1 cannot be explained merely on the basis of the absolute duration of the determiner across different levels of the distal /s/ speech rate manipulation. Eliminating this confound provides stronger evidence that the interpretation of function words can be modulated by information encountered considerably later in the utterance.

4. Discussion

Our results provide evidence that listeners combine multiple temporally distributed prosodic cues to the plurality of a referring expression during real-time spoken language comprehension. Prosodically conditioned percepts of short words like determiners can be influenced by congruent or conflicting information in the speech signal that occurs substantially downstream. These findings suggest that listeners maintain and update provisional hypotheses about previously encountered material across multiple morphophonemic units.

Our findings are closely aligned with recent work demonstrating that language processing is influenced by information spanning a wider temporal integration window than standardly assumed [23], [24], [25]. For example, when listeners hear a target word *leash* in a sentence context, lexical competition with *leaves* is stronger when the target word follows the verb *shakes* (whose rhyme *rakes* is semantically related to *leaves*) than when it follows the verb *rattles* [23]. This suggests that residual uncertainty about the perceived verb influences lexical competition effects several syllables downstream.

The present work further demonstrates that these "right-context" effects also extend to uncertainty about the timing and number of constituents in preceding speech, based on preceding prosodic information. These findings are difficult to explain with respect to traditional feed-forward models of spoken language comprehension that assume that listeners map acoustic patterns onto more abstract representations (e.g. words and morphemes) prior to interpreting the perceived representations with respect to sentence- and discourse-level context. Rather, our results suggest that listeners maintain and update probabilistic inferences about speakers' intended meaning (such as the intention to produce a singular or plural construction) based on available prosodic information across a relatively wide window.

5. Conclusions

Prosody influences spoken language processing in a gradient, probabilistic fashion. Further, prosodically-conditioned percepts are maintained and updated across multiple morphophonemic units. These findings are most naturally explained within a probabilistic data-explanation account of spoken language processing, involving probabilistic inference about the communicative intentions that give rise to the acoustic realization of an utterance. These inferences inform fine-grained probabilistic expectations about how aspects of lexical alternatives will be realized in context. They can be also updated in light of subsequent information encountered in the unfolding utterance.

The role of intonation in early word recognition and learning

Abstract

The motivation for our study is to investigate how English-acquiring toddlers are guided by the mapping between intonation and information structure during on-line reference resolution and in novel word learning tasks. We ask whether specific pitch movements (*deaccented*, *monotonal*, *bitonal*) more systematically predict patterns of attention and subsequent novel word learning abilities depending on the referring or learning condition (*new*, *given, contrastive*). Experiment 1 examines the attentional patterns of 18-month-old toddlers when referents are either *new* or *given* in the discourse, and carry one of the three pitch movement types. Contrary to previous work, results show increased attention to the target in the deaccented condition if the referent is *new* to the discourse. Also, both monotonal and bitonal pitch movements direct attention to the target even when the target is *given*. Thus, pitch type interacts with information structure in directing toddler attention. Experiment 2 tests two-year-olds in a novel word learning task, varying pitch type and contrastiveness during learning. Preliminary results show that learning is aided when the novel word is introduced in contrast to a previous referent. Together, these two experiments demonstrate the role of pitch type and information structure in guiding attention and aiding early word learning.

Index Terms: intonation, information structure, first language acquisition

1. Introduction

From birth, infants are sensitive to native language rhythm and pitch patterns ([1], [2]). They can then approximate adult-like intonation contours from the onset of production ([3], [4], [5]) and align these contours with felicitous semantic and pragmatic intentions ([6]). However, little research has been conducted on the early comprehension of contours as they reflect information status.

Previous research shows that toddler attention to referents can be mediated by both intonation and information structure in discourse ([7]). In turn, attention to a referent is essential for making the correct word-to-object or word-to-action mappings necessary for early word learning ([8]). The motivation for our study is two-fold: 1) to investigate how American English-acquiring 18-month-olds are guided by mappings from intonation to information structure during on-line reference resolution in discourse (Experiment 1), and 2) to investigate how the pitch accent on a novel word interacts with its referential status to aid early word learning in American English-acquiring 24-month-olds (Experiment 2).

Social pragmatics and intentionality are often cited as essential in order to achieve successful word learning ([9], [10]). Our study tests outcomes when live interactions are removed from the experimental design and any degree of intentionality is only accessible through the utterances themselves and their corresponding prosody.

This study focuses on two pitch accents in American English, the simple monotonal H* and the complex bitonal L+H*. Previous work in adult speech perception shows that the simple H* pitch accent can be associated with either new or contrastive information in discourse, and the complex L+H* is more typically associated with a contrastive interpretation ([11]). Our experiments exploit these mappings in American English in order to test how these pitch accents interact with referential newness, givenness, and contrastiveness during early attentional processes and word learning.

2. Experiment 1

Previous research by Grassmann and Tomasello (2010) claimed that German-acquiring two-year-olds attend to a referent of a familiar word if and only if the word is both *stressed* and *new* to the discourse ([7]). Their experiment consisted of three conditions where the target referent could be introduced in a short discourse context with (a) stress only, (b) newness only, or (c) stress and newness. They used a live speaker to present the stimuli to each subject in order to ensure a level of intentionality on the side of the speaker and measured looking time and pointing to a referent as their dependent variables.

Our experiment expands upon the work by Grassmann and Tomasello (2010) but makes a number of methodological changes. First, we add in a deaccented condition to the design to act as a control against the accented (or 'stressed') conditions. Second, we ask whether specific pitch movements more systematically predict patterns of attention to a referent, rather than using one "stressed" category. Third, since a live speaker may have produced varying intonation contours, we control for speaker variations by using pre-recorded stimuli. Finally, we isolate the role of pitch in guiding attention, holding duration and intensity constant. This is a first step towards understanding how each of the acoustic correlates of intonation contribute and interact in guiding attention.

Specifically, we consider how unique pitch movements facilitate attention when a referent is either *new* or *given* in the discourse. The pitch types tested are a simple monotonal rise (~H*), a complex bitonal rise (~L+H*), and a deaccented control pattern. First, we predict that regardless of pitch type, newness will guide attention to a referent. Second, a semantically and pragmatically appropriate pitch accent will guide attention to both *new* and *given* referents.

2.1. Method

2.1.1. Participants

Data were analyzed for 48 American English-acquiring 18-month-old toddlers (27 female). The age of participants ranged from 529 to 589 days, with a mean age of 551 days. Thirteen additional participants were discarded due to fussiness (9), experimental error (1), or equipment malfunction (3). All participants were from Providence, RI, USA, and surrounding areas.

2.1.2. Stimuli

An adult female speaker produced all target and distractor utterances. In order to create the three different pitch types, the speaker first produced carrier sentences with H* accents on the target words using careful speech (slow and clear), but not child-directed speech. The pitch contour of only the target word was then digitally manipulated in Praat ([12]) to create the simple monotonal and complex bitonal versions. Deaccented target words were spliced into the carrier phrase and matched for duration and intensity to the two accented versions. All test stimuli were resynthesized. Naïve listeners judged the resynthesized target speech sounds as natural.

There were 6 (C)CVC monosyllabic target words and 18 (C)CVC monosyllabic distractors used in the procedure (See Table 1 for a full list of stimuli by trial). All target words were phonologically distinct within a trial and primarily sonorant in nature. All of the target and distractor words are commonly known by 18-month-olds. Previous knowledge of the words was confirmed by a vocabulary questionnaire completed by the caregiver. If the toddler was not familiar with a particular word, then that particular trial was eliminated during analysis (this was not a common occurrence, and it only affected at most one trial per participant).

Table 1. *Stimuli for Experiment 1.*

Trial Number	Target Word	Distractors/Fillers
Practice	spoon	cake
		bear
		fish
1	ball	sock
		lamb
		cat
2	moon	dog
		shoe
		book
3	cow	pig
		tree
		duck
4	doll	bus
		cup
		sun
5	plane	star
		truck
		dress

2.1.3. Design and procedure

We used a 2x3-mixed design to test toddlers' responses to changes in information status and intonation, isolating the specific role that pitch plays in directing attention to *new* or *given* referents. The independent variable of Information Structure *(new* vs. *given)* was manipulated within subjects, whereas the independent variable of Pitch Type (*deaccented, simple, complex)* was manipulated between subjects.

Each trial consisted of a Context Phase and a Test Phase. During the Test Phase, the test utterance played and the *proportion of looking time (PLT) to the target* was collected using the SMI iView X™ RED eye tracker. The Context Phase consisted of two parts (or slides), which established the Prior Discourse Context before the Test Phase was introduced (See Figure 1). Importantly, the target referent in the Test Phase was either *new* or *given* to the discourse as well as in contrast to an item in the previous slide, making both the simple (~H*) and the complex (~L+H*) movements acceptable in this location.

There were 5 familiarization trials and 2 test blocks per between-subjects condition. A test block included 1 practice trial and 5 test trials for a total of 6 trials in each block. With two blocks per condition (one *new* and one *given* condition), there were a total of 2 practice trials and 10 test trials (12 total trials). Trial order within a block was randomized and block order was counter-balanced across participants. The location of the target items on the screen (left or right) was also counter-balanced within and across conditions.

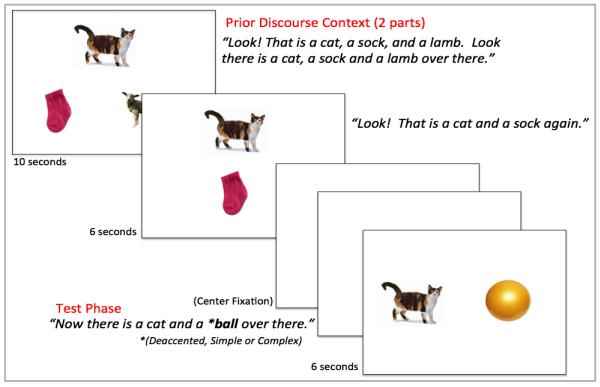

Figure 1: *Example new trial from Experiment 1.*

2.2. Results

A 2x3 repeated measures ANOVA shows a significant main effect of Information Structure ($F(1,45) = 32.36$, $p < .001$, $\eta_p^2 = .418$) and a significant main effect of Pitch Type ($F(2,45) = 6.34$, $p = .004$, $\eta_p^2 = .220$). The two-way interaction of Information Structure by Pitch Type approached but did not quite reach significance ($F(2,45) = 3.01$, $p = .059$).

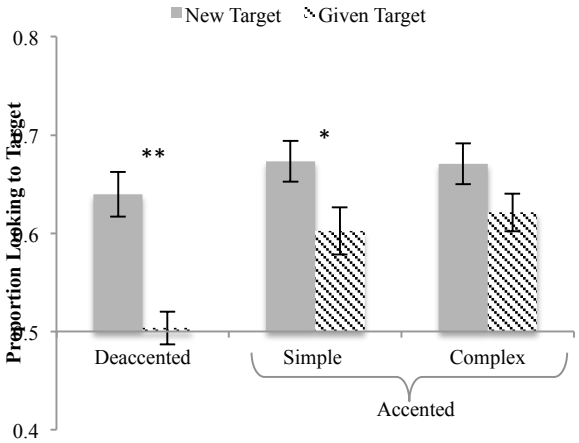

Figure 2: *Bar graph of proportion looking to a new or given target referent for each pitch type condition. Error bars show +/- SE. *: p < .05, **: p < .01.*

Planned comparisons between groups reveal more looking to a target than a distractor when the referent is *new* to the discourse context, regardless of pitch accent type (See Figure 2). Additionally, both types of accentuation (*simple* and

complex) guide more looks to the target than to the distractor when the target referent is either *new* or *given* to the discourse context. In the *simple* condition, there was significantly longer looking to the target when it is *new* to the discourse than when it is *given*. This difference between *new* and *given* target referents does not reach significance in the *complex* condition. Crucially, there are more looks to the target than the distractor referent in all conditions except when the target is *deaccented* and *given* in the discourse.

2.3. Discussion

Contrary to previous literature, *newness* is sufficient to draw 18-month-olds' attention to a referent in a discourse, even without pitch accentuation. A preference for the novel (or *new*) stimulus item over a familiar (or *given*) one suggests a more mature level processing by 18-months-olds ([13], [14]). Toddlers prefer to look at the more prominent or salient item in the discourse, where salience in this case is achieved through pitch movement and newness effects.

Additionally, even in the case of a target referent that is *given* in the discourse, both *simple* and *complex* pitch movements guide attention to this referent. Thus, the presence of either *newness* or a *pitch accent* shifts attention to a target referent in a discourse, regardless of pitch movement type. This suggests that the more salient or prominent the stimulus item, the more a toddler will look. When a target is both new and carries a pitch movement, the result is even greater looking to the target. For *given* information, attention is being driven by the pitch movement on the referent word.

Importantly, we observe robust effects for the variable of pitch type even when only the acoustic dimension of pitch is manipulated. With intensity and duration held constant, any observed pitch accent effects were a consequence of pitch (f0) manipulation. Thus, even with a more complex discourse phase and limited acoustic cues to stress, we find a very different pattern of results from previous research.

In this experiment, the two pitch types analyzed were a simple monotonal and a complex bitonal pitch movement. Future work will extend analyses to other types of pitch accents, discourse contexts, as well isolate the roles of other acoustic cues to prosody (i.e. duration and intensity). Critically, significant methodological differences change the complexion of results in comparison to previous work. Understanding the mechanisms for guiding attention is essential for subsequent early word learning.

3. Experiment 2

As demonstrated in Experiment 1, toddler attention to a referent is mediated by both the intonation and the information structure of the discourse. Experiment 2 extends these findings to investigate how pitch type interacts with contrastiveness during a novel word learning task.

Both newness and pitch were shown to aid in guiding attention during a discourse context in Experiment 1, where the target item was also in contrast to a previous referent. Contrastiveness here is defined as introducing a referent in direct opposition to a one that is previously mentioned. This type of contrast without pitch accentuation on the target word was not sufficient to guide attention to the intended referent. Interestingly, with the addition of a context appropriate pitch accent movement, attention increased to a target referent over a distractor. The goal of experiment 2 is to explore how discourse contrastiveness interacts with intonation to aid in early word learning.

First, we predict that contrastive learning situations are more likely to shift attention to a referent and aid in word learning, particularly when paired with the more prominent contrastive accent ([15]). Second, from Experiment 1 we know that accentuation facilitates attention to a referent. Thus, we predict that contrastiveness and the presence of a pitch accent will aid in the learning of a novel word.

3.1. Method

3.1.1. Participants

Preliminary data were analyzed for 12 American English-acquiring 24-month-old toddlers (7 female). The age of participants ranged from 722-767 days, with a mean age of 743 days. Four additional participants were discarded due to fussiness (3) or inattentiveness (1). All participants were from Providence, RI, USA, and surrounding areas.

3.1.2. Stimuli

The same female speaker who recorded the stimuli for Experiment 1 produced all utterances using careful speech (slow and clear), but not child-directed speech. The speaker was trained in intonational phonology and was able to produce H* and L+H* accents consistently across the different stimulus items. Each target word was produced naturally in an utterance with an H* accent, a L+H* accent, or as deaccented. The target word was then spliced out of the original utterance and into a carrier sentence. This ensured that the only difference between the different pitch type conditions was the pitch accent of the target word, and not the other parts of the sentence. All splices were made at zero-crossings.

Stimuli included two CVC monosyllabic target novel words and 4 CVC monosyllabic distractors (See Table 2 for a full list of stimuli by learning condition). All target words were phonologically distinct. All of the distractor words were animals commonly known by 24-month-olds. Previous knowledge of the words was confirmed by a vocabulary questionnaire completed by the caregiver. Novel words were associated with novel animals designed for this experiment. There are four novel animals, two for each learning condition.

Table 2. *Audio stimuli for Experiment 1.*

Learning Condition	Novel Target Word	Distractors/Fillers
Noncontrastive	*wug* (IPA: /wʌg/)	sheep bear pig
Contrastive	*neem* (IPA: /nim/)	duck bear pig

3.1.3. Design and procedure

We tested participants using a 2x3 mixed design with *contrastiveness* (within-subjects) and *pitch type* (between-subjects) as independent variables. *Contrastiveness* varied in how the target word was presented during learning, either *contrastive* or *noncontrastive* in relation to a preceding discourse element/referent (see Figure 3 for an example of a

noncontrastive learning condition). The *pitch type* variable consisted of three levels. A novel target word could bear a *simple* monotonal (H*) pitch accent, a *complex* bitonal (L+H*) pitch accent, or a *deaccented* pattern.

In a *contrastive* learning condition, the target word was always presented in opposition to one referent in the preceding discourse element (e.g. *Look! There is a bear and pig over there. Oh! There is a bear and a* ***WUG***$_{contrastive}$ *over there.*). In a *noncontrastive* learning condition, the target novel word was presented as presentationally new in relation to the previous discourse referents (e.g. *Look! There is a bear and pig over there. Oh! There is a sheep and a* ***wug***$_{noncontrastive}$ *over there.*) (See Figure 3). In this condition, the novel target was never presented in contrast to a previous referent.

An experimental condition consisted of a two-part Learning Phase and a Test Phase. The Learning Phase consisted of two 12-trial learning blocks (one *contrastive* and one *noncontrastive*). A distinct novel word was presented in each of these learning blocks. Each block included 4 target trials (where the novel word-animal pairing was presented), 4 distractor trials (where a second unnamed novel animal was presented), and 4 filler trials of familiar animals. The Test Phase consisted of 10 trials: 6 test trials and 4 control trials (See Figures 3 and 4). During a control trial, two familiar animals were presented and the toddler was asked to identify one of the referents. During a test trial, the target novel animal was presented with the distractor novel animal. The *proportion of looking time (PLT) to the target* was collected during the Test Phase to assess whether or not the child learned the novel word-animal pairings. We used the same eye-tracking paradigm as Experiment 1.

Block order and novel animal assignments were counter-balanced across conditions. Test trials were randomized and the location of the target item (left or right) was counter-balanced within and across conditions.

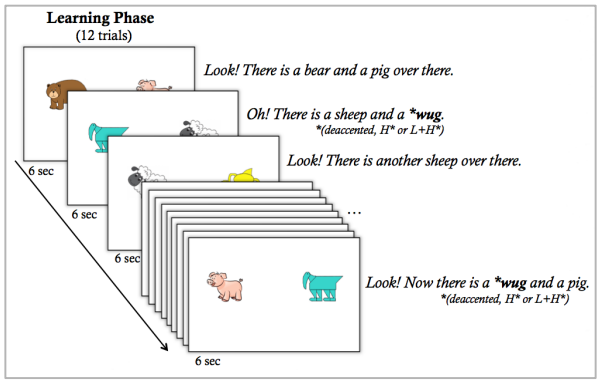

Figure 3: *Example noncontrastive learning phase from Experiment 2. The novel target word 'wug' could bear one of three pitch accent types depending on the condition.*

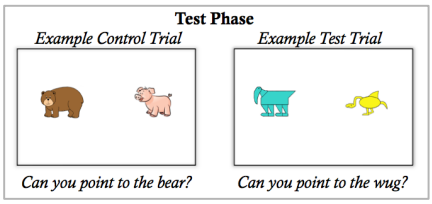

Figure 4*: Example control and test trials from the Test Phase of Experiment 2.*

3.2. Results

Preliminary results exhibit two primary patterns (See Figure 2). The conditions that show substantially more looking to the target novel animal at test are the *contrastive* accented conditions, both *simple* and *complex*. In addition, there is also more looking to the target novel animals in the *noncontrastive-complex* condition.

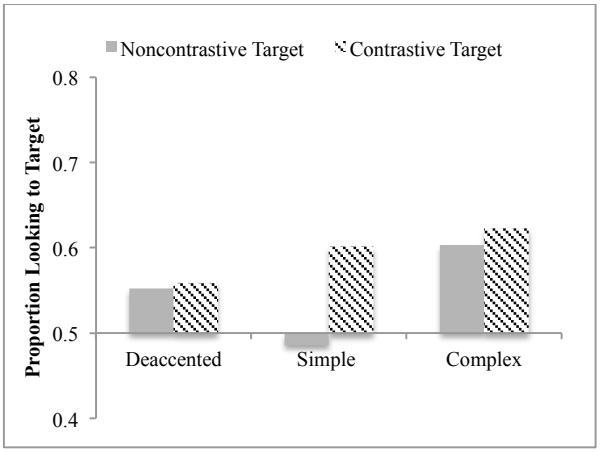

Figure 5: *Bar graph of proportion looking to a contrastive or noncontrastive target novel word referent for each pitch type condition.*

3.3. Discussion

As predicted, the initial pattern of results suggest that contrastiveness, with either a simple or a complex pitch accent, guides more looks to the target novel animal at test. Additionally, the use of a complex pitch accent during the noncontrastive learning situation also directs more looks to the target novel animal than the distractor. These results suggest learning of the novel word-animal association in these conditions, which we predicted to be the most salient during learning. Overall, these data show a preliminary pattern for how intonation and contrastiveness interact to aid in early word learning. Data collection is ongoing.

4. General Discussion

Intonation and information structure both play a role in directing toddler attention and facilitating early word learning. Experiment 1 demonstrates that either newness or the presence of a pitch movement (i.e. only f0 variation) guide 18-month-olds' attention during reference resolution. Future work will test other acoustic correlates of intonation (intensity and duration), and analyze how they interact to guide attention. Preliminary results from Experiment 2 show that contrastiveness and/or a complex pitch accent aid 24-month-olds in learning a novel word. Even with live interactions removed from both methodologies, this set of experiments show the interacting effects of prosody and information structure on attention as well as in successful word learning.

Prominence perception in and out of context

Abstract

The perception of prosodic prominence is known to be influenced by several distinct factors. In this study, we investigated the role of context, both global and local, in the prominence judgements of naïve listeners. Monolingual English listeners marked where they heard prominence on pairs of two-word phrases (e.g. *blue ball*, *green drum*). Stimuli varied in whether or not the first phrase implied a contrastive focus on the second phrase. We found clear evidence of a hierarchy of prominence across pitch accent types: L+H* > H* > !H* > unaccented. Additionally, we found that contrast status only affected prominence markings when the participants were made explicitly aware of the discourse context and were instructed to imagine themselves physically present to observe the conversation. This effect of global context suggests that information structure cannot be reliably interpreted in the absence of an established discourse context. Taken together, these results suggest that naïve listeners are sensitive to prominence differences at levels corresponding to categorical annotations. Perception of a word's relative prominence was consistently influenced by phonetic and phonological factors, while pragmatic factors (such as contrast-evoking context) required more elaborate plausibility manipulations in order to affect prominence perception.

Index Terms: prominence, perception, discourse, focus, contrast

1. Introduction

Intonational phonology assumes a strictly layered hierarchical prominence organization [1]. Words with pitch accent are more prominent than words without pitch accents, and the nuclear pitch accent—in American English, the final one in the utterance—is more prominent than other pitch accents [2]. For the most part, these assumptions have gone largely unchallenged.

Previous studies [3, 4, 5] have shown that the perception of prosodic prominence is based on the listeners' expectations in addition to properties of the signal. For instance, [3] found that information structural considerations, such as anticipating a contrastive focus, can influence perception of prominence such that a semantically or pragmatically salient word can be perceived as prominent even in the absence of acoustic or phonological salience. The scientific goal of this research project is to establish what factors underlie the perception of prominence—factors such as acoustics, phonology, lexico-syntactic phrasing, pragmatic context—and how these factors interact. Additionally, we seek to describe the constraints on the use of these factors predictively in speech comprehension [6].

Several investigations of prosodic prominence have obtained judgements from naïve, untrained listeners in tasks where they are asked to mark prominences on a transcript of aurally presented speech [4, 7, 8, 9, 10, 11]. For longer speech samples, such a task can involve considerable memory load. In the current study, we used a similar metalinguistic judgement task where native speakers of American English were asked to indicate which words in a short phrase sounded prominent. In particular, we examined the role of discourse-level factors and paradigmatic phonological structure in influencing listeners' judgements about which words are prominent.

2. Methods

2.1. Materials

Materials were selected from a ToBI-annotated corpus of spontaneous speech collected from naïve speakers instructing Christmas tree decoration [12]. Twenty-two utterances consisting of adjective-noun combinations, each denoting a particular tree ornament (e.g. red house), were extracted from one female speaker. Utterances either had the pitch accent tune [H* !H*] or [L+H* 0] on the adjective and noun respectively, where 0 represents an unaccented word. The first of these tunes can be considered a 'neutral' prosody, while the second is commonly associated with contrastive focus on the adjective. The stimulus phrases involved eight different adjectives (*beige*, *blue*, *brown*, *clear*, *gray*, *green*, *navy*, and *orange*) and six different nouns (*ball*, *bell*, *candy*, *drum*, *house*, and *onion*).

2.2. Procedure

In each trial, a pair of two-word phrases were displayed on screen (see Figure 1), and after 250ms, the recordings were presented over headphones with 500ms of silence between the two. The participant's task was to highlight, using a button box, which words out of the four on screen sounded prominent. They could highlight as many or as few words as they liked, and there was no time constraint on their choices.[1]

Each pair of utterances was played twice, allowing the participants to double-check their marking before proceeding to the next trial. Each phrase pair either contained a lexically established contrast between first and second utterances (e.g. *blue ball*, *green ball*), and thus an implied contrastive adjective focus on the second adjective, or no contrast (e.g. *red house*, *green ball*). The pitch accent tune types in the first and second utterances were fully crossed, leading to 48 trials. Thus, this offered a total of 192 possible prominence markings, with an equal number of presentations of each pitch accent type; see Table 1.

Additionally, the pragmatic context of the phrases was manipulated between subjects. In the 'monologue' condition, the two phrases were presented one after another, with no intervening material during the 500ms interval. This way, the audio

[1] Participants also completed three other similar tasks; data from these other tasks are not analyzed in the current paper.

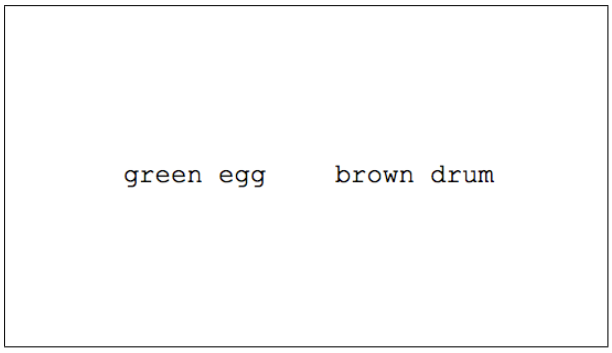

Figure 1: *Example of visual presentation of orthographic representation of stimuli. Once a word was selected as prominent, it turned red.*

sounded like a monologue, a person saying a string of phrases. In the 'plain dialogue' condition, the two phrases were presented with a 'connective' utterance intervening between them. These connectives were extracted from the speech of the male Christmas tree decorator from the same corpus, and consisted of short utterances such as "okay, next", "alrighty, next" and similar. In this condition, there was still a total of 500ms of silence between the first and second phrases.

Finally, the 'narrative dialogue' condition was exactly the same as the plain dialogue condition with the exception of the instructions to the participants. In this condition, participants were made fully aware of the provenance of the recordings and the purpose of the utterances (*viz.*, decorating a Christmas tree). They were presented with a short extract of the conversation between the instructor and the decorator, the visual materials used to elicit speech (see Figure 2), a diagram of the experimental apparatus and procedure, and the physical location the recordings were made. At the beginning of each block, they were instructed to imagine that they were physically present with both participants in the dialogue they heard, and to mark the words that sounded "important to the conversation".

The experiment thereby constituted a 2×2×2×3 fully crossed design, with the relevant factors being pitch accent sequence of the first phrase ([H* !H*] vs [L+H* 0]), pitch accent sequence of the second phrase ([H* !H*] vs [L+H* 0]), contrast status of the pair of phrases (contrastive or non-contrastive), and pragmatic context of the utterances (monologue vs plain dialogue vs narrative dialogue). Pragmatic context was manipulated between subjects; all other factors were within subjects.

2.3. Participants

A total of 125 monolingual speakers of American English participated in the experiment for either partial course credit or a

First phrase		Second phrase	
Adj	Noun	Adj	Noun
[H*	!H*]	[H*	!H*]
[H*	!H*]	[L+H*	0]
[L+H*	0]	[L+H*	0]
[L+H*	0]	[H*	!H*]

$10 payment. 43 participated in the monologue condition, 42 in the plain dialogue condition, and 40 in the narrative dialogue condition.

2.4. Analysis

The results were analyzed using a mixed effect logistic regression model to predict whether or not the *second adjective* (the potentially putatively focused element) was marked as prominent. The model had fixed effects of the pitch accent sequence of the first phrase ([H* !H*] vs [L+H* 0]), pitch accent sequence of the second phrase ([H* !H*] vs [L+H* 0]), contrast status of the pair of phrases (contrastive or non-contrastive), and the condition (monologue vs plain dialogue vs narrative dialogue). All of the fixed effects were coded with sum contrasts, with the exception of condition which used treatment contrasts with the monologue condition as baseline. Additionally, since a number of participants reported during debriefing that they attended to the article *a* at the beginning of some phrases, the presence or absence of the article at the beginning of the first phrase and the second phrase were also added as fixed effects. Additionally, all possible three-way interactions between contrast status, 1st phrase pitch accent sequence, 2nd phrase pitch accent sequence, and condition were included, except for any interactions involving both of the pitch accent sequences.[2] Random intercepts of the second adjective lexical identity, second noun lexical identity, and subject identity were used, and a random slope for contrast status by subject.

In selecting the stimuli, we have relied upon ToBI transcriptions of the target phrases to classify them into groups for analysis. However, different coding systems exist, and it is theoretically possible to achieve different results from the use of different systems. In order to minimize this possibility, we sought independent phonetic evidence for classifying our stimuli, and so each stimulus phrase underwent acoustic analysis. For each phrase, measurements were made on both the adjective and the

[2]For clarity, the interaction term formula, in R-style syntax, was `contrast * condition * (1stpitchaccent + 2ndpitchaccent)`.

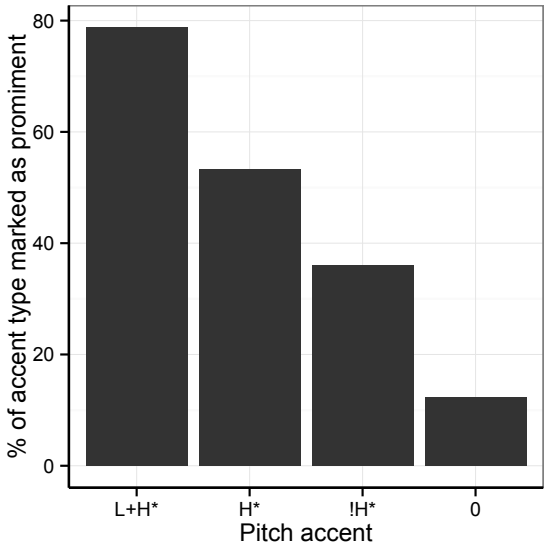

Figure 3: *Percentage of prominence endorsements on each type of pitch accent presented. 0 represents unaccented words.*

noun to extract the word duration, the vowel duration, the peak f0, the mean f0 within the vowel, and two measures of spectral tilt. The spectral tilt measures were the difference between the mean intensity of two different spectral bands, either 2kHz in bandwidth (i.e. 0-2kHz minus 2-4kHz) or 4kHz in bandwidth (i.e. 0-4kHz minus 4-8kHz). Additionally, two relative measures were taken which relate the adjective to the noun: the slope from the adjective peak f0 to the noun peak f0; and the slope from the adjective vowel mean f0 to the noun vowel mean f0. Each of these fourteen acoustic variables was entered as a predictor into a regression tree analysis [13] predicting the pitch accent sequence of the phrase (either [H* !H*] or [L+H* 0]). The resulting tree was pruned to minimize the cross-validation standard error, and of the predictor variables, only the f0 peak of the noun was found to act as a substantial cue to pitch accent. The tree correctly classified the phrases' pitch accent sequences 86.4% of the time (chance: 50%). This cue takes advantage of the relatively large f0 difference between !H* nouns and unaccented noun in our stimuli set. Therefore, with a small degree of error, it is possible to classify a phrase as [L+H* 0] if the noun peak f0 is low, and as [H* !H*] if the noun peak f0 is high.

A second mixed-effects logistic regression model was constructed, identical to the first except with the noun peak f0 measurements in place of the pitch accent transcriptions. This acoustically-based model allowed for a comparison of the phonological transcription with the acoustic details in their ability to account for the observed data. This comparison between the pitch-accent-based model and the acoustics-based model ensured that any observed effects were not simply artifacts of the transcription scheme or idiosyncrasies of the stimuli.

3. Results

Figure 3 depicts the overall prominence marking counts for each kind of pitch accent presented to the participants. This figure collapses over word position and condition; i.e., it depicts all of the prominence markings on all of the words in all of the conditions, split by pitch accent type. As can be seen, the endorsement rates depict a clear hierarchy of prominence, bolstering previous claims that the distinctions between these pitch accents in English (particularly between H* and L+H*) are mainly ones of prominence [14, 15, 16]. We now turn to the modeling results.

Effect	β	z	p
Intercept	0.922	2.228	0.026
PA2	1.676	10.462	< 0.001
Art1	-0.509	-6.220	< 0.001
Art2	0.358	2.232	0.026
Contrast $\times$ PA2	0.499	2.192	0.028
Contrast $\times$ PA2 $\times$ narrative	0.853	2.646	0.008

Table 2: *Summary of significant effects for the pitch-accent-based model. PA2 = pitch accent sequence of the second phrase; Art1 = presence of article in the 1st phrase; Art2 = presence of article in the 2nd phrase.*

The significant fixed effects of the pitch-accent-based model are summarized in Table 2. A significant effect of the pitch accent sequence of the second phrase was observed, such that adjectives with L+H* were more likely to be endorsed as prominent (78.9%) than those with H* (52.8%), as expected given previous research on accent type prominence (e.g. [14]). Two effects of article presence were observed: when the first phrase bore an article, the second adjective was significantly less likely to have a prominence marking (62.4%) than when the first phrase did not have an article (68.5%); similarly, when the second phrase bore an article, the second adjective was more likely to have a prominence marking (70.7%) than when there was no article (59.1%).

Additionally, an interaction between the pitch accent sequence of the 2nd phrase and contrast status was observed. This interaction is depicted in Table 3; when the sequence of phrases led to an implied contrastive focus on the adjective (e.g. *blue ball*, *green ball*), more prominence markings were observed on adjectives with a L+H* pitch accent. Interestingly, this effect of implied contrast was not observed on H* adjectives, suggesting that listeners did not interpret the [H* !H*] phrases with contrastive focus, despite the context.

Finally, and most crucially, a three-way interaction between contrast status, pitch accent, and pragmatic condition was observed. In contrastive contexts in the narrative dialogue condition, more endorsements were observed on L+H* adjectives when compared to the monologue condition. Essentially, the contrast effect for L+H* words (the two-way interaction mentioned in the preceding paragraph) is even stronger in the narrative dialogue condition. Recall that in the narrative dialogue condition, participants were encouraged to imagine themselves actually being present as the conversation took place. This effect is visualized in the right panel of Figure 4; note that in the other conditions, where the participants were not made aware

	H*	L+H*
Non-contrastive	54.1%	75.9%
Contrastive	51.5%	82.0%

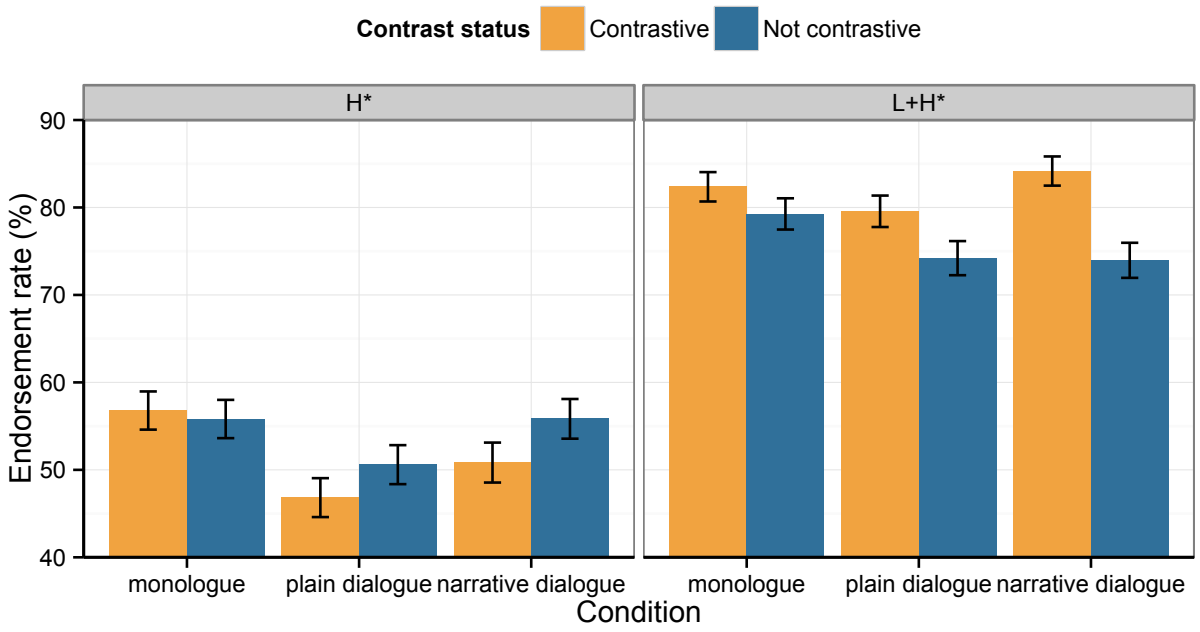

Figure 4: *Percentage of prominence markings on the second adjective of the phrase pair, broken up by pitch accent, pragmatic condition, and contrast status. Bars indicate standard error.*

of the discourse intent, the effect is much smaller.

The results of the acoustics-based model was comparable, in that the narrative dialogue condition sees contrast status effects that are not observed for the other conditions. See Table 4 for a summary of main effects. A likelihood ratio test comparing the two models confirmed that they did not differ in data likelihood ($p > 0.5$).

Effect	β	z	p
Intercept	9.721	8.835	< 0.001
Nf0	-0.040	-8.652	< 0.001
Art1	-0.440	-5.310	< 0.001
Contrast $\times$ Narrative	2.658	2.270	0.023
Contrast $\times$ Nf0 $\times$ Narrative	-0.012	-2.261	0.024

4. Discussion and conclusion

In addition to the expected effect where L+H* adjectives are marked as more prominent than H* adjectives, unexpected effects of article presence on the first and second phrases were observed. The trend in these effects appears to be that an article at the beginning of a phrase makes the adjective appear more prominent. During debriefing, some participants noted that they thought the article signaled "something really important coming up", particularly when it was pronounced as [eɪ]. This intuition is supported by a model of the entire dataset, collapsing across conditions and phrase position, predicting prominence marking based on article presence and word class. The model revealed that in phrases that follow an article, adjectives are more likely to be marked as prominent ($\beta = 0.994$, $z = 16.884$, $p < 0.001$), while nouns are less likely to be marked ($\beta = -1.072$, $z = -13.859$, $p < 0.001$).

The pitch accent prominence hierarchy depicted in Figure 3 is particularly striking. However, care must be taken in its interpretation, since in this study all of the L+H*s and H*s were associated with phrase-initial adjectives, and all of the !H*s and unaccented words were phrase-final nouns. Nevertheless, our findings are consistent with the expected patterns of prominence in American English (e.g. [17]). The consistency of these findings also illustrate the fact that prominence is indicated in the same locations by the ToBI annotators of these stimuli, by our naïve participants, and by the results of the acoustic analysis.

Finally, our main result is an effect of discourse context evoked by elaborately illustrated task instructions. Only when participants were made fully aware of the intent of the discourse and instructed to imagine themselves as being physically present in the conversation was an effect of contrast status observed. This is to say, only when participants are able to construct a common ground with the interlocutors does their prominence perception reflect information-structural concerns. Prosodic prominence on its own can be perceived in extremely impoverished contexts (the monologue condition), but the information-structural notion of contrast requires an established discourse context before perception and interpretation is possible.
