Social and Linguistic Speech Prosody

1 Frontmatter/Preface

1.1 Statistics by Country (showing number of authors)

Authors from 45 countries sent in submissions to Speech Prosody 2014
5 countries didn't make it - we hope they'll try again for SP8!

1.2 Accepted authors by country:

Algeria	1
Australia	6
Austria	1
Bangladesh	1
Belgium	6
Brazil	17
Canada	12
China	16
Costa Rica	1
Czech Republic	7
Denmark	1
Estonia	9
European Union	281
Finland	8
France	59
Germany	70
Hong Kong	6
Hungary	26
India	4
Iran	1
Ireland	12
Israel	3
Italy	15
Japan	29
Mexico	1
Netherlands	16
Norway	1
Poland	8
Portugal	6
Qatar	1
Russian Federation	2
Saudi Arabia	1
Slovakia	3
South Africa	2
Spain	18
Swaziland	1
Sweden	7
Switzerland	12
Taiwan	7
UK	25
USA	76

1.3 Acceptance rates:

We have seen a 35% increase in acceptances since Speech Prosody in Nara, 10 years ago, and a 68% increase in submissions.

2004 (in Nara): 164/180; 29 oral and 135 poster
2014 (in Dublin): 222/303; 42 oral and 180 poster

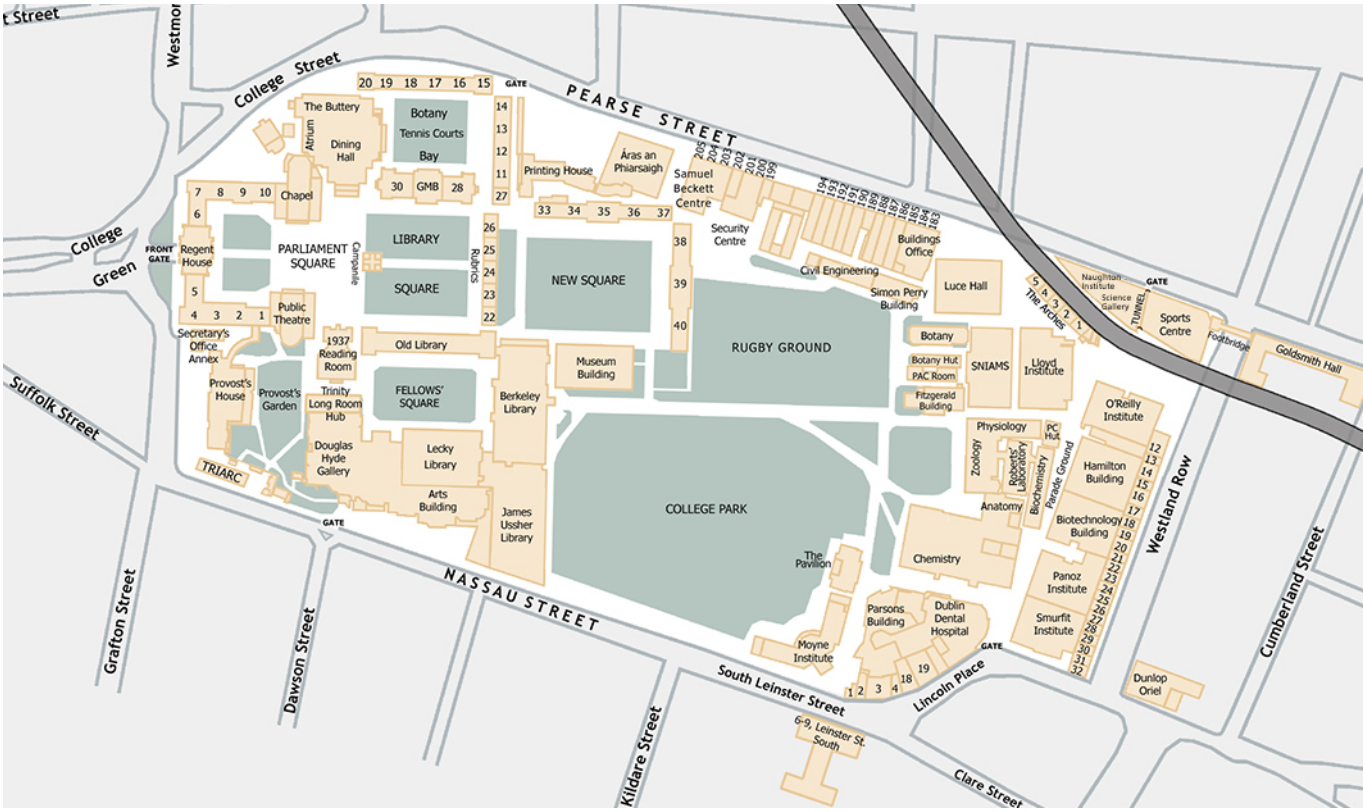
2004: 91% acceptance rate
2014: 73% acceptance rate

2004: 21% oral/poster ratio
2014: 23% oral/poster ratio

altogether 480 authors and 4 keynote speakers are represented at SP7

Speech Prosody - brought to you in Dublin by the Pros Bros!

(photo courtesy of Jolanta Bachan, Brighton 2012)



Finding us!

Speech Prosody 2014 will be hosted in the 'Ed Burke' Theatre, deep in the Arts Building of Trinity College Dublin (*the* University of Dublin ;-)

Trinity College is an academic island of quiet history right in the centre of Dublin City (the Aircoach stops just outside) and the Arts Building has an entrance in Nassau Street, facing Dawson Street but it is much nicer to enter from Fellows' Square (through Front Gate) and enjoy the old College

(please don't forget to visit the Long Room (Old Library) while you are here ;-)

and actually, while you're here, the Chester Beatty Library in Dublin Castle is also well worth a visit

and while we're on the subject of libraries, Marsh's Library is offering a great exhibition on Japan!

. . . . . but this is all for Saturday - we hope you'll be with us full-time until then . . .

An essay on 'ProsBros' (1st version, DG)

'ProsBros', alternatively 'Pros-Bros', 'Pros Bros' … what's that? By induction from context and some help from Monty Python, you will have concluded that 'ProsBros' is the name of a set:

ProsBros = {Nick, Daniel, Dafydd}

That's it, a nickname for the three of us. (Why NICKname, by the way? Not fair.) So why 'ProsBros'? Analogical thinking will no doubt yield the tentative hypothesis that 'Pros' is an abbreviation for 'prosody'. Well done, correct! But 'Bros'? Analogical thinking may lead you to think that it is the plural of 'Bro', which is an abbreviation of 'brother', almost correct, though as you will see it is actually a direct abbreviation for 'brothers'. Now, having clarified the extensional semantics and the morphology, the intensional semantics, pragmatics and phonetics remain to be clarified.

First, semantics. Yes, we wrote our dissertations on prosody (Daniel and Dafydd on intonation, Nick on timing), and have since continued to work in the field, with occasional deviations (the most deviant being Dafydd). Yes, we have all worked with computational phonetic tools, yes, we have all worked extensively with speech corpora (the most well-known being Dan's), yes, we have all worked with speech synthesis (most of all, Nick).

Second, pragmatics. Yes, we are roughly the same generation. Yes we have been friends for decades. We are three expat Brits (hence the undeniable influence of Monty Python on this note) who have each worked mainly on other languages than English: Nick on Japanese, Dan on French, and Dafydd on German (and a collection of African and Asian languages). We have been heavily involved in creating and supporting international infrastructures in these fields: Speech Prosody, COCOSDA, international project consortia. Ironically, we have been often been vicarious representatives of these speech communities in committees and conferences: "What is the Japanese perspective on this, er, Nick?" ... "What is the French perspective on this, er, Dan?" ... "What is the German perspective on this, er, Dafydd?"

Third, phonetics. Yes this one of the main areas in which we work. Now note that 'Pros' and 'Bros' could both rhyme with 'Oz', 'boss', 'rose' or 'gross', yielding 16 possible combinations. Following Occam's Razor, we reject 'rose' and 'gross' as too complex (alternatively: too emotional), leaving 4 combinations, and to restrict the search space we propose a new markedness constraint 'Disyllabic Nickname Rhyme Harmony' (*DNRH) in Optimal Nickname Theory:

**XAYB*, where onset(*X*), onset(*Y*), rhyme(*A*), rhyme(*B*), for *A*≠*B*

The *DNRHC permits only [prɔsbrɔs] and [prɔzbrɔz] (ignoring other segmental details). Controversially, in acknowledgment of a plethora of languages with final devoicing, [prɔsbrɔs] is marginally preferred to [prɔzbrɔz], and together with the English Compound Stress Rule, ['prɔsbrɔs] emerges as the favoured pronunciation, though ['prɔzbrɔz] is a close second.

However, the selection is finally clinched by further analogical thinking, which will initially only be accessible to Brits. So a little cultural history: in 1898 the legendary sartorial hire business 'Moss Bros', well known throughout the UK and beyond, was established in London by the brothers Alfred and George Moss, who deserve the Noble Prize [sic] for achieving the remarkable goal of ensuring that businessmen worldwide (and some businesswomen) wear the same style of suit, shirt and tie. No, we do not normally wear these suits, shirts and ties, but we were strongly influenced by the name of the business (and, as noted above, by Monty Python).

Now the gentle reader may wish to face the challenge of a final exercise in induction and analogical thinking: How is 'Moss Bros' pronounced?

Programme

Speech Prosody - a brief history

(according to the pros bros)

The first international meeting on Speech Prosody that we know of was a three-day seminar on Intonation and Discourse organised by the British Association for Applied Linguistics in Birmingham in April 1982. Strangely enough, the second meeting was held just two weeks later in Paris: a workshop on Prosody organised by the European Association for Psycholinguistics. This was soon followed by a Working Group on Intonation that was a satellite event preceding the 13th International Congress of Linguists in Tokyo.

And then, after that, nothing for more than ten years...

Before the next prosody meeting, the 12th ICPhS meeting was held in Aix-en-Provence in August 1991 where we were struck by the large number of papers on the topic of Speech Prosody - more than 20% of the papers which were directly related to this topic and the small room assigned was overflowing into the corridors! Dan asked Mario Rossi, the conference chairman, to announce an ad-hoc meeting before one of the plenary sessions and over 100 people turned up, no doubt wondering what to expect. As it happened we had no more idea than they did but among suggestions made then were: setting up an international organisation - organising conferences on prosody - and setting up a prosody mailing list.

George Allen volunteered to set up an email list for prosody and this list was a valuable resource for many years, although the fact that it included both literary prosody (versification) and speech prosody was slightly confusing for some people. There would be a flurry of engineers signing off the list after a posting on mediaeval versification, followed by an equally urgent flurry of linguists quitting the prosody ship after an engineer had posted something on hidden Markov models for speech recognition. We eventually decided to replace the list by one specifically devoted to Speech Prosody.

In the years following this meeting, ICSLP (International Conference on Spoken Language Processing) and ESCA (European Speech Communication Organisation) organised some more workshops on prosody (Lund 1993, Yokohama 1994, Athens 1995, Kraków 1999) and workshops on prosody also became a regular feature of the ICPhS meetings (Stockholm 1995, San Francisco 1999). Despite this welcome increase in the number of meetings, there was still something missing. From one meeting to the next there was no way of telling when or where the next meeting would be held. Each meeting was organised as a separate event with no co-ordination. This made it hard for potential participants to plan to present a paper on prosody. It was particularly true for doctoral students, who had no way of knowing if there would be an appropriate meeting somewhere where they could present their research before the end of their thesis preparation.

In September 1999, ESCA and ICSLP agreed to combine and were renamed ISCA (International Speech Communication Association) and the new organisation soon set up Special Interest Groups to promote research on specific topics of speech communication or for specific languages. With the wider availability of internet, it was now quite easy to contact a large number of specialists on Speech Prosody, asking if they would agree to support the creation of a Special Interest Group on Speech Prosody (SPròSIG). The response was enthusiastic - 72 established researchers in the field from 23 different countries agreed to support the SIG and in January 2000 the group was recognised by ISCA.

The 'Prosody 2000' Kraków meeting, chaired by Wiktor Jassem, was a kind of Proto-Speech Prosody, actually a combination of two workshops - one on Speech Recognition and Synthesis, organised by our prosody sister Grazyna Demenko with the help of Dafydd Gibbon, and one on Prosodic Transcription and Modelling organised by Esther Grabe, Kai Alter and Hansjörg Mixdorff.

The ISCA/SPròSIG event, the First International Conference on Speech Prosody, Aix-en-Provence, April 3 2002 chaired by Daniel Hirst, was a success with 152 submitted papers plus 6 invited keynote speakers, 12 invited co-speakers. It was attended by 317 people. Of course the question everybody asked was: would it last? The list of Speech Prosody meetings speaks for itself: 2004 Nara Japan, 2006 Dresden Germany 2008, Campinas Brazil, 2010 Chicago USA, 2012 Shanghai China, 2014 Dublin, Ireland; and the next will be in 2016 - but where ???

A modification of the constitution of SPròSIG in 2010 added a Permanent Advisory Committee, consisting of the founder officers of SPròSIG (Daniel Hirst, Nick Campbell, Bernard Bel), the current elected officers (currently Keikichi Hirose, Yi Xu, Mark Hasegawa-Johnson, Hansjorg Mixdorff) as well as the chair and co-chair of the last 5 conferences.

At the last meeting in Shanghai (2012), the PAC decided to nominate Hiroya Fujisaki as Honorary Life Member of the PAC. The 2011 board meeting of the International Phonetic Association resolved to co-sponsor the Speech Prosody Special Interest Group - this resolution was adopted formally in October 2012. The Speech Prosody SIG is, consequently, now officially affiliated with both ISCA and IPA.

Speech Prosody is too serious a matter to be left in the hands of just engineers... ... or just linguists. We really need each other, and Speech Prosody is a way to bring us all together!

Daily Event Programme

Speech Prosody will feature 222 papers in plenary oral and poster format: there will be 4 invited keynotes each followed by 3 oral presentations on a related theme, and 3 oral thematic sessions of 6 papers each. Each day will have a poster session and posters can remain in place throughout the day. There is no distinction in rank between an oral and a poster presentation. There will be 2 special sessions, a Round Table, and a Panel Discussion, with a special commemoration of Prof Miyoko Sugito, the honorary co-chair of Speech Prosody 2004, to remember her contributions to our field. Lunch will be provided each day.

Day-1.1 Tuesday May 20th, 1:30pm - 2pm : Opening (3 bros:-welcome!)
Day-1.2 Tuesday May 20th, 2pm - 3:30pm : plenary (1+3 oral) Invited Keynote
Day-1.3 Tuesday May 20th, 4pm - 5:30pm : special (Booster & Round Table)
Day-1.4 Tuesday May 20th, 5:30pm - 6pm : SSSpASSS (20 Special Session posters)
Day-1.5 Tuesday May 20th, 6pm - 7:30pm : (28 Posters with **WELCOME RECEPTION**)

Day-2.1 Wednesday May 21st, 9am - 10:30am : plenary (1+3 oral) Invited Keynote
Day-2.2 Wednesday May 21st, 11am - 1pm : (6 oral) - Speech Rhythm and Timing
Day-2.3 Wednesday May 21st, 2pm - 4pm : special session - Slavic Prosody
Day-2.4 Wednesday May 21st, 4:30pm - 6pm : (48 posters) Perception and Intonation
Day-2.5 Wednesday - evening - **Reviewers' Reception** in Trinity College Long Room

Day-3.1 Thursday May 22nd, 9am - 10:30am : 3-1-plenary (1+3 oral) Invited Keynote
Day-3.2 Thursday May 22nd, 11am - 1pm : (48 posters) Theoretical and Linguistic Prosody
Day-3.3 Thursday May 22nd, 2pm - 3:30pm : Panel Session & memorial
Day-3.4 Thursday May 22nd, 4pm - 6pm : (6 oral) Perception and Production
Day-3.5 Thursday May 22nd, 7pm - 9:30pm : **BANQUET - Old Dining Hall** - *ALL WELCOME!*

Day-4.1 Friday May 23rd, 9am - 10:30am : (48 posters) Intonation and Speaking Style
Day-4.2 Friday May 23rd, 11am - 1pm : (6 oral) Intonation - general
Day-4.3 Friday May 23rd, 2pm - 3:30pm : plenary (1+3 oral) Invited Keynote
Day-4.4 Friday May 23rd, 3:30pm - 4pm : closing

Day-5 Saturday May 24th, **FREE DAY**

Day One

Tuesday May 20th, 1:30pm - 2pm : Opening (welcome to Speech Prosody!)

Tuesday May 20th, 2pm - 3:30pm : plenary (1+3 oral presentations) (p.1)

Invited Keynote: Fred Cummins - followed by 3 oral presentations
Chair: Ailbhe Ní Chasaide

Coffee break - 3:30 - 4pm

Tuesday May 20th, 4pm - 5:30pm : (Booster & Round Table) (p.2)

SSSpASSS: Special Session: **Social prosody: Affective Social Speech Signals**
Chair: Véronique Aubergé
Véronique and team to introduce SSSpASSS posters (booster: 2-min per paper) with Round Table discussion to follow, then posters in the exhibition space with welcome reception

Tuesday May 20th, 5:30pm - 6pm : SSSpASSS Posters) (p.2)

Chair: Gu Wentao

Tuesday May 20th, 6pm - 7:30pm : - Prominence & Phrasing - (28 posters) (p.7)

Chair: Juraj Šimko

Day Two

Wednesday May 21st, 9am - 10:30am : plenary (1+3 presentations) (p.15)

Invited Keynote: Stefanie Shattuck-Hufnagel - followed by 3 oral presentations
Chair: Julia Hirschberg

Coffee break - 10:30 - 11am

Wednesday May 21st, 11am - 1pm : oral (6 presentations) (p.16)

- Speech Rhythm and Timing - Chair: Amalia Arvaniti

Lunch break - 1 - 2pm (lunch provided)

Wednesday May 21st, 2pm - 4pm : special session - Slavic Prosody (p.18)

special session - Slavic Prosody (another SP!) Chairs: Zofia Malisz & Marzena Żygis

Coffee break - 4:00 - 4:30pm

Wednesday May 21st, 4:30pm - 6pm : poster (48 presentations) (p.19)

- Perception and Intonation - Chair: Oliver Jokisch

evening - Reviewers' Reception in Trinity College Long Room (by invitation)

Day Three

Thursday May 22nd, 9am - 10:30am : plenary (1+3 presentations) (p.31)

Invited Keynote: Jürgen Trouvain followed by 3 oral presentations
Chair: Nigel Ward

Coffee break - 10:30 - 11am

Thursday May 22nd, 11am - 1pm : poster (48 presentations) (p.32)

- Theoretical and Linguistic Prosody - Chair: Alice Turk

Lunch break - 1 - 2pm (lunch provided)

Thursday May 22nd, 2pm - 2:30pm : Remembering Sugito Miyoko (p.44)

Chair: Sadanobu Toshiyuki

Thursday May 22nd, 2:30pm - 3:30pm : Terminology in Prosody Research (p.44)

Chair: Fujisaki Hiroya

Coffee break - 3:30 - 4pm

Thursday May 22nd, 4pm - 6pm : oral (6 presentations)

- Perception and Production - Chair: Agnieszka Wagner

Thursday May 22nd, 7pm - 9:30pm : BANQUET - Old Dining Hall - ALL WELCOME!

Day Four

Friday May 23rd, 9am - 10:30am : poster (48 presentations) (p.46)

- intonation and speaking style - Chair: Laura Dilley

Coffee break - 10:30 - 11am

Friday May 23rd, 11am - 1pm : oral (6 presentations) (p.59)

- Intonation - Chair: Hansjörg Mixdorff

Lunch break - 1 - 2pm (lunch provided)

Friday May 23rd, 2pm - 3:30pm : plenary (1+3 presentations) (p.61)

Invited Keynote: Anne Cutler - followed by 3 oral presentations
Chair: Chiu Yu Tseng

Friday May 23rd, 3:30pm - 4pm : closing

Saturday May 24th, Free Day - go explore Dublin!!!

The Authors index

(sorted by given name - for an index sorted by family name see the Author index at the end of the proceedings (p.1180))

Page numbers refer to the abstract entry where a link can be found to the full paper.

Abstracts

1 Day One - May 20th

Tuesday - Opening Session

1:30pm - 2pm : 1-0-opening (3 bros:welcome!etc)

1.1 Tuesday Session One

2pm - 3:30pm : 1-1-plenary (1+3 presentations)

1.1.1 KeyNote 1

Fred Cummins - 30-min
From Prayer to Protest: An Initial Look at Joint Speech
Joint speech is an umbrella term covering choral speech, synchronous speech, chant, and all forms of speech where many people say the same thing at the same time. Prosodists, more than most, should be aware of the incompleteness of a structuralist description of language. Much of our use of language is ignored or missed when linguistic behaviour is viewed through the narrow lens of phonological/syntactic structure. I will discuss Joint Speech, as found in prayer, protest, classrooms, and sports stadia around the world. Despite its deep embedding in practices we value very much, joint speech has not hitherto attracted the attention of scientists as a distinct form of language behavior, because it is uninteresting from a structuralist point of view. If we merely take the time to look, however, there is much to be found in joint speech that is crying out for elaboration and investigation. I will attempt to sketch the terra incognita that opens up and present a few initial findings (phonetic, anthropological, neuroscientific) that suggest that Joint Speech is far from being a peripheral and exotic special case. It is, rather, a central example of language use that must inform our theories of what language and languaging are.

1.1.2 p.65

Zhihua Xia, Rivka Levitan, Julia Hirschberg,
Prosodic Entrainment in Mandarin Chinese and English: A Cross-Linguistic Comparison
Entrainment is the propensity of speakers to begin behaving like one another in conversation. We identify evidence of entrainment in a number of acoustic and prosodic dimensions in conversational speech of American English speakers and Mandarin Chinese speakers. We compare entrainment in the Columbia Games corpus and the Tongji Games Corpus and find some remarkable similarities between the two.

1.1.3 p.70

Rob Voigt, Robert J. Podesva, Dan Jurafsky,
Speaker Movement Correlates with Prosodic Indicators of Engagement
Recent research on multimodal prosody has begun to identify associations between discrete body movements and categorical acoustic prosodic events such as pitch accents and boundaries. We propose to generalize this work to understand more about continuous prosodic phenomena distributed over a phrase - like those indicative of speaker engagement - and how they covary with bodily movements. We introduce movement amplitude, a new vision-based metric for estimating continuous body movements over time from video by quantifying frame-to-frame visual changes. Application of this automatic metric to a collection of video monologues demonstrates that speakers move more during phrases in which their pitch and intensity are higher and more variable. These findings offer further evidence for the relationship between acoustic and visual prosody, and suggest a previously unreported quantitative connection between raw bodily movement and speaker engagement.

1.1.4 p.75

Štefan Beňuš, Marián Trnka,
Prosody, voice assimilation, and conversational fillers
Conversational fillers (CFs), commonly transcribed as uh, um, or er, typically start with a schwa-like vowel, and signal multiple social, interactive, meta-cognitive, and pragmatic functions. They also co-occur with prosodic boundaries, increase saliency of inter-word disjunctures, and participate thus in coding the prosodic structure. Contrary to these functions, CFs are assumed not to participate in the phonological system of a language. This paper uses two types of Slovak conversational speech corpora for investigating the the prosodic and phonological behavior of CFs. In Slovak, the vowel inventory does not include a schwa, and word-final obstruents undergo voice assimilation that is triggered by word-initial vowels but interacts with the strength of the prosodic boundary between the two words. Our data show the propensity of CFs to neutralize word-final voicing, and function thus as prosodic breaks, but also non-negligible number of cases of CFs triggering voicing of word-final obstruents, supporting their relevance for cognitive phonology.

1.2 Tuesday Special Session - SSSpASSS

4pm - 5:30pm : Booster & Round Table

Special Session: Social Prosody: **Affective Social Speech Signals**

Véronique and team to introduce SSSpASSS posters (booster: 2-min per paper) with Round Table then poster session to follow after break (posters with Welcome Reception)

5:30pm - 6pm : (20 poster presentations)

Tuesday Session Two - SSSpASSS Posters

1.2.1 p.81

Marta Maffia, Elisa Pellegrino, Massimo Pettorino,
Labeling expressive speech in L2 Italian: the role of prosody in auto-and external annotation
The present study is intended to compare two approaches of labeling expressive corpora: auto-annotation and annotation by external lay listeners. These two methods have been applied to the semi-spontaneous emotional speech produced by Chinese learners of L2 Italian, involved in the CardTask, a mood-induction procedure that permits to control the context of interaction, preserving the spontaneity of reactions. The emotional responses to the stimuli presented in the task were object of an auto-annotation session. The same samples were then administered only in the auditory mode to 20 Italian and 20 Chinese lay listeners. The results of perceptual tests have underlined some similarities and differences both between auto- and external annotation, and between the rates given by Italian and Chinese external listeners. The labels chosen by native Italians were similar to those selected in the auto-annotation session, particularly in the case of anxiety, fear and disgust. The correspondence between the results of the two annotation methods may be ascribed to the different prosodic patterns characterizing the emotional states. The results of the annotation made by Chinese listeners show that they found it hard to give a specific emotional label to utterances produced in a second language relying only on prosodic patterns.

1.2.2 p.86

Yuko Sasa, Véronique Aubergé,
Socio-affective interactions between a companion robot and elderly in a Smart Home context: prosody as the main vector of the "socio-affective glue"
The aim of this preliminary study of feasibility is to give a glance at interactions in a Smart Home prototype between the elderly and a companion robot that is having some socio-affective language primitives as the only vector of communication. Through a Wizard of Oz platform (EmOz), a robot is introduced as an intermediary between the technological environment and some elderly who have to give vocal commands to the robot to control the Smart Home. The robot vocal productions increases progressively by adding prosodic levels: (1) no speech, (2) pure prosodic mouth noises supposed to be the "glue's" tools, (3) lexicons with supposed "glue" prosody and (4) subject's commands imitations with supposed "glue" prosody. The elderly subjects' speech behaviors confirm the hypothesis that the socio-affective "glue"

effect increase towards the prosodic levels, especially for socio-isolated people.

Towards Automatic Recognition of Attitudes: Prosodic Analysis of Video Blogs
Understanding of speakers' attitude is essential for establishing successful human interaction. In this paper we analyse attitude manifestations in video blogs. We describe the main features of this novel communication medium and focus our attention on its possible exploitation as a rich source of information for human-human and human-machine communication. We describe the manual annotation of attitudes and the prosodic analyses. Finally we present a preliminary attitude automatic annotation system that attains 65% accuracy.

Processing emotional prosody in Mandarin Chinese: A cross-language comparison
To understand how emotional prosody is processed in Mandarin Chinese and whether it differs from that of other languages, we conducted a perceptual-acoustic study on a set of Chinese vocal emotional stimuli and examined how they were perceived and acoustically characterized, in comparison with four other languages, English, Arabic, German, and Hindi, reported by Pell et al. [1]. Chinese pseudo-utterances spoken in seven emotions (anger, disgust, fear, sadness, happiness, pleasant surprise, and neutrality) were first identified by a group of native Mandarin speakers in a seven forced choice task, and then subjected to acoustic analyses. Results revealed that among the seven emotions, neutrality, anger, sadness, and fear tended to be recognized most accurately. Acoustic analysis demonstrated the importance of three acoustic parameters (f0 mean, f0 range, and speech rate) in characterizing vocal emotions in Mandarin. Both the perceptual and acoustic characteristics are highly similar, although not identical, to that observed by Pell et al. [1] in English, Arabic, German, and Hindi, indicating a set of universal principles in vocal emotion communication across languages.

Acoustic-prosodic and paralinguistic analyses of "uun" and "unun"
The speaking style of an interjection contains discriminative features on its expressed intention, attitude or emotion. In the present work, we analyzed acoustic-prosodic features and the paralinguistic functions of two variations of the interjection "un", a lengthened pattern "uun" and a repeated pattern "unun", which are often found in Japanese conversational speech. Analysis results indicate that there are differences in the paralinguistic function expressed by "uun" and "unun", as well as different trends on F0 contour types according to the conveyed paralinguistic information.

Speaking style prosodic variation: an 8-hour 9-style corpus study
This paper presents the results of a prosodic and phonostylistic analysis based on C-PhonoGenre, a 9-hour-long spoken French corpus, including 10 speakers on average recorded in 10 speaking situations. The corpus was automatically segmented at phonetic, syllabic, word levels (EasyAlign), and larger pause-separated units. Part-of-speech annotation (DisMo) and prominent syllable detection (ProsoProm) was added automatically. The corpus was also manually annotated at the syllabic level for stylistic variants, such as post-tonic schwas, liaisons, elisions, disfluencies, audible breaths and noises. Acoustic analyses (ProsoReport, DurationAnalyser) provide more than 100 micro- and macro-prosodic measures, which we correlate with the phonostylistic and linguistic annotation. This analysis finally yields a contrastive, fine-grained prosometric description of phonostylistic and situational variation, over 4 situational gradual dimensions: audience, media, preparation, and interactivity. Further statistical analysis was carried out to explore the discriminative and explanatory power of combinations of prosodic measures.

Certainty and uncertainty in Brazilian Portuguese: methodology of spontaneous corpus collection and data analysis
This work presents a methodology used to collect some spontaneous social affect corpus and preliminary prosodic analysis of certainty and uncertainty in Brazilian Portuguese. The corpus was collected by a Wizard of Oz (Emoz)method, the scenario to induce certainty and uncertainty is based on the situation of a job interview, for which a companion robot (Emox) is supposed to be a trainer. The subjects were convinced to benefit of a free training of this "revolutionary" method to train to job interview. In this scenario the linguistic expressions are partially controlled, in order to focus the certainty/uncertainty expression mainly on paraphrasing and prosody. Data were preliminary analyzed for audiovisual prosody: videos analysis were made regarding eyes, mouth and face/head movements, while audio analysis were made about acoustic prosody parameters of fundamental frequency and duration. The first results show that using Emoz within such a scenario is an efficient way to induct spontaneous but comparable speech production. Prosodic results show that fundamental frequency and duration measurements, as well as eyes, mouth and face/head movements, are differently used in certainty and in uncertainty production in Brazilian Portuguese.

Between Recognition and Resignation The Prosodic Forms and Communicative Functions of the Czech Confirmation Tag "jasně"
Like question tags, confirmation tags such as the Czech affirmative particle jasně can be used with various prosodic characteristics that augment, reverse or otherwise modify their relatively unspecific lexical meaning. We extracted 172 instances of jasně from several dialogues and assessed their discourse function. 36 prosodic correlates in temporal, amplitude and fundamental frequency domains were measured and used in three computational classifiers: linear discriminant analysis, classification trees and artificial neural networks. All three methods significantly reflected the functional assessments and additionally indicated the relative importance of individual predictors in a mutually consistent manner.

Automatic Analysis of Emotional Prosody in Mandarin Chinese:Applying the Momel Algorithm
Based on the Momel algorithm, a set of acoustic parameters was analyzed automatically on Chinese emotional speech. Global prosodic features were calculated on the sentence level, which showed a concordance with the usual pattern reported in the literature. Local constraints were also considered on the syllable layer. An ANOVA showed that there were interactive effects among emotions, syllable positions and syllable tones on certain parameters. Further more, by examining the pitch movements, no significant difference was found between neutral speech and active emotional speech, which was different from the performance in non-tonal languages. However when reducing the tonal influence by using only tone 1 syllables in the utterance, this inverse effect disappeared. Hence we posited an interpretation that due to the existence of lexical tone in Mandarin Chinese, the paralinguistic use of pitch movements has been reduced.

Prosodic Profiles of Social Affects in Mandarin Chinese
An acted corpus of 19 prosodic social affects is devoted to this work, which investigates the production side of prosodic attitudes in Mandarin Chinese, with the aim of extracting the more prominent patterns of acoustical variations. Results are then compared to previous perception data obtained on the same expressions. The F0, intensity and duration characteristics of 76 utterances conveying 19 prosodic attitudes are statistically examined in this study. All attitudes are regrouped into 5 clusters according to their prosodic features. The result of the statistical analysis shows that the prominent differentiation between clusters is mostly related to F0 and duration parameters; some similarities are noted between the clustering of attitudes from acoustic features and from perceptual confusions obtained in previous

experiments; inside each cluster, some attitudes show typical characteristics in F0 and duration.

Prosodic cues for emotion: analysis with discrete characterization of intonation
In this paper we study the relationship between acted perceptually unambiguous emotion and prosody. Unlike most contemporary approaches which base the analysis of emotion in voice solely on continuous features extracted automatically from the acoustic signal, we analyze the predictive power of discrete characterizations of intonations in the ToBI framework. The goal of our work is to test if particular discrete prosodic events provide significant discriminative power for emotion recognition. Our experiments provide strong evidence that patterns in breaks, boundary tones and type of pitch accent are highly informative of the emotional content of speech. We also present results from automatic prediction of emotion based on ToBI-derived features and compare their prediction power with state-of-the-art bag-of-frame acoustic features. Our results indicate their similar performance in the sentence-dependent emotion prediction tasks, while acoustic features are more robust for the sentence-independent tasks. Finally, we combine ToBI features and acoustic features together and further achieve modest improvements in sentence-independent emotion prediction, particularly in differentiating fear and neutral from other emotion.

Massimo Pettorino, Elisa Pellegrino, Marta Maffia,
"Young" and "Old" Voice: the prosodic auto-transplantation technique for speaker's age recognition
The present study is intended to figure out the extent to which prosody and intonation entail listeners' ability to estimate the speaker's age. The performance of a 40-year old anchorman and that produced by the same speaker at the age of 80 were spectro-acoustically analyzed in order to identify the prosodic features of the "young" and the "old" voice. The results of the analyses have shown relevant differences between the two voices on suprasegmental level. To test the effects of these differences on perceptual level, through the prosodic transplantation technique, the F0 values and the durations of segments and silences were transferred from the "young" to the "old" voice and viceversa. Two age recognition tests, based on original and transplanted voices, were administered to Italian listeners. The results of perceptual tests have confirmed the strict relationship between some rhythmic and prosodic features and the speaker's age and have demonstrated the effectiveness of the transplantation technique. With advancing age, articulation rate and speech rate slow down, voice register raises and tonal range widens. Moreover, the "old" voice is also characterized by a higher percentage of vocalic portion that determines a shift of Italian rhythm towards the isomoraic pattern

Expressive prosody vs neutral prosody : From descriptive binary to continuous features
In this paper, we propose to compare expressive and neutral oral renditions of a children's tale in french by examining the segmentations performed by twelve high level french readers. We used a software dedicated to this kind of analysis (Analor) which takes into account different parameters (pause, pitch gesture, pitch jump) and their relative strength to determine pertinent prosodic units (phrases). The extraction of these phrases and their features enables us to observe the influence of both the type of oralisation (expressive or neutral) and punctuation signs on the organization of speech flow. Results show that prosodic phrases in the expressive readings are more numerous (specially at comma locations), that their boundaries are more clearly demarcated, and that they have more varied contours than those in neutral readings.

Challenges for Robust Prosody-based Affect Recognition
Prosody-based affect recognition has great potential impact for building adaptive speech interfaces. For example, in intelligent systems for personalized learning, sensing a student's level of certainty, which is

often signaled prosodically, is one of the most interesting states to interpret and respond to. However, robust uncertainty recognition faces several challenges, including the lack of gold-standard labels, and differences in expressivity among speakers. In this paper we explore the intersection of these two issues. We have collected a corpus of spontaneous speech in a question-answering task. Three kinds of certainty labels are associated with each utterance. First, speakers rated their own level of certainty. Second, a panel of listeners rated how certain the speaker sounded. Third, an externally crowdsourced difficulty score is generated for each stimulus (the question). We present an analysis of the prosodic characteristics of individual speaking styles, as they relate to these three different measurements of certainty.

Prosodic analysis of spoken Japanese attitudes
The aim of this paper is to provide cues for prosodic characterization of attitudes in Japanese. This is comparable with similar researches made on others languages (e.g. American english, Brazilian portuguese, etc.). The presented work focuses on an objective analysis results of the Japanese based on the audio signal structure. In the proposed experiments, the speech signal of several Japanese native speakers is analyzed, The used signals were recorded in a particular context where the corresponding attitude is clearly identified and segmented. The presented results are based on a previous study where 16 attitudes were defined to describe the emotional content of human spoken language. Thus we compare the signal properties which can characterize each attitude.

Noam Amir, Eitan Globerson,
On the Role of Pitch in Perception of Emotional Speech
Two experiments investigated the role of intonation in perception of basic emotions. In the first experiment, pitch contours of stimuli from a corpus containing portrayals of anger, joy, fear and sadness were manipulated with respect to range, mean and smoothness. In the second experiment, pitch contours of identical words portraying different emotions were exchanged. In each experiment, the emotional category and intensity of the original and manipulated stimuli were evaluated by two separate groups of 20 participants. Results of the first experiment show mainly that pitch mean and range should vary congruently to portray activation correctly, and demonstrate the interaction in varying these two parameters. Results of the second experiment show that a pitch contour conveying high activation is not sufficient in conveying the appropriate emotion, if the other paralinguistic cues are not also in accordance. A pitch contour indicating low activation, on the other hand, is apparently a more powerful cue and thus less reliant on other cues.

Politeness, culture, and speaking task - paralinguistic prosodic behavior of speakers from Austria and Germany
This paper tests previous findings for polite speech of low pitch, low intensity, higher number of hesitation markers and filled pauses against those parameters in a different socio-cultural background. Two similar groups of (19+13) participants, from Austria and from Germany, were recorded. The adopted experimental approach used 16 tasks aiming at different speech acts in situations that evoke either polite or informal speech. The analyzed acoustic and electroglottographic signals reveal main effects for lower pitch, lower intensity and HNR only for the German group. Open quotient values differ only for female speakers. In both groups significantly lower word rate and lower speaking rate as well as higher rates of filled pauses and hesitation markers are found in formal (polite) conditions. However individual speakers can show indifferent or opposing behavior for a given parameter with compensatory utilisation of other parameters in order to express politeness (formality).

Speech rate in the expression of anger: a study with spontaneous speech material
The study of the acoustic expression of emotion is, in general, the analysis of whether prosodic variables such as intonation (F0), speech rate, pauses, rhythm, intensity and duration, are reliable clues for the characterization of the emotional states of the speaker. The present paper aims to verify whether an association exists in Brazilian Portuguese between the basic emotion of "anger" and the prosodic variable "speech rate", as the literature often suggests there is for other languages. The corpus consisted of fragments of spontaneous speech recorded from a radio program. The fragments were selected on the basis of a perceptual test. For the production analysis, only excerpts that were identified by more than 75% of the participants of the perceptual test as associated to the categories "anger" and "neutral" were selected. The results demonstrated that, for the data that were used for the analysis, there is a general reduction in speech rate when utterances are associated with the emotion of "anger", if compared to utterances spoken in a "neutral" mode by the same speaker, contrary to what literature often indicates for other languages.

Audiovisual perception of expressions of Mandarin Chinese social affects by French L2 learners
This study focuses on confusions made by French L2 learners vs. native subjects in the perception of 11 audiovisual Mandarin Chinese attitudes, selected from a broader set of 19 attitudes previously evaluated in audio condition by both native Chinese and naïve French listeners. Two groups of French L2 learners of Mandarin Chinese were selected according to their level assessed by the Common European Framework of Reference for Languages: 9 beginners (A1) vs. 10 intermediate learners (A2). Subjects evaluated the 11 attitudes in audio, visual and audiovisual condition. Comparison of confusions between learners of level A1 vs. A2 indicates few significant differences, mostly in audiovisual condition and without a clear gain for one group over the other: confusions patterns are closer to the native reference for group A1 in expression of doubt, and for group A2 in expression of contempt. The comparison of French L2 learners pooled together vs. native speakers reference sheds light on major confusions to be targeted by specific methods and exercises. In audio-only condition, neutral surprise and politeness are less recognized by learners, who confuse contempt with question and question with obviousness. In visual-only condition, obviousness is more confused with declaration, contempt with irritation, and disappointment with doubt. In audio-visual condition, recognition of neutral surprise is lower, while infant-directed speech is better recognized; neutral surprise is more confused with irritation and contempt with disappointment. Cross-modality comparisons suggest a limited contribution of informations conveyed by acoustic prosody in the identification of audiovisual social affects by L2 learners.

Explorations in the prosodic characteristics of synchronous speech, with specific reference to the roles of words and stresses
We examine the prosodic characteristics of read speech produced alone or in synchrony with a co-speaker in English. Previous work has demonstrated a marked difference between these two speaking conditions in Mandarin, but not English. We employ word lists that are either simple sequences of trochees, or

complex lists with regular stress alterantion but irregular word boundaries. Inter-onset intervals are examined and no major differences between solo and synchronous interval sequences are found. Viewed from the perspective of two generative models, however, there is weak evidence for some small difference in the dependence of interval duration on serial position.

Zhen Qin, Annie Tremblay,
Effects of native dialect on Mandarin listeners' use of prosodic cues to English stress
This study investigates the effect of native dialect on the use of prosodic cues to English stress by Standard Mandarin (SM) listeners, Taiwanese Mandarin (TM) listeners, and English listeners. Both SM and TM use fundamental frequency (F0) to realize lexical tones, but only SM uses duration together with F0 to realize lexically contrastive full-full vs. full-reduced stress patterns. Native English listeners and second language learners of English who spoke SM or TM as native language and were at similar proficiencies in English completed a sequence-recall task. English disyllabic non-words that differed in stress placement were resynthesized to contain only F0 cues, only duration cues, or converging F0 and duration cues. The results showed that SM-speaking learners used duration more than TM-speaking learners to recall English non-words. Native dialect is suggested to be considered in second language speech processing models.

The interplay between prosodic phrasing and accentual prominence on articulatory lengthening in Italian
The distribution of preboundary lengthening within the phrase-final word is controversial. In CV syllables immediately preceding a prosodic boundary, the acoustic duration of the syllable onset C is less involved than that of the following rime V in the lengthening phenomenon. Moreover, preboundary lengthening might be extended to the stressed/accented rime within the phrase final word. On the other hand, articulatory constriction gesture for the onset consonant can be lengthened despite not being immediately adjacent to a boundary. In this study, we explore the effects of prosodic boundary and prominence in Italian, at both acoustic and articulatory level. Bilabial consonants in CV onset position were examined. The consonants were inserted in unstressed (word final) and stressed (penultimate vs. antepenultimate) syllables occurring in the vicinity of prosodic boundaries of different levels. In final syllables, the acoustic duration of the onset consonant was not affected by the prosodic boundary manipulation whereas the closing gesture duration showed a pattern of lengthening which was stronger for higher level prosodic boundaries. In non-final syllables, no acoustic/articulatory effect was found for onset consonants but only on the stressed vowels in penultimate position. Structural, phonological and phonetic constraints might be at work in determining preboundary lengthening.

Quasi-neutralization of stress contrasts in Spanish
We investigate the realization and discrimination of lexical stress contrasts in pitch-unaccented words in phrase-medial position in Spanish, a context in which intonational pitch accents are frequently absent. Results from production and perception experiments show that in this context durational and intensity cues to stress are produced by speakers and used by listeners above chance level. However, due to substantial amounts of phonetic overlap between stress categories in production, and of numerous errors in the identification of stress categories in perception, we suggest that, in the absence of intonational cues, Spanish speakers engaged in online language use must rely on contextual information in order to distinguish stress contrasts.

The effects of stress/accent on VOT depend on language (English, Spanish), consonant (/d/, /t/) and linguistic experience (monolinguals, bilinguals)
This study examines Voice Onset Times of coronal stops in utterance-initial position in two languages.

Crucially, the effects of lexical stress (stressed, unstressed syllable) on VOT are analyzed. The study investigates aspirated stops (English /t/), short-lag voiceless stops (English /d/, Spanish /t/) and prevoiced stops (Spanish /d/). Three groups of speakers provide data: English monolinguals, Spanish monolinguals, and proficient Spanish-English bilinguals. The study finds that lexical stress lengthens aspiration (English /t/) and prevoicing (Spanish /d/) but it does not alter significantly short-lag stops (Spanish /t/, English /d/). Monolinguals and bilinguals differ slightly in their phonetic behavior. Implications for gestural coordination as well as for feature theory are discussed.

Bogdan Ludusan, Guillaume Gravier, Emmanuel Dupoux,
Incorporating Prosodic Boundaries in Unsupervised Term Discovery
We present a preliminary investigation on the usefulness of prosodic boundaries for unsupervised term discovery (UTD). Studies in language acquisition show that infants use prosodic boundaries to segment continuous speech into word-like units. We evaluate whether such a strategy could also help UTD algorithms. Running a previously published UTD algorithm (MODIS) on a corpus of prosodically annotated English broadcast news revealed that many discovered terms straddle prosodic boundaries. We then implemented two variants of this algorithm: one that discards straddling items and one that truncates them to the nearest boundary (either prosodic or pause marker). Both algorithms showed a better term matching F-score compared to the baseline and higher level prosodic boundaries were found to be better than lower level boundaries or pause markers. In addition, we observed that the truncation algorithm, but not the discard algorithm, increased word boundary F-score over the baseline.

Chiu Yu Tseng, Chao Yu Su,
Binary Contrast and Categorical DifferentiationProsodic Characteristics of English Word Stress in Broad and Narrow Focus Positions
Assuming that categorical differentiation is major acoustic characteristics of English lexical stress through binary instead of more complex 3-way distinction, we investigated lexical stress in broad and narrow focus positions and found how binary distinction is achieved by the concomitancy of secondary stress defined by its position and distance in relation to primary stress. Similar results are found in broad (sentence initial) and narrow focus as well. These results suggest that binary categorical contrast is the optimal choice while differentiation is dependent on robust contrast patterns in the speech signal.

Núria Esteve-Gibert, Ferran Pons, Laura Bosch, Pilar Prieto,
Are gesture and prosodic prominences always coordinated? Evidence from perception and production
This study explores the temporal coordination between gesture and speech by addressing two main questions: (1) Are speakers sensitive to the misalignment between gesture prominence and prosodic prominence? (2) Is this sensitivity modulated by the semantic information conveyed by gesture and speech modalities in production? Experiment 1 tested question (1) and Experiment 2 tested question (2). Results from Experiment 1 revealed that the combinations in which prominences were misaligned were less acceptable than combinations with aligned prominences, and that the metrical pattern of the target word had an effect on the speakers' sensitivity: unsynchronized trochees (with the gesture prominence at the

post-tonic syllable) were frequently accepted, while unsynchronized iambs (with the gesture prominence at the pre-tonic syllable) were rejected. Results from Experiment 2 revealed that when the pointing gesture adds information to speech, i.e. it is supplementary to speech, the prominences are frequently misaligned (with gesture occurring after the speech), as if two different speech acts were produced. These findings suggest that the semantic content of gesture-speech combinations might influence the speakers' sensitivity of the misalignment between prosodic and gesture prominences.

Stefan Baumann, Anna Roth,

Prominence and Coreference On the Perceptual Relevance of F0 Movement, Duration and Intensity

We conducted a web-based experiment on German testing the perception of an element's prosodic prominence in relation to its status as a potential coreferent of an antecedent. Data were elicited by asking subjects to judge the probability of a coreference relation between a context noun (antecedent) and a target word (anaphor), whose lexically stressed syllable was manipulated as to the parameters F0 movement, duration and intensity. Results suggest a direct but inverse relationship between prominence and coreference judgements indicating that the likelihood of a coreference interpretation decreases with increasing prosodic prominence. F0 movement turned out to be the dominant cue for prominence as the main trigger for the perception of pitch accents with rises being perceived as more prominent than falls. In turn, lack of tonal movement probably led to perceived deaccentuation and thus favoured the evaluation of a target word as being coreferential with an antecedent. Duration was found to be a significant factor as well, while intensity did not prove to be relevant for the task given. Thus, the present study with its revised methodology adds new aspects to the debate of which parameters are crucial for prominence perception, directly linking it to the investigation of information structure.

An acoustic study of Estonian word stress

This study investigates the acoustic correlates of word stress in Estonian. It forms part of a broader international collaboration the aim of which is to develop a universal language independent model for evaluating lexical stress regardless of the phonological structure of a given language. To this aim the characteristics of word stress in a range of languages is studied using unified methodology. For the present study, four acoustic measures were analysed as a function of speaking style and stress: vowel duration, F0 mean, F0 standard deviation, and spectral emphasis. The results show that the strongest correlate of style and stress in Estonian is vowel duration, but stress has a strong interaction with the Estonian three-way quantity system.

Prominence Contrasts in Czech English as a Predictor of Learner's Proficiency

The study investigates prominence patterns in Czech-accented English comparing the production of non-native speakers of English at two distinct stages of phonological acquisition (beginners and intermediates) with a native performance. Word stress in Czech is entirely different from English, it has a fixed position, a delimitative function and rather impalpable acoustic manifestations. Alternations in the realization of word stress were analyzed by measuring the ratios or differences of acoustic correlates of prominence: duration, fundamental frequency, sound pressure level and spectral slope. Since word stress is a relational phenomenon, these characteristics were measured in two adjacent syllables one of which was a canonical stress bearer. The results reveal a clear difference between native and non-native treatment of word stress in all parameters examined. In the non-native sample distinct interferences of L1 across the two groups were detected: the subjects displayed different exploitation of duration, spectral slope and SPL with relation to their proficiency in L2 English. Out of these, duration ratio proves to be the most significant correlate. Furthermore, our findings indicate a strong effect of prosodic context coinciding with the prominence features, particularly in intonation declination and phrase-final lengthening.

Alice Turk, Stefanie Shattuck Hufnagel,
A sketch of an extrinsic timing model of speech production
In this paper, we motivate and present a sketch of an extrinsic timing model of speech production. It is a three-stage model, involving 1) a phonological planning stage, where symbolic segmental representations are sequenced and slotted into an appropriate prosodic structure, and where appropriate acoustic cues are selected for each segment in its context, and 2) a phonetic planning stage, where cues are mapped onto sets of articulators and appropriate values for spatial and temporal parameters of movement are computed, and 3) a motor-sensory implementation stage, where articulator movements are generated and tracked. We cite model components from the literature that accomplish many of the functions this type of model requires.

SLAM: Automatic Stylization and Labelling of Speech Melody
This paper presents SLAM : a simple method for the automatic Stylization and LAbelling of speech Melody. This main contributions over existing methods are : the alphabet of melodic contours is fully data-driven, an explicit time-frequency representation is used to derive complex melodic contours, and melodic contours can be determined over arbitrary prosodic/syntactic units. Additionally, the system can handle some specificities of spontaneous speech (e.g., multi speakers, speech turns and speech overlaps). A preliminary experiment conducted on 3 hours of spoken French indicates that a small number of contours is sufficient to explain most of the observed contours. The method can be easily adapted to other stressed languages. The implementation is open-source and freely available.

Antonio Simoes,
Lexical Stress in Brazilian Portuguese in Contrast with Spanish
This study discusses stress assignment in prosodic, non-verbal words in Brazilian Portuguese, in comparison with descriptions of stress assignment for Spanish [9, 13, 15, 16, 17, 18]. Given the conflicting claims regarding stress assignment in Brazilian Portuguese (see [11, 1, 2, 10, 3]) there is still a need to revisit discussions on stress assignment in Portuguese. In general, stress assignment in Spanish has been satisfactorily explained through the interplay between the morphological and phonological domains. Similar descriptions for Portuguese still requires far more abstraction and use of artifacts than in Spanish, which makes Mattoso Cmara Jr.'s [4, 5] claim that lexical stress is unpredictable in Brazilian Portuguese surprisingly unchallenged.

Rena Nemoto,
Prosodic Characteristics of Vocalic Hesitations in Comparison with Overlong Vowels in Estonian
The goal of this paper is to investigate vocalic hesitations in Estonian and compare them to the related vowels of overlong (Q3) quantity degree. We wonder if there are some languagespecific characteristics of hesitations. If yes, which kind of characteristics can be observed in Estonian language? We analyze duration, fundamental frequency (f0), intensity, and first two formants using 39.5 hours of manually transcribed monoor dialogue speech from a spontaneous speech corpus. Investigated vocalic hesitations and Q3 vowels are: /ee, ää, aa, , öö/. The characteristics of hesitations as compared to those of Q3 vowels show that hesitations have longer duration range. Hesitations generally include lower f0 and intensity values. However, the values vary in terms of vowels. First two formants of hesitations tend to be located at more centralized positions in a vocalic triangle than related Q3 vowels.

Articulatory Reorganizations of Speech Rhythm due to Speech Rate Increase in Brazilian Portuguese
This paper examines how speech rate increase acts to change speech rhythm at the articulatory level.

Main results show that speech rate increase worked to change articulatory parameters in the following way: a) decrease of acceleration duration; b) decrease of y-extremum; c) decrease of constriction displacement; d) decrease in modulus of peak and/or valley velocity; e) decrease of gestural duration; and f) constant proportional time-to-peak (or valley) velocity. Besides, results have shown that speech rate tends to affect all gestures in an utterance independently of their phrasal position. Nevertheless, there was evidence that some articulatory parameters could, if properly manipulated, provide cues for rhythmic restructurings in speech. Finally, results show that the dynamical speech rhythm model (Barbosa, 2007) is more appropriate to deal with Brazilian Portuguese acoustical data than the pi-gesture model (Byrd &Saltzman, 2003), and that both models could explain articulatory reorganizations due to speech rate increase.

Prosody in Turkish learners of German as a Foreign Language
Results of a pilot study are reported which investigates the prosodic realization of information structure by six learners of German as a Foreign Language (GFL) with Turkish as first language. Question-answer pairs were read out loud which systematically varied the position of narrow focus in the response by means of a preceding wh-question. A qualitative analysis of the results shows deaccentuation of postfocal constituents in the case of subject focus for 4/6 GFL speakers but no consistent pitch increase on focused constituents. Two speakers did not change prosody due to information structure. The results are discussed in connection with the acquisition of prosody as a marker of information structure. Deaccentuation has been reported to cause problems in L2 prosody. In Turkish, deaccentuation occurs postfocally. The claim will be motivated that the occurrence of deaccentuation in the L1 is a necessary but not sufficient condition for early acquisition of deaccentuation in a foreign language.

Synthesizing sports commentaries: One or several emphatic stresses?
Emphatic stresses are known to fulfill essential functions in expressive speech. Their integration in speech synthesis usually relies on a prosodic annotation of the training corpus. Emphasized syllables are then assigned a single label or can receive several labels according to their acoustic realization. While it is more complex to predict those various labels for a new text to synthesize, it might allow for a better rendering of the stress in the synthesized speech. This paper examines whether the use of more than one emphatic label improves the perceived expressivity of the synthesized speech. It relies on a manually-annotated expressive corpus of sports commentaries. Statistical acoustic analyses show that four distinct realizations of emphatic stresses can be distinguished. However, perceptual tests indicate that the integration of this distinction in HMM-based speech synthesis does not lead to a significant improvement in expressivity. This seems to imply that the different acoustic realizations of the stress are not required to be explicitly annotated in the training corpus.

Sources of variation of articulation rate in native and non-native speech: comparisons of French and German
Speech tempo including articulation rate is often considered as a good predictor in the diagnosis of foreign language proficiency and its comprehension. In this study we investigate various sources of variation of articulation rate such as the L2 proficiency level, individual tempo habits in L1 and L2, and more extensive exposure to native speech. In addition, we also discuss the difficulty of the most informative unit for rate metrics which allows comparisons between French and German. The materials used are French and German read sentences, produced as L1 and L2 speech. In contrast to other studies individual habits of articulation rate in the L1 was only partially observed in the corresponding L2 data (a slow L1 speaker does not necessarily articulate slowly in the L2). The convergence of most French learners to the German model speakers shows the advantage of having additional input for phonetic exercises. The fastest German learners also converge to the rather slow French model speaker.

Extending AuToBI to prominence detection in European Portuguese

This paper describes our exploratory work in applying the Automatic ToBI annotation system (AuToBI), originally developed for Standard American English, to European Portuguese. This work is motivated by the current availability of large amounts of (highly spontaneous) transcribed data and the need to further enrich those transcripts with prosodic information. Manual prosodic annotation, however, is almost impractical for extensive data sets. For that reason, automatic systems such as AuToBi stand as an alternate solution. We have started by applying the AuToBI prosodic event detection system using the existing English models to the prediction of prominent prosodic events (accents) in European Portuguese. This approach achieved an overall accuracy of 74% for prominence detection, similar to state-of-the-art results for other languages. Later, we have trained new models using prepared and spontaneous Portuguese data, achieving a considerable improvement of about 6% accuracy (absolute) over the existing English models. The achieved results are quite encouraging and provide a starting point for automatically predicting prominent events in European Portuguese.

Prosodic prominence detection in Italian continuous speech using probabilistic graphical models

Prosodic prominence, a speech phenomenon by which some linguistic units are perceived as standing out from their environment, plays a very important role in human communication. In this paper we present a study on automatic prominence identification using Probabilistic Graphical Models, a family of Machine Learning Systems able to properly handle sequences of events. We tested the most promising members of such models on utterances selected from a manually annotated Italian speech corpus, obtaining very good recognition results crucially converging with the prominence detection responses provided by a pool of native speakers.

Robert Fuchs,

Integrating variability in loudness and duration in a multidimensional model of speech rhythm: Evidence from Indian English and British English

Most research on speech rhythm has focussed on duration. For example, [1] suggested the normalised Pairwise Variability Index for vocalic intervals (nPVI-V) in order to measure the variability of vocalic durations. This paper argues that speech rhythm research should also take into account other correlates of prominence as well as their interaction. The duration-based nPVI, or nPVI-V(dur), is supplemented by an nPVI-V(avgLoud) that measures variability in average loudness. These two metrics account for variability in duration and loudness, but cannot measure if loudness and duration reinforce each other by varying simultaneously in the same direction. This simultaneous variability is accounted for by the combined nPVI-V(dur+avgLoud), which is higher than the average of the other two measures, if vocalic intervals that are longer than average are also louder than average. The three metrics are subsequently applied to recordings of a reading task performed by 20 speakers of Indian English (IndE) and 10 speakers of British English (BrE). Results indicate that IndE has less variability in duration and less variability in loudness than BrE. In addition, IndE has less simultaneous variability in duration and loudness than BrE. This indicates that duration and loudness are less often used together as cues to prominence in IndE than in BrE.

A Durational Study of German Speech Rhythm by Chinese Learners

This study focuses on the temporal and metrical features of the German speech produced by Chinese speakers. German is described to be a stress-timed language, while standard Chinese is regarded as a syllable-timed language. It has been suggested that the rhythm of the target language can be influenced by the learners' native language. In this study we conducted an investigation of ten sentences with 18

Chinese students in the low intermediate proficiency level in comparison with six native German speakers. We compared the duration values in terms of pairwise variability indices, and found that most of these Chinese speakers have a lower nPVI-V and a higher rPVI-C than the German speakers. We illustrate that the conventional duration measures of nPVI-V can be influenced by the syllable structures of the utterance and the classification approach of vocalic intervals, and a comparable nPVI-V can hardly be expected from different investigations. Furthermore, we argue that duration values alone cannot fully capture the rhythmic patterns of speech because other prosodic parameters such as pitch and energy also join to contribute to rhythmic characteristics of the speech.

Erwan Pépiot,
Male and female speech: a study of mean f0, f0 range, phonation type and speech rate in Parisian French and American English speakers
Many studies have been conducted on acoustic differences between female and male speech. However, they have generally been led on speakers of only one language, and have focused on a single acoustic parameter. The present study is an acoustic analysis of dissyllabic words or pseudo-words produced by 10 Northeastern American English speakers (5 females, 5 males) and 10 Parisian French speakers (5 females, 5 males). Several prosodic parameters were measured: mean f0, f0 range, phonation type (through H1-H2 intensity differences) and words' duration. Significant cross-gender differences were obtained for each tested parameter. Moreover, cross-language variations were observed for f0 range, and H1-H2 differences. These results suggest that cross-gender acoustic differences are partly language-dependent and could be socially constructed.

Hansjörg Mixdorff, Angelika Hönemann, Oliver Niebuhr, Christoph Draxler,
Perceived Prominence Reflected by Imitations of Words with and without F0 Continuity
This paper continues our work on the perception of prominence as a function of F0 continuity. In an earlier study the first author had shown that F0 intervals occurring at lexically stressed syllables and measured using the amplitude of Fujisaki model accent commands strongly contribute to the perceived prominence of that syllable. More recent work explored how F0 continuity influenced prominence ratings of single word utterances. The outcome indicated that listeners made use of the physically available F0 information and therefore words containing gaps in the contour were perceived as less prominent. It was also shown that subjects were able to interpolate missing parts as long as the F0 peak was still present. The current study explores whether subjects compensate the lack of prominence in words containing F0 gaps by asking them to produce a word with the same accent strength as that of a spoken word stimulus, the spoken word being either the same or different from the one they are asked to utter. We evaluated word durations, F0 intervals and intensities of the responses as correlates of prominence and found that listeners indeed seem to adjust depending on the kind of stimulus they have heard.

Toshiyuki Sadanobu,
The Structure of Japanese Phrase in Accordance with Speaking Modes
While English is often spoken in an increment of clause (i.e. subject and predicate), Japanese of a smaller phrase called "bunsetsu" (e.g. noun phrase and case particle). Previous studies on Japanese language, however, have traditionally been focusing on clause structure, and little attention has been paid on the

structure of “bunsetsu” (non-predicate one, especially). This paper describes the basic structure of non-predicate “bunsetsu” from grammatical point of view, and elucidates that the structure of non-predicate “bunsetsu” varies in accordance with four speaking modes ((i) Sentence mode A; (ii) Sentence mode B; (iii) “Bunsetsu” mode; and (iv) Character mode), which are identified on the criteria of compatibility among seven phenomena attested in Japanese speech. To be more concrete, this paper shows that it is only the mode (iii) that enables copula, “bunsetsu”-final particle (“Kantoujoshi” in Japanese), final leaping, and combination of breaking and prolongation in non-predicate “bunsetsu”).

Stefanie Shattuck-Hufnagel 30-min
Cue-based analysis of speech: implications for prosodic labelling systems

Over the past few decades it has become clear that an adequate account of systematic context-driven variation in word forms requires representations below the level of the abstract symbolic phoneme or even the allophone. One proposal for this sub-allophonic level of description is in terms of feature cues, such as the cues to articulator-free features and articulator-bound features proposed by Halle (1992) and by Stevens (2002), also assumed in the concept of enhancing cues in Stevens and Keyser (2010), Keyser and Stevens (2006) and Stevens, Keyser and Kawasaki (1986). This proposal of a level of representation of discrete feature cues, along with continuous-valued cue parameters, has the potential to bridge the gap between abstract symbolic categories of the phonology and the concrete spatial and temporal specifications that drive the articulatory-acoustic implementation of word forms in continuous communicative speech. Such an approach suggests that phonetic transcription might benefit from a focus on capturing the individual cues to feature contrasts that are realized in the speech signal. Does this approach to understanding phonetic variation in word forms have implications for prosodic labelling? We will explore this possibility, taking as our point of departure Arbisi-Kelm’s (2006) proposal for labelling the separate correlates of prosodic disfluency in stuttered speech, adapted by Brugos and Shattuck-Hufnagel (2012) for prosodic disfluencies in utterances produced by typical speakers. Our hypothesis is that variation in cue selection and cue parameter values is systematically governed by context, and that cue-level transcription may be needed to capture systematicity in the phonetic implementation of prosodic phonology as well as of lexical phonology.

2.1.2 p.321

Yuki Asano,
Stability in perceiving non-native segmental length contrasts
Previous studies have demonstrated that listeners show high sensitivity in discriminating non-native prosodic contrasts thanks to auditory memory (Hayes and Masuda 2008; Hirano 2011). We tested the limits of discriminating Japanese consonantal length contrasts with three groups of listeners (German learners of Japanese, German non-learners and Japanese natives) under increasing task demands. We increased auditory memory load through a longer inter-stimulus interval (=ISI) (2500ms vs. 300ms) and added psycho-acoustic complexity (trials with task-irrelevant pitch falls that occurred simultaneously with the consonant vs. with monotonous pitch). Results showed very good discrimination in all groups when task demands were lowest. With increasing task demands, only non-natives’ discrimination abilities decreased: non-learners were strongly affected by both ISI and pitch, while learners only by pitch. The psycho-acoustic complexity of the stimuli had a stronger impact on performance than increased memory load. Our findings suggest that L2 learners can establish novel phonological representations, but the ability to use them can be applied still only under favorable listening conditions with no distracting acoustic information. The non-native listeners’ reduced sensitivity under increasing task demands appears to be the reason why even advanced learners still face difficulties in natural learning situations.

Investigating the relationship between accentuation, vowel tensity and compensatory short-

ening
The aim of this study was to investigate the relationship between compensatory shortening and coarticulation in German tense and lax vowels and to determine whether this relationship was influenced by prosodic accentuation. While previous studies focussed on temporal vowel reduction due to compensatory shortening, and often found conflicting results, our study extends previous results by including a formant analysis of spatial reduction in two types of compensatory shortening. Polysyllabic shortening was tested in monosyllabic versus disyllabic words, while incremental coda shortening was tested in words with final singleton versus final cluster. Speakers produced minimal pairs differing in vowel tensity in accented and deaccented contexts for both shortening conditions. Vowel duration was influenced primarily by vowel tensity as well as by accentual lengthening for tense but not lax vowels. While vowel duration was not affected by compensatory shortening, formant analyses revealed an effect of coda cluster for tense vowels as well as clear effects of accentuation and vowel tensity. There was no effect of polysyllabic shortening on formants. Further to previous studies on compensatory shortening, these results reveal that compensatory shortening is not limited to temporal reduction, but can have an impact on vowel quality as well.

The form and use of uptalk in Southern Californian English
This study examines the phonetics, phonology and pragmatic function of uptalk, utterance-final rising pitch movements, as used in Southern Californian English. Twelve female and eleven male speakers were recorded in a variety of tasks. Instances of uptalk were coded for discourse function (statement, question, confirmation request, floor holding) based on context. The excursion of the pitch rise and the distance of the rise start from the onset of the utterance's last stressed vowel were also measured. Confirmation requests and floor holding showed variable realization. Questions, on the other hand, showed a rise that typically started within the stressed vowel and had a large pitch excursion, while uptalk used with statements exhibited both a smaller pitch excursion and a later rise that often started after vowel offset. This pattern suggests that statements have a L* L-H% melody while questions have L* H-H%. Gender differences were also found: female speakers used uptalk more often than males, and showed greater pitch excursion and later alignment, all else being equal. Other social parameters, however, such as social class and linguistic background did not affect the use of uptalk.

Agnieszka Wagner,
Rhythmic structure of utterances in native and non-native Polish
This paper presents results of an ongoing study concerning speech rhythm in native and non-native Polish. The goal of the analyses described in the paper was to characterize rhythmically Polish utterances realized by native and non-native speakers with German and Korean accent. The analyses are limited to the domain of duration, but in the future other prosodic parameters will also be investigated. In the current study, different rhythm metrics (%V, V, C, PVIs and Varcos) were applied to provide quantitative description of temporal patterning in native and non-native Polish. Following the assumption that perceived speech rhythm is the effect of meter and grouping which are closely related to prominence and phrasing, durational marking of various levels of prominence and prosodic edges was also analyzed between the three accents (native Polish and German- and Korean-accented Polish). The analyses aimed also at rhythmic classification of Polish - for that purpose the results of quantitative description with rhythm metrics and phonotactic properties of the speech material used in the current study were compared with the data for other languages presented in the literature.

2.2.2 p.342

Hugo Quené, Rosemary Orr,
Long-term convergence of speech rhythm in L1 and L2 English

When talkers from various language backgrounds use L2 English as a lingua franca, their accents of English are expected to converge, and talkers' rhythmical patterns are predicted to converge too. Prosodic convergence was studied among talkers who lived in a community where L2 English is used predominantly. Speech rhythm was operationalized here as the peak frequency in the spectrum of the intensity envelope, normalized to the speaking rate (in syll/s). Results indicate that talkers produced intensity contours with maximum periodicity at frequencies of about 0.32 times their syllable rates, i.e., peaks in intensity tend to occur every 1/0.32 syllables. These results were collected repeatedly, from 5 recordings conducted over 3 years with the same talkers. We found that variance between talkers in their rhythm decreases over time, thus confirming the predicted convergence in speech rhythm in L2 English. These findings show that speech rhythm in L2 English tends to converge, and that this prosodic convergence continues to proceed over several years, as well as over communicative settings.

Probing Theories of Speech Timing using Optimization Modeling
We implement two theories about the temporal organization of speech in an optimization-based model of speech timing and conduct simulation experiments in order to test whether both theories can account for the phenomenon of foot-level shortening (FLS) observed in English speech corpora. Results suggest that a model that induces compensatory timing relations between syllables and feet predicts empirical results very accurately. However, we also observe that the FLS effect can equally well be explained under the assumption that suprasegmental timing is confined to localized lengthening effects at the heads and edges of prosodic domains. Implications for theories of speech timing are discussed.

2.2.4 p.351

Sandra Peters, Felicitas Kleber,
The influence of accentuation and onset complexity on gestural timing within syllables
This paper presents results from a production experiment using electromagnetic articulography. The main aim of the study was to investigate how phrasal accent and the number of onset consonants influence the gestural timing of syllable constituents in German. Five speakers of German with sensors attached to the tongue tip, tongue body and lower lip were recorded reading sentences with either accented or unaccented target words that contained simplex (one consonant) and complex (two consonants) onsets. The nucleus was always /a/ and the coda consonant was always /p/. We analyzed acoustic segment duration and gestural overlap (in terms of lag measurements). Onset complexity influenced both CV and VC overlap and accentuation affected gestural overlap to a greater extent than acoustic vowel duration. However, the extent of overlap differed between segment sequences and accentuation patterns: while for CC and VC sequences trends for greater overlap in deaccented than in accented condition were found, CV overlap decreased with deaccentuation. Shorter plateau durations in this context explain the diminished CV overlap in a prosodically weak context. The findings are discussed with respect to the predictions made by articulatory phonology regarding gestural timing and with respect to timing stability in weak versus strong prosodic contexts.

2.2.5 p.356

Núria Esteve-Gibert, Joan Borrs-Comes, Marc Swerts, Pilar Prieto,
Head gesture timing is constrained by prosodic structure
There is an increasing consensus to regard gesture and speech as parts of an integrated communication system, in part because of the findings related to their temporal coordination at different levels. In general, results for different types of gestures show that the most prominent part of the gesture (the apex) is typically aligned with accented syllables. The aim of the present study is to test for this coordination by focusing on head movements taken from a semi-spontaneous setting in order to look at the effects of upcoming phrase boundaries on their timing. Our results show that while apexes of head gestures are synchronized with accented syllables, upcoming phrase boundaries have an effect on the timing of three gestural points, namely the start, apex, and end time of head gestures. Crucially, these points are aligned differently with respect to the stressed syllable for trochees as compared with iambs/monosyllables, showing that head nods are retracted before upcoming phrase boundaries. This result corroborates previous results by Esteve-Gibert &Prieto for pointing gestures in laboratory settings.

2.2.6 p.361

Helen Türk, Pärtel Lippus, Karl Pajusalu, Pire Teras,
The ternary contrast of consonant duration in Inari Saami
The three-way distinction of quantity occurs in several Finnic and Saami languages. The paper focuses on the length contrast of consonants in Inari Saami. Similarly to Estonian and other Finno-Ugric languages where three quantities are described, in Inari Saami the distinction between single consonants, short geminates or consonant clusters, and long geminates or consonant clusters appears only on the boundary of a stressed and unstressed syllable of a disyllabic foot. Our results show that in Inari Saami the duration of consonants is inversely related to the duration of both preceding and following vowels, and there is a tendency towards foot isochrony. The results are in line with previous studies on quantity opposition in Inari Saami and in other Finnic languages, showing the ternary distinction of consonant quantities as a foot-level feature of the language.

2.3 Wednesday Session Three

Slovak prosody in the phonetics-phonology debate: Yers and emergent prosodic breaks.
Prosody is central for understanding the cognitive system underlying human speech and relates to both more granular aspects of our phonological competence as well as more continuous aspects of observable articulatory movements and resulting acoustic characteristics. The understanding, and formal treatment, of the relationship between these two inter-related components of human speech is at the core of the cognitive approach to speech. In this presentation I contribute to this discussion by drawing links between two seemingly unrelated lines of my research on Slovak, and argue that understanding the continuous prosodic nature of speech is critical for improving our understanding of cognitive competence underlying it. The first aspect concerns yer vowels as the prototypical problem of Slavic phonology, the second involves the nature of prosodic boundaries.

Time and timing in intonational phonology: analysing pitch categories in Russian (and other Slavonic languages)
Many Slavonic languages are still lacking a comprehensive description of their intonational phonologies. Given that decisions regarding the number of relevant categories and their types are the key issues of any phonological analysis, this presentation will concentrate on how time and timing can inform intonational phonology. Evidence from Russian (and also Bulgarian, Czech and Polish) will demonstrate that time pressures arising from intermittent voicing and an upcoming phrase boundary have different effects on Slavonic vs. Germanic languages. Potential implications of these findings for prosodic typology will be discussed.

2.3.3 p.368

Jaye Padgett, - 30-min (invited)
On the origins of the prosodic word in Russian
The Prosodic Word is a foundational notion in phonological theories, being relevant for the statement of many phonological generalizations. In spite of their importance, there are basic open questions about prosodic words. Where do they come from? Can their structure in one language vs. another be predicted? In this paper I suggest a research program that attempts to address such questions by viewing prosodic words as emergent over time from the interaction of phonetics, phonologization, and syntactic structure.

Local and Global Acoustic Correlates of Information Structure in Bulgarian
In this study the prosodic exponents of information structure are examined in the production of six Bulgarian sentences under different focus conditions (broad focus and non-contrastive and contrastive

narrow focus). Results show that speakers consistently discriminate broad and narrow focus by both local and global acoustic cues. Local cues are the phonetic properties of the accented syllables, while global cues reflect broader phonetic patterns in the intervals before and after the accented syllable, which vary independently of the tonal accent. Contrastive and non-contrastive accents are differentiated exclusively by local cues, but only when the focus is early in the sentence.

2.3.5 p.377

Agnieszka Wagner,
Description of Polish speech rhythm using rhythm metrics and time-delay approach: A comparative study
The goal of this study is to provide a multidimensional description of rhythmic structure of Polish utterances. For this purpose a time-delay approach proposed in [1] is applied and results of qualitative and quantitative analyses based on time-delay plots are compared with results obtained with selected rhythm metrics. The study shows that description that relies on a combination of rhythmic scores is inconclusive and difficult to interpret, because it does not account for rhythmic structuring nor grouping. The time-delay approach, on the contrary, appears to be very efficient in exploring short-time and long-term timing variability that determines Polish speech rhythm.

Event-Related Investigation of Initial Accent Processing in French
This study investigates stress processing through the Event-Related brain Potential (ERP) technique. It aims at evaluating whether French listeners can perceive and discriminate the Initial Accent (IA) and whether IA is encoded in the phonological representation. Participants listened to trisyllabic words in two stress-pattern conditions, with (+IA) or without (-IA) initial accenting, in an oddball paradigm. The EEG was recorded in both a passive and an active listening task, and in two different oddball versions: one where standard stimuli were +IA words and deviants -IA words, and the reverse for the other version (-IA standard, +IA deviant). Behavioral results show faster processing and less errors for +IA stimuli. ERP results show larger MisMatch Negativity component for -IA words, pointing out 1) that French listeners are sensitive to f0 manipulation, and 2) that +IA is the preferred stress template in French. Altogether, our results indicate that French listeners not only discriminate stress patterns but that IA is encoded in long-term memory, hence phonologically relevant.

2.4.2 p.388

Alejna Brugos, Jonathan Barnes,
Effects of dynamic pitch and relative scaling on the perception of duration and prosodic grouping in American English
Results of two perception experiments suggest that using timing measures alone to compute prosodic structure misses valuable information from pitch. Previous research showed that pitch can distort perceived duration: tokens with dynamic or higher f0 are perceived as longer than comparable level-f0 or lower-f0 tokens, and silent intervals bounded by tokens of widely differing pitch are heard as longer than those bounded by tokens closer in pitch (the kappa effect). Phrase edges (signalled by increased duration, pause, phrase tones, and f0 reset) set the scene for pitch to modulate perceived duration. Two new experiments used the same duration and f0 manipulations (level vs. varying-slope rises, at varying pitch ranges) of segmentally-identical base files, in two separate tasks: 1) a linguistic grouping task using an ambiguously-structured phrase and 2) a psychoacoustic study on perceived duration. Results show that effects on perceived duration due to dynamic pitch can be either strengthened or nullified depending on relative scaling of compared tokens. These same manipulations push grouping judgments beyond what

would be expected from distortions of perceived duration. This suggests that listeners integrate pitch and timing cues when judging linguistic structure, supporting measures of relative boundary size that combine duration and pitch measures.

Canan Ipek, Sun-Ah Jun,
Distinguishing Phrase-Final and Phrase-Medial High Tone on Finally Stressed Words in Turkish
The goal of this paper is to investigate the nature of the high tones realized on finally stressed words in Turkish. Following Ipek &Jun's [1] AM model of intonational phonology of Turkish, it was hypothesized that the high tone realized on the last syllable of a phrase (i.e., Intermediate Phrase (ip)) is realized differently from that of a phrase-medial prosodic word (PW), reflecting the prosodic hierarchy. Acoustic data show that an ip-final High tone shows larger f0 rise than a PW-final High tone, and the ip-final syllable is longer than the PW-final syllable. Furthermore, the degree of coarticulation is weaker across an ip boundary than a PW boundary. These findings support the prosodic structure and tonal categories proposed in Ipek &Jun's [1] model of Turkish intonation.

Willemijn Heeren, Vincent van Heuven,
The interaction of accent and boundary tone in perception of whispered speech
We investigated how the perception of Dutch whispered boundary tones depends on the presence of an accent in the utterance-final word, i.e. the boundary tone landing site. Listeners performed near ceiling in normal speech, whereas the same listeners' performance dropped about 30% in whisper, while processing speed decreased in whisper compared to normal speech. Accent position furthermore influenced boundary tone perception. Initial-stress words showed a question bias that affected recognition of that speech act when accent and boundary tone did not coincide. On final-stress words, in which boundary tone and accent coincided, statements and questions were identified equally well.

Links between Manual Punctuation Marks and Automatically Detected Prosodic Structures
This paper presents a study of the links between punctuation and automatically detected prosodic structures, as observed on large speech corpora that were manually annotated during speech transcription evaluation campaigns in French. These corpora contain more than 3 million words and almost 350 thousands punctuation marks. The detection of the prosodic boundaries and of the prosodic structures is based on an automatic approach that integrates little linguistic knowledge and mainly uses the amplitude and the inversion of the F0 slopes as described in [1], as well as phone durations. The paper first analyzes the occurrences of the punctuation marks with respect to various sub-corpora, which also highlights the variability among annotators. Then, the paper focuses on analyzing prosodic parameters with respect to the punctuation marks, followed or not by a pause, and on analyzing the links between the automatically detected prosodic structures and the manually annotated punctuation marks.

Perception of Peak Placement in Tashlhiyt Berber
Previous production studies on Tashlhiyt Berber have demonstrated that questions and statements have similar intonation contours, i.e., a final rise to a F0 peak and subsequent fall. The contours tended to differ in overall pitch register and peak location: questions (a) revealed a stronger tendency to be realized with the F0 peak on the final syllable than statements and (b) even within the same syllable, peaks were often aligned later in questions than in statements. The peak location, however, was reported to vary strongly both within and across speakers, interpreted as free alternation of tonal association. Given this high degree of variation, the question arises as to how relevant this variation is for communication. The present perception study shows that both pitch register (low vs. high) and tonal placement (peak on

penultimate vs. final syllable) affect listeners' judgments on sentence modality as well as reaction times. Whereas peak alignment within the syllable (early vs. late) did not affect judgments, it did have an effect on reaction times. By demonstrating their perceptual impact, this study confirms that the patterns found in production are communicatively relevant.

Cristel Portes, Uwe Reyle,
The meaning of French"implication"contour in conversation
French intonational contours inventory has a rising-falling tune which presents very interesting semantic properties. It has been called "intonation d'implication" by Delattre (1966) suggesting that the contour triggers an implicit meaning, i.e. an implicature in Gricean terms. Besides, the "implication" contour have been claimed to convey various attitudinal meanings from obviousness to exasperation, and also to mark contrastive focus. The aim of the present paper is to give a unified account of these seemingly differing semantic descriptions of the "implication" contour in French, using a dynamic semantic framework, namely Discourse Representation Theory (DRT). We claim that the main semantic component of the "implication" contour is to convey a contradiction (or a contrast). We first present our DRT-theoretical approach, and then apply it to occurrences of the "implication" contour in a corpus of conversational dialogue.

Combination of variations of pairwise classifiers applied to multiclass ToBI pitch accent recognition
In this paper we present some experiments on multiclass ToBI pitch accent classification. The system is based on the fusion of pairwise classifiers, which are specialized in the distinction of pairs of prosodic labels. Several machine learning techniques, including neural networks, decision trees and support vector machines, are combined in different ways in order to find the best overall combination. Variations of pairwise classifiers are introduced in order to take into account the influence of the samples of the remaining classes during the training of the binary classifiers. The use of these techniques allowed us to improve the results, both the overall classification accuracy and the balance across the different ToBI pitch accent classes.

Aoju Chen,
Production-comprehension (A)Symmetry: individual differences in the acquisition of prosodic focus-marking
Previous work based on different groups of children has shown that four- to five-year-old children are similar to adults in both producing and comprehending the focus-to-accentuation mapping in Dutch, contra the alleged production-precedes-comprehension asymmetry in earlier studies. In the current study, we addressed the question of whether there are individual differences in the production-comprehension (a)symmetricity. To this end, we examined the use of prosody in focus marking in production and the processing of focus-related prosody in online language comprehension in the same group of 4- to 5-year-olds. We have found that the relationship between comprehension and production can be rather diverse at an individual level. This result suggests some degree of independence in learning to use prosody to mark focus in production and learning to process focus-related prosodic information in online language comprehension, and implies influences of other linguistic and non-linguistic factors on the production-comprehension (a)symmetricity.

Phonetic variations : Impact of the communicative situation
While speech synthesis research is now focussing on the generation of various speaking styles or emotions,

very few studies have considered the possibility of including phonetic variations according to the communicative situation of the targeted speech (sports commentaries, TV news, etc.). This paper proposes a phonetic analysis of large French corpora to assess the influence exerted by three situational 'traits': read/spontaneous, media/non-media and expressive/non-expressive. It shows that some variations, like elision, tend to be more frequent in spontaneous and non-media speech, conversely to liaisons which appear more often in read and media speech. Interestingly, no phonetic variation draws a clearcut distinction between expressive and non-expressive speech. Finally, a prosodic analysis indicates that the phonetic variations are not directly correlated with the rhythmic features of their corresponding situational 'trait'.

Differences between the acoustic typology of autonomy-supportive and controlling sentences

The current study was first to describe distinct patterns of prosody that discriminate motivationally laden speech. To do this we applied self-determination theory, a widely used motivational framework. Participants in the US and UK were asked to read out loud either autonomy-supportive sentences (that support choice and volition) or controlling (pressuring and coercive) sentences. Data analyses were conducted using a conservative hierarchical linear modeling approach to account for nesting of sentences within individuals. Across both countries and controlling for gender, autonomy-supportive sentences were read using lower pitch, less intensity, and a slower speech rate than were controlling sentences. Multiple regression analyses showed links between these patterns of prosody for each participant and his or her current level of motivation, providing additional validity to results. Findings inform both the motivation and prosody literatures and offer a first description of how different kinds of motivational speech may sound.

Congenital Amusia in linguistic and non-linguistic pitch perception: What behavior and reaction times reveal

Congenital Amusia is a developmental disorder that has a negative influence on pitch perception. While it used to be described as a disorder of musical pitch perception, recent studies indicate that congenital amusics also show deficits in linguistic pitch perception. This study investigates the perception of linguistic and non-linguistic pitch by ten German amusics and their matched controls. To test the influence of amusia on linguistic pitch perception, the present study parametrically varied pitch differences in steps of one semitone in resynthesized statement-question pairs. In addition, we looked at the influence of stimulus duration, continuity of pitch and direction of pitch change (statement or question). Performance accuracy and reaction times were recorded. Behavioral results show that amusics performed worse than controls over all conditions. The reaction time analysis supports these findings, as amusics were significantly slower across all conditions. Both groups were faster in discriminating statements than questions. Performance accuracy supports these findings, as questions were also harder to discriminate. The present results warrant further investigation of the linguistic factors influencing amusics' perception of intonation.

Computational annotation-mining of syllable durations in speech varieties

There are many techniques for modelling properties of speech duration patterns, including models of rhythm as oscillation, partial models of rhythm types as departures from isochrony, models of tempo acceleration and deceleration, and models of duration hierarchies and their relation to hierarchies in word and phrase structure. Except for oscillator modelling, many approaches use data extraction from speech annotations, often with mainly manual methods. We employ computational data-mining for phonetic research, as opposed to phonological research on the one hand or speech technological research on the other, and explore the potential of the computational annotation data-mining paradigm for improving efficiency and scope of analysis. We show consistent variation in syllable duration patterns in selected speech varieties in English, Chinese and Polish, chosen for their known different prosodic typological properties. Results include a possible limen of 50ms for relevant timing patterns. For data-mining we use the Time Group Analysis (TGA) methodology, directly in the TGA online tool and integrated into

the Annotation Pro+TGA desktop software.

Sentence type and prenuclear contours in Brazilian Portuguese: production and perception
In this paper we examine how the interrogative sentence mode is encoded in some dialects of Brazilian Portuguese (BP) and how questions differ from their declarative counterparts. Our aim is to identify which specific prosodic features, including prenuclear pitch range values, are systematically associated with the interrogative mode of enunciation. In the interdialectal comparison, the speakers from Blumenau (SC) and Aracaju (SE) distinguish themselves from the speakers of the other varieties in their prenuclear patterns, significantly higher for the yes/no interrogatives than the declarative counterparts. This is not the case with other dialects in our study. Perception tests corroborated the production results.

Ji Young Kim,
Use of suprasegmental information in the perception of Spanish lexical stress by Spanish heritage speakers of different generations
The present study examines the perception of Spanish lexical stress by Spanish heritage speakers of different generations and compares their performance to that of Spanish native controls and English second language (L2) learners of Spanish. Previous studies have shown that English L2 learners experience great difficulty in perceiving Spanish lexical stress. Such difficulty is argued to be derived from English listeners using different strategies from Spanish listeners in the perception of stress. Given that Spanish heritage speakers share the same dominant language with English L2 learners (English), but differ from them with regard to the first language (Spanish), the present study intends to seek whether heritage speakers show similar or different patterns when compared with L2 learners. The present study also intends to account for the heterogeneity among heritage speakers by comparing heritage speakers of different generations. Using a forced-choice identification task with stressed minimal pairs of paroxytone and oxytone verbs, results showed that while 1st generation US-born heritage speakers pattern like Spanish native controls by paying more attention to the acoustic cues of the stimuli, 1.5/2nd generation US-born heritage speakers pattern like English L2 learners by showing bias towards paroxytone verbs.

Applying a fuzzy classifier to generate Sp_ToBI annotation: preliminar results
One of the goals of the Glissando research project1 is to enrich a radio news corpus [1] with Sp_ToBI labels. In this paper we present the application of the automatic predictions of a fuzzy classifier to speed the labeling process. The strategy is proposed after completing the following steps: a) manual annotation of a part of the Glissando corpus with Sp_ToBI labels and checking of the coherence of the labels; b) training of the automatic system; c) validation or correction of the automatic system's predictions by a human expert. The automatic judgments of the classifier are enriched with confidence measures that are useful to represent uncertain situations concerning the label to be assigned. The main aim of the paper is to show that there exists a correspondence between the uncertain situations that are identified during an inter-transcriber experiment and the uncertain situations that the fuzzy classifier detects. Labeling time reduction encourages the use of this strategy.

The production and perception of L1 and L2 Dutch stress.
This study aims at exploring the production and perception of Dutch word stress by Francophone learners of (Belgian) Dutch. For this purpose a production experiment was first carried out. In line with other studies, it was hypothesized that participants would show a tendency to stress the final syllable. Even though this hypothesis was confirmed, there was also a substantial lack of agreement between the five labellers who perceptually annotated the data for stress position. To further investigate this matter, acoustic measures were extracted. The data suggest that both groups of speakers do not use acoustic

correlates to signal prominence in the same way, the Dutch group using intensity, vocalic nucleus duration and pitch movement more, while the French group prefers duration and pitch movement. This study also led us to develop tools to phonetise, syllabify and facilitate the acoustic analysis of Dutch speech.

Evaluation of bone-conducted ultrasonic hearing-aid regarding transmission of speaker gender and age information

Human listeners can perceive speech signals in a voicemodulated ultrasonic carrier from a bone-conduction stimulator, even if the listeners are patients with sensorineural hearing loss. Considering this fact, we have been developing a bone-conducted ultrasonic hearing aid (BCUHA). The purpose of this study was to assess the usefulness of the BCUHA in transmission of speakers' physical attributes: gender and age. The evaluation used gender and age-identification experiments. The experiments were also conduced under air-conduction (AC) and cochlear implant simulator (CIsim) conditions. The results showed that: the BCUHA can well transmit speakers' gender information; the BCUHA can transmit speaker age information better than CIsim.

Rhythm and Expression in The Cat in the Hat

In recent years, there has been increasing interest in whether rhythmic interventions support young children's literacy development [1]. To begin to explore this connection, we assessed several aspects of rhythmicity and expressivity of productions of the notably rhythmic and rhyming children's book, The Cat in The Hat by Dr. Seuss. Participants subjectively rated either the rhythmicity or expressivity of speech taken from recordings of the book read aloud. These perceptual ratings were correlated with acoustic measures of rhythmicity and expressivity. Moreover, we observed a surprising lack of consistency between perceptual ratings of rhythmicity and expressivity. However, we observed a consistent relationship between the perceptual ratings of the first couplet of verses and the second. These findings can inform our investigation of the role of rhythm in literacy development.

Lengthened Consonants are Interpreted as Word-Initial

Prosody facilitates listeners' segmentation of the speech stream into a sequence of words and phrases. With regard to speech timing, vowel lengthening is interpreted as a cue to an upcoming boundary, in accordance with the iambic-trochaic law. However, the impact of consonant lengthening on segmentation, in the absence of other boundary cues, has not been tested. In a series of artificial language learning experiments, we examined how durational variation affects listeners' extraction of novel trisyllables defined by transition probabilities. In line with previous research, syllables containing lengthened vowels were interpreted by listeners as word-final. However, syllables with lengthened onset consonants were interpreted as word-initial. Thus, the structural interpretation of durational variation depends upon localization: longer vowels cue a following boundary; longer consonants cue a preceding boundary.

Prosody patterns of feedback expressions in Hungarian spontaneous speech

Speech communication incorporates non-verbal signals and semi-lexical vocal phenomena as well as words used as the listener's responses to the speaker's message. They are most common in conversation with various functions regardless of language. A specific subcategory is feedback expressions (FEs) that can be found in the listener's production as well as in the current speaker's speech production when reacting to the former speaker's message. This paper reports on the temporal and intonational characteristics of four types of FEs identified in 20 interviews and conversations from the BEA Hungarian database. Altogether 262 occurrences were categorized into four discourse functions signaling 'attention', 'comprehension', 'agreement' and 'other attitude'. Durations showed statistically significant differences across

discourse functions. They were significantly longer in females than in males in all functions. The pitch range data revealed a statistically significant difference depending on discourse function and gender only in the case of the 'attention' function. The dominant frequency contour was a rise in the functions of 'attention' and 'agreement' (90%). The same contour was observed only in 75.5% of the 'comprehension' function. An integrated approach is proposed to analyze these phenomena in spontaneous speech.

Eduardo Patricio Velázquez Patiño,
Intonation Patterns of Morelos Nahuatl
There are still relatively few studies on the phonetics and phonology of the indigenous languages of Mexico, and just a minority of them deals with less explored areas like prosody or, specifically, intonation. This study reports a preliminary analysis of Nahuatl intonation, taking into account its phonological characteristics: a) trochaic binary rhythm; b) generation of secondary stress inside rhythmic structures; c) generation of rhythmic groups according to clause structures; d) phonetic syllable lengthening at the end of sentences; e) laryngealization or voicelessness at the end of utterances, and f) vowel lengthening. Data collected by means of different methods, developed in order to obtain authentic and spontaneous utterances, show that different sentence types tend to have specific intonation patterns with many typologically common features and some original characteristics.

Amelia Kimball, Jennifer Cole,
Avoidance of Stress Clash in Perception of American English
We examine stress clash in perception, asking to what degree listeners perceive speech as metrically regular. We assess metrical regularity through a stress perception task carried out by untrained listeners annotating transcripts of spontaneous conversation and sentences designed to be metrically regular. Results show listeners report perceiving fewer stress clashes than predicted by random placement of stresses or by concatenating the citation form stress patterns of each individual word in a given sentence. These results suggest that listeners perceive spontaneous conversational English as metrically regular.

Transitions, pauses and overlaps: Temporal characteristics of turn-taking in Czech
This study aims to describe temporal characteristics of pausing and turn-taking phenomena in conversation. The material comes from the VASST corpus of contemporary Czech and uses four spontaneous dialogues in the form of an informal interview. We describe both general and idiosyncratic effects found in our data and compare them with results from other languages. In our material, transitions with a silent gap, overlaps and back-channels all display notably similar durational distributions with the median around 360 ms and a marked skewing. The four dialogues did not differ in the proportion of turns belonging to the interviewer (58%) vs. interviewee (42%), which is hypothesized to characterize the experimental task. Despite a number of general tendencies, individual differences in pausing and turn-taking behaviour of the speakers were found as well. For instance, the ratio of pauses and gap transitions proved to be highly dialogue-specific. We also gathered evidence for a substantial change in the speech behaviour of the interviewer resulting from a change of her communication partner.

Candide Simard, Claudia Wegener, Albert Lee, Faith Chiu, Connor Youngberg,
Savosavo word stress: a quantitative analysis
This paper presents a quantative analysis of stress in Savosavo (unclassified), an endangered language spoken on Savo Island, (Solomon Islands). Acoustic analyses comprise the measurements of F0, duration, and intensity for each syllable in a dataset carefully selected from elicited speech from one speaker only, aiming to test the effect of increasing morphological complexity on stress realization in a system that displays some variation. Statistically significant variation is found in all correlates between stressed and unstressed syllables, thus fitting with widely attested manifestations of stress cross-linguistically. Findings were further tested with a re-synthesis tool, to confirm our initial hypotheses. Our results demonstrate that the current annotation scheme is a reliable representation of the data, and that the qTA component embedded in PENTAtrainer is effective in modelling F0 contours, even with less controlled data as input. We will argue for the usefulness of instrumental phonetic investigations in describing lesser-known languages, to enhance our understanding of the characterization of the prosodic systems of the world's languages.

The Perception of Prosodic Focus in Persian
In a previous production experiment, post-focus compression (PFC) of F0 and intensity were found to be present in Persian. It was also shown that F0 and duration were the main correlates of prosodic focus in Persian. However, the perceptual relevance of PFC in Persian was not yet clear. The present paper reports the findings of an experiment on focus perception in Persian. Native speakers of Persian listened to sentences produced with focus in different positions as well as the neutral-focus sentence, and judged the presence and location of focus. Results show that final focus is identified much less well than other types of focus, and most of its confusion is with neutral focus. This shows that the presence of PFC is a main factor in recognizing prosodic focus in Persian.

Catherine Lai,
Final Rises in Task-oriented and Conversational Dialogue
This paper examines the distribution of utterance final pitch rises in dialogues with different task structures. More specifically, we examine map-task and topical conversation dialogues of Southern Standard British English speakers in the IViE corpus. Overall, we find that the map-task dialogues contain more rising features, where these mainly arise from instructions and affirmatives. While rise features were somewhat predictive of turn-changes, these effects were swamped by task and role effects. Final rises were not predictive of affirmative responses. These findings indicate that while rises can be interpreted as indicating some sort of contingency, it is with respect to the higher level discourse structure rather than the specific utterance bearing the rise. We explore the relationship between rises and the need for co-ordination in dialogue, and hypothesize that the more speakers have to co-ordinate in a dialogue, the more rising features we will see on non-question utterances. In general, these sorts of contextual conditions need to be taken into account when we collect and analyze intonational data, and when we link them to speaker states such as uncertainty or submissiveness.

Philippe Martin,
Spontaneous speech corpus data validates prosodic constraints
In the Autosegmental-Metrical model, the prosodic structure is defined as a hierarchy of Accent Phrases (AP). Groups of AP form intermediate prosodic phrases ip, which in turn are grouped into Intonation Phrases IP, and finally sequences of IP form the sentence intonation unit. In this hierarchy several constraints affect the prosodic structure, such as the AP 7 syllables rule, the stress clash conditions, eurhythmicity and syntactic clash. These constraints have been established essentially from read sentences data. They lead to an experimental justification in the observed synchronization of AP's syllabic chunking by Delta brain waves. This paper investigates the validity of the prosodic structure constraints on spontaneous speech data in French, as well as the adequacy of the Delta waves characteristics to

synchronize AP data.

Michael Phelan,
Hearing the Structure of Math: Use and Limits of Prosodic Disambiguation for Mathematical Stimuli
Listeners use the prosodic cues of an utterance to help determine its syntactic structure, but how does this process happen in the specialized domain of mathematics? Mathematical expressions can contain deeply embedded structures, and listeners encounter read mathematical expressions (RMEs) far less frequently than other potentially ambiguous utterances. How does experience with listening to math affect our ability to hear the structure of an RME via its prosody? Are there limits to the amount of structure we can pull out of the prosody of an utterance? A perception experiment was conducted with subjects aged 7-59 to help answer these questions. Participants heard recordings of RMEs and attempted to determine which of two or more mathematical structures the reader intended. When subjects chose between two options for phrases like nine times A minus two, they chose the mathematical expression that had bracketing matching the prosody of the utterance. However, for more complex phrases like the square root of sixteen over A plus twelve, results were at chance. Age played a surprising role: subjects' performance increased dramatically from age 7 to 16, but adults' performance varied widely. This is attributed to variation in exposure to read mathematics.

Sujan Kumar Roy, Md. Khademul Islam Molla, Keikichi Hirose,
Robust Pitch Estimation using Ensemble Empirical Mode Decomposition
This paper presents an efficient pitch estimation algorithm for noisy speech signal using ensemble empirical mode decomposition (EEMD) based time domain filtering. The dominant harmonic of noisy speech is enhanced to make pitch period more prominent. The normalized autocorrelation function (NACF) of the modified signal is then decomposed into time varying subband signals using EEMD. In contrast to the ordinary EMD, it does not introduce any mode mixing during decomposition. The subbands containing pitch component are selected and separated yielding partially reconstructed signal. The pitch period is determined from thus separated signals. The experimental results show that the proposed algorithm performs better compared to other recently reported algorithms in noisy environment.

Mónica Domínguez, Mireia Farrús, Alicia Burga, Leo Wanner,
The Information StructureProsody Language Interface Revisited
Several grammar theories relate information structure and prosody, highlighting a major correspondence between theme and rheme, and intonation patterns. Although these theories have been successfully exploited in some specific speech synthesis applications, they are mainly based on short default-order sentences, which limits their expressiveness for real discourse with longer sentences and complex structures. This paper revises these theories, identifying cases in which they are valid, and providing a new proposal for cases in which a more complex model is needed. Specifically, our experiments performed on real discourse from the Wall Street Journal corpus show that we need a model that: (1) foresees a hierarchical theme/rheme structure, and (2) introduces, apart from the traditional theme and rheme, a new element—the specifier.

Prosody is perceived in the gestures of the speaker
It has been suggested that speech and hand gestures could form a single system of communication that facilitates the interaction between the speaker and the listener. What kind of information do gestures carry? In the present study, two experiments test the possibility that spontaneous gestures accompanying speech carry prosodic information. Experiment 1 shows that gestures provide prosodic information as adults are able to perceive the congruency between a low-pass filtered thus unintelligible - speech stream and the gestures of the speaker. These results show that prosody is not a modality specific phenomenon

and can be perceived in spontaneous gestures that accompany speech.

Joseph Tyler,
Rising pitch and quoted speech in everyday American English
Phonetic variation in rising pitch has been analyzed for how it correlates with contextual factors like speaker gender, utterance type (questions vs. statements) and turn position (turn-medial vs. turn-final). This paper analyzes variation in terminal rising pitch between quoted and non-quoted speech, using data from the Santa Barbara Corpus of Spoken American English. Results show rises in quoted speech start and end higher, rise more overall, but are no different in duration. These results are gender-dependent, however, for while women produce 65% of all rises in the corpus sample, they produce 100% (n=23) of the quoted speech rises.

2.4.35 p.553

Daniel Aalto, Stina Ojala,
Fine temporal structure of Finnish sign language
Signs can be divided to syllables and further into transitions and nuclei based on the signing flow of the handshapes. Here, a mixed effects linear regression model is used to describe the variation in the duration of the syllable nuclei in a data set of 341 signs (474 syllables) produced by five native FinSL signers during a map task. The phonetic fixed variables are the duration of the adjacent transients and syllable nuclei; phonological fixed variables are the syllabic length of the sign, the syllable position within the sign, and the sign type (functional or content bearing). Both preceding and following nucleus had a significant effect on the nucleus duration, while an asymmetric effect was found for the transitions: only the postnuclear transition had a significant effect. The syllable structure had no effect. However, the nuclei were shorter in function signs. These results suggest that signs are produced in two stages where the first stage, preparatory transition, is merged with the production of the previous syllable, and the second stage consists of executing the sign.

Hiroko Muto, Yusuke Ijima, Noboru Miyazaki, Hideyuki Mizuno,
Pause insertion prediction using evaluation model of perceptual pause insertion naturalness
This paper describes a pause insertion prediction technique for generating more natural synthesized speech for text-to-speech (TTS) synthesis systems. A novel point of the proposed technique is the use of an evaluation model of perceptual pause insertion naturalness in addition to a prediction model based on machine learning. The evaluation model represents the relationship between several features related to pause insertion and the perceptual pause insertion naturalness obtained in a subjective evaluation. First, using a prediction model based on machine learning, we obtain the N-best sequences that indicate whether or not a pause is present at each phrase boundary. We then estimate pause insertion naturalness scores for each N-best sequence using the evaluation model and select the sequence with the highest naturalness score. Objective and subjective evaluation results show that the proposed technique gives better results than a conventional technique.

Sophie Herment, Nicolas Ballier, Elisabeth Delais-Roussarie, Anne Tortel,
Modelling interlanguage intonation: the case of questions
In this paper, we study the intonational patterns observed in learners' productions in order to evaluate what motivates the deviations observed: systemic differences between the learners' L1 and the L2, differences in phonetic implementation, etc. The analysis consists of a cross-comparison of the intonation of yes-no questions in French, English and English as an L2. It is based on five information-seeking yes-no questions that were extracted from the AixOx corpus, which contains a set of 40 texts that were read by 10 native French speakers, 10 Native English speakers and 20 French learners of English. The analysis of the data showed that the differences between native and non-native speakers do not affect

the form of the nuclear contour. It mostly shows that French speakers of English have a tendency to assign a rising pitch movement at the end of any prosodic words, which leads to a clear difference in rhythm.

2.4.38 p.563

Fabian Santiago, Paolo Mairano, Elisabeth Delais-Roussarie,
Non-native perception of final boundary tones in French interrogatives
In this paper, we report a perception experiment in which native and non-native listeners judged resynthesized questions varying in respect to two aspects: their morphosyntactic structure (presence/absence of an interrogative marker) and the form of their final tonal contour (falling, rising and extra rising). The goal of the experiment was to exanimate how non-native listeners of French did perceive the extra-rising final contour that was observed in learners' productions. Do they consider it as unmarked form during the acquisition process? By and large, the results of the experiment show that native listeners preferred rising contours over falling ones in all question types, whereas non-native listeners rated the extra rising contours higher than French natives in stimuli having a morphosyntactic structure that differs from the one used in their L1. These results suggest that rising contours represent a default tonal form associated with the interrogative modality at the beginning of the L2 acquisition process.

Katalin Mády, Ádám Szalontai,
Where do questions begin? – phrase-initial boundary tones in Hungarian polar questions
Hungarian prosody is left-headed, as suggested by the placement of the accent on the initial syllable on the level of prosodic words and the placement of the strongest pitch accent on the first accented word of the prosodic phrase. Earlier studies have pointed out that the left edge of the intonational phrase can bear a phrase-initial boundary tone that distinguishes between string-identical wh-interrogatives and wh-exclamatives. In this paper, two other string-identical sentence types, polar questions and declaratives, are investigated with respect to their prosodic features. Polar questions were characterised by a higher f0 maximum and a lower sentence-initial f0 than declaratives. The only pitch accent within the sentence was low, whereas declaratives had falling pitch accents. Sentence-final f0 and the pitch level of the accented syllable did not show a consistent pattern across speakers. It is concluded that low sentence-initial f0 together with the high tone on the penultimate syllable is a relevant marker of polar questions in Hungarian.

Xiaoming Jiang, Marc Pell,
Encoding and decoding confidence information in speech
This study aims to investigate the perceptual-acoustic correlates of vocal confidence. Statements with different communicative functions (e.g., stating facts, making judgments) were spoken in confident, close-to-confident, unconfident and neutral voices. Statements with preceding linguistic cues (e.g. I'm positive, Most likely, Maybe, etc.) or no linguistic cues were presented to sixty listeners in a perceptual study. The listeners were asked to judge whether statements conveyed some level of confidence, and if so, they were asked to evaluate the level of confidence of the speaker. The results demonstrated that the intended levels of confidence varied in a graded manner in the perceptual rating score; the more confident the statement intended to be, the higher the rating. In general, the neutral voice was judged to be more confident than the close-to-confident voice, but less than the confident voice. The presence of a linguistic cue tended to increase ratings of confident voices but decrease ratings of voices in the less confident voice conditions. To evaluate how specific prosodic cues are used to encode and decode confidence information, acoustic analyses were performed on the stimuli without the linguistic cue based on the mean perceptual rating of speaker confidence for each item. Results showed that statements rated as confident versus unconfident differed in the mean and the variance of fundamental frequency (f0) as well as speech rate, with confident statements exhibiting lower mean f0, smaller f0 variance, and faster speaking rate than unconfident statements. The perceived level of confidence was differentiated in the mean fundamental frequency in a parametric way, the lower the level of confidence, the higher the mean f0. Confident voices were also distinct from the other three conditions in terms of mean and range of amplitude (i.e., loudness). These findings shed light on how linguistic and paralinguistic cues reveal confidence-related information to listeners during speech.

Jane Kühn,
Aspects of Prosodic Phrasing in Turkish
This pilot study investigates the prosodic marking of contrastive in-situ focus in monolingual Turkish. The results of the production study are based on a phonological and phonetic analysis of information structure modified target sentences. The prosodic analyses reveal (i) feature that derive properties of prosodic phrasing which are inherent to phrase languages. It is shown that Turkish is a radical splitting language since each prosodic word (ω) forms its own phonological phrase ϕindicated by a high phrase tone (H-) aligned to ω- final syllables. The languages preference for radical splitting of simple SOV sentences is maintained in information structure modified targets by one speakers group, but modified by another group in favor of wrapping adjacent given constituents into one ϕ. The analyses reveal (ii) that prosodic cues are not crucial to mark in-situ focus in Turkish, but they may be used to contextualize information structure. If focused constituents are marked at all by prosodic means they do not show an increased pitch like most Germanic languages, but focused constituents are aligned to prosodic boundaries. The data motivate the claim that prosodic alignment is an adequate way to describe the prosodic realization of focus in Turkish.

Perceptual evaluation of the effect of mismatched Fujisaki model commands and surface tone in Sesotho
Sesotho is a tonal Southern Bantu language which has so far received extremely little attention by the speech research community. We consider tone modelling for Sesotho using the Fujisaki model-based analysis with a view to the development of a text-to-speech (TTS) system. Fujisaki analysis can be used to indicate the tone associated with a syllable, but it often differs from the surface tone that would be available for TTS synthesis. We investigate instances in which the surface tone differs from the tone indicated by Fujisaki analysis, and determine the effect of these discrepancies on speech quality. The amplitude of Fujisaki tone commands is manipulated to match the surface tones, and the resulting resynthesized speech subsequently analysed by perceptual tests. We find that the effect of inserting tone commands at high surface tone syllables is more severe than matching the Fujisaki tone commands with low surface tone syllables, in terms of naturalness. Furthermore, some discrepancies can be attributed to errors in the surface tonal transcription. However, on average, all manipulations lead only to a mild degradation in speech quality. We conclude that the Fujisaki model is a feasible way to model tone in Sesotho even in the presence of limited and under-developed linguistic resources.

Suki Yiu,
Musical Intervals of Tones in Cantonese English
It has been shown that the relative pitch levels of Cantonese tones closely correspond to musical intervals (MIs). Given that an emerging tone language, Cantonese English, has developed tone under the substrate influence of Cantonese, this paper examines the correspondence between the newly emerged tones and MIs, and how the musical analogy relates to those established for Cantonese. The fundamental frequencies of the tones produced by six speakers of Cantonese English were extracted with Praat, then time-normalized across rhymes. The mean values of the interval points of two tones were expressed in terms of ratio, then matched with the closest MI on the musical scale. This paper demonstrates that the pitch levels of tones in Cantonese English correspond to MIs, given the converging ranges of MIs for different speakers and similar MIs of different tone pairs for different speakers. It also shows that the MIs of tones in Cantonese English are related to the corresponding tone pairs for Cantonese. The viability of MI as a means to understand the tonal system of non-tonal languages whose speakers' native language is tonal extends the link between the use of pitch in speech tones and music.

Rhythmic Patterns in Native and Non-Native Mandarin Speech
Rhythm plays an important role in the naturalness of speech. This study compared rhythmic patterns

of Mandarin speech between native speakers and two groups of L2 speakers whose first languages were Cantonese and English, respectively. The study started from isolated words, but focused on continuous speech, for which eleven durational metrics were used as objective rhythm indicators. The results on continuous speech showed that nonnative Mandarin gave a quite similar rhythmic mode as native one in terms of rate-normalized/independent metrics, but shifted towards the stress-timed class in terms of raw metrics, regardless of the rhythmic class of the L1. This seems to conflict with the L1 transfer effect and the results for isolated words, but it coincides with auditory impression and can be explained by speech rate difference and the lengthening effects associated with the change in prosodic structure.

3 Day Three

3.1 Thursday Session One

May 22nd, 9am - 10:30am : 3-1-plenary (1+3 presentations)

3.1.1 KeyNote 3 (p.598)

Jürgen Trouvain 30-min
Laughing, breathing, clicking the prosody of nonverbal vocalisations

When analysing human spoken communication the focus on the linguistic side lies on speech with its verbal message, whereas the focus on the non-linguistic side usually is on the visually transported information such as gestures and facial expression. However, speech, especially in talk-in-interaction, also features numerous nonverbal vocalisations including various forms of laughter and inhalation noises as their most frequent forms. Although nonverbal vocalisations are usually short in duration they may provide rich information on linguistic, paralinguistic and extralinguistic levels including prosodic phrasing, cognitive load, affective state or speaker identity. The talk provides an overview on the phonetic and prosodic structure and the timing of laughter and audible breathing. Special attention is put on conversational speech where we can frequently find situations in which interlocutors temporally overlap. An emphasis is given to apical click sounds that often occur with inhalation before upcoming articulation but also during word-finding difficulty.

Tuning in to whispered boundary tones
Very little is known about how listeners incorporate "intonational" information in whispered speech during online language processing. We present data showing that listeners can incorporate information about boundary tones in whispered speech rapidly, but this process is complicated by additional structural biases as well as by the fact that speakers do not produce cues to boundary tones consistently in whisper. Listeners, however, are able to adapt to these differences in order to correctly identify different boundary tones in whisper.

3.1.3 p.608

Oliver Niebuhr,
"A little more ironic" Voice quality and segmental reduction differences between sarcastic and neutral utterances
The presented production experiment analyzes the phonetic differences between neutral (i.e. sincere) and sarcastically ironic utterances in German. Results show in line with previous studies that sarcastic irony is expressed by longer utterance durations, lower and flatter F0 contours, and a lower intensity level. Moreover, extending previous findings, sarcastic irony is also characterized by a more variable (in tendency breathier) voice quality and a higher degree of segmental reduction, probably reflecting the speakers' dissociation from the wording of their utterances.

Is breathing sensitive to the communication partner?
This paper investigates breathing profiles in eleven female speakers (subjects) when talking successively with the same two females (partners). Breathing kinematics of the two interlocutors was recorded synchronously by means of two Inductance Plethysmographs. In order to understand the implication of breathing in dialogue, we analyzed changes in breathing pauses according to the main dialogue events (listening, backchannels, turns start and turns continuation). Breathing and syllable rates were also compared among partners and subjects. The duration of inhalations and related pauses was reduced before a turn continuation in comparison to a turn start. The delay between speech offset in a breathing cycle and the onset of the next inhalation increased when a speaker and a listener swap roles as compared to a speaker who continued the turn. This was observed for both partners and subjects. The partners differed in their breathing and articulation rates but the two rates were not clearly correlated. In agreement with previous works, the current study shows that breathing kinematics is strongly linked to dialogue events. However, it doesn't show any clear effect of partner on speaker's breathing. This last result is discussed relative to methodological aspects.

Carlos Gussenhoven, Lu Wang,
Yuhuan Wu tone and the role of sonorant onsets
Co-occurrence restrictions on tones and consonants in Yuhuan Wu Chinese syllables provide a powerful illustration of the phonetic basis of phonological contrasts, with sonorant contexts allowing more tone contrasts than other contexts. Interestingly, the language also reveals that the phonetic implementation of tones depends on the phonological contrast it is involved in. Such phonetic enhancement may be the opposite of what could be expected on the basis of speech ergonomics. Moreover, the language has two tone deletion rules that exempt tones in the context with the largest number of contrasts, showing a phonological version of enhancement.

An Investigation of Prosody in Hindi Narrative Speech
This paper investigates how prosodic elements such as prominences and prosodic boundaries in Hindi are perceived. We approach this using data from three sources: (i) native speakers of Hindi without any linguistic expertise (ii) a linguistically trained expert in Hindi prosody and finally, (iii) automatic classifiers trained on English for prominence and boundary detection. We use speech from a corpus of Hindi narrative speech for our experiments. Our results indicate that non-expert transcribers do not have a consistent notion of prosodic prominences. However, they show considerable agreement regarding the placement of prosodic boundaries. Also, relative to the non-expert transcribers, there is higher agreement between the expert transcriber and the automatically derived labels for prominence (and prosodic boundaries); this suggests the possibility of using classifiers for automatic prediction of these prosodic events in Hindi.

3.2.3 p.628

Zenghui Liu, Aoju Chen, Hans Van de Velde,
Prosodic focus marking in Bai
This study investigates prosodic marking of focus in Bai, a Sino-Tibetan language spoken in the Southwest of China, by adopting a semi-spontaneous experimental approach. Our data have shown Bai speakers increase the duration of the focused constituent and reduce the duration of the post-focus constituent to encode focus. However, duration is not used in Bai to distinguish focus types differing in size and contrastivity. Further, pitch plays no role in signaling focus and differentiating focus types. The results thus

suggest that Bai uses prosody to mark focus, but to a lesser extent, compared to Mandarin Chinese, with which Bai has been in close contact for decades, and Cantonese, to which Bai is similar in the tonal system.

3.2.4 p.633

Maria Paola Bissiri, Margaret Zellers, Hongwei Ding,
Perception of Glottalization in Varying Pitch Contexts in Mandarin Chinese
Although glottalization has often been associated with low pitch, evidence from a number of sources supports the assertion that this association is not obligatory, and is likely to be language-specific. Following a previous study testing perception of glottalization by German, English, and Swedish listeners, the current research investigates the influence of pitch context on the perception of glottalization by native speakers of a tone language, Mandarin Chinese. Listeners heard AXB sets in which they were asked to match glottalized stimuli with pitch contours. We find that Mandarin listeners tend not to be influenced by the pitch context when judging the pitch of glottalized stretches of speech. These data lend support to the idea that the perception of glottalization varies in relation talinao language-specific prosodic structure.

Robert Bo Xu, Peggy Pik Ki Mok,
Cross-linguistic perception of Mandarin intonation
This study investigated how phonological knowledge and psychoacoustic mechanism interact in intonation perception. In the experiment, Mandarin and Cantonese listeners identified Mandarin statement and question in both unfiltered and low-pass filtered contexts. The results show that the importance of different perceptual factors varies depending on the perception materials. Language background plays an important role even in processing low-level psychoacoustic materials.

Segmental and prosodic cues to vowel identification: The case of /I i i:/ and /U u u:/ in Saterland Frisian
Saterland Frisian has a complete set of closed short tense vowels. Together with the long tense vowels and the short lax vowels they constitute series of phonemes that differ by length and/or tenseness. We examined the cues that distinguish the front unrounded and the back rounded series of short lax and short and long tense vowels in triplets by eliciting 'normal speech' and 'clear speech' in a reading task from two speakers. Short and long vowels were distinguished by vowel duration, and lax and short vowels by their location in the F1-F2 space. The durational difference between short tense and long tense vowels, however, was largely restricted to the 'clear speech' condition. In 'clear speech', f0 excursion and centralization in the F1-F2 space were used as additional means to make short tense vowels more distinct from long tense vowels. These results suggest that length and tenseness are used as distinctive features, while f0 excursion and centralization in the F1-F2 space were optionally used to enhance the contrast between short and long tense vowels.

An acoustic-perceptual approach to the prosody of Chinese and native speakers of Italian based on yes/no questions
The present study investigates the prosody of yes/no questions (in comparison with statements) in Chinese learners and native speakers of Italian. Acoustic analyses and a perceptual test were performed, in order to identify the main trends in non-native productions. Results show the relevance of prosody, which differentiates elementary, intermediate and advanced Chinese learners of Italian. Listening tests based on prosody transplantation also suggest that non-native segments with a native Italian prosody are rated as less accented than are native Italian segments with a non-native prosody. Similar trends were found, overall, in terms of question/assertion discrimination, confirming the relative importance of prosody. These findings could be helpful for teachers and learners of Italian as a foreign language.

Wei Lai, Ya Li, Hao Che, Shanfeng Liu, Jianhua Tao, Xiaoying Xu,
Final Lowering Effect in Questions and Statements of Chinese Mandarin Based on a Large-scale Natural Dialogue Corpus Analysis
To support text-to-speech with detailed prosody rules and generate natural prosody, the paper studied the pitch variation near the end of sentences based on a Chinese natural dialogue corpus. An additional lowering effect on the last prosodic word was found in both questions and statements, and proved to be independent of tone influence. Nevertheless, this effect, which is referred to as final lowering in other languages, was claimed to be absent in Chinese by some previous experimental studies. The cause of such a contradiction is very likely to be the difference between experimental speech vs. natural speech. Based on this observation, this paper proposed a combination of the two methods in intonation studies, in which experimental speech serves as an entry point to develop new topics, and natural speech serves as a necessary extension to revise and apply prosody rules.

Intonation Unit Size in Spontaneous Hebrew: Gender and Channel Differences
In this corpus-driven research, the question of whether there is a tempo at the Intonation Unit (IU) level, and whether defined IUs differ not only with regard to their pitch contour and boundary tones but also with respect to their phonological size. For this reason, the inventory of syllable size (in terms of segments (phonemes)) and word size (in terms of syllables) was examined, and then each IU category (mainly Terminal vs. Continuous) was measured with respect to the number of syllables and words it contains. Moreover, terminal IU size was also measured with regard to the amount of embedded continuous IUs. Results showed that terminal IUs in spontaneous Israeli Hebrew (IH) do not necessarily consist of embedded continuous IUs. This can be explained due to their massive use as short feedback units in spontaneous speech. Statistical measurements for gender and channel (Face-to-Face vs. telephone conversations) variables were carried with no significance for gender, but with statistically significance for several channel aspects. Last, estimated durational measurements of the IU size are presented.

Acoustic Cues to Tone and Register in Bai: Adult Baseline Data
This paper presents the results of a study of the acoustic cues associated with the tense/lax distinction in Bai, a Tibeto-Burman register tone language spoken in Yunnan, China. The purpose of the paper is to provide baseline adult data for comparison with infant speech in an acoustic study of infants' acquisition of Bai register tones in the second and third years of life. The results show that among adults, F0, F1, and spectral tilt combine to create the tense/lax contrast in Bai. While these three cues tend to be correlated, individual speakers differ in their use, particularly spectral tilt. The patterns in this study suggest that as Bai infants acquire tones in the second and third years of life, their utterances are likely to become structured around these three acoustic cues in previously unattested ways that exemplify the complex interaction between universal physiological and developmental tendencies and the ambient phonological tone system of Bai.

Word accent and intonation in Baltic
We examine the realization of word accent contrasts in Standard Latvian and East Aukštaitian Lithuanian across intonational contexts. In our Latvian data the contrast is manifested as level vs. falling pitch in most contexts, in addition to a durational difference. In Aukštaitian Lithuanian, instead, differences in vowel quality and duration cue the lexical contrast in the nuclei that we examine. While Latvian retains a tonal contrast, in Aukštaitian Lithuanian it has been replaced with a combined segmental/quantitative contrast, where the so-called circumflex tone corresponds to relatively shorter duration and, in the case of diphthongs, centralized quality in the first half. We discuss the implications of these findings for further typological work.

Neville Ryant, Malcolm Slaney, Mark Liberman, Elizabeth Shriberg, Jiahong Yuan,
Highly Accurate Mandarin Tone Classification In The Absence of Pitch Information
A deep neural network (DNN) classifier based only on 40 mel-frequency cepstral coefficients (MFCCs) achieved 29.99% frame error rate (FER) and 16.86% segment error rate (SER) in recognizing five tonal categories in Mandarin Chinese broadcast news. With the addition of sub- band autocorrelation change detection (SACD) pitch-class features, the classifier scored 27.58% FER and 15.56% SER. These results are substantially better than the best previously reported results on broadcast-news tone classification, and are also better than a human listener achieved in categorizing test stimuli created by amplitude- and frequency-modulating complex tones to match the extracted F0 and amplitude parameters. The same DNN architecture scored substantially worse when trained and tested with SACD pitch-class parameters alone: 39.22% FER and 24.89% SER. RAPT F0 estimates are worse yet: 44.37% FER and 27.28% SER. The 40 MFCC parameters do not encode F0 in any obvious way and attempts to predict SACD or other pitch features from them work badly. These surprising results raise difficult questions for theories of Chinese tone.

Marzena Zygis, Daniel Pape, Luis Jesus, Marek Jaskula,
Intended intonation of statements and polar questions in Polish in whispered, semi-whispered and normal speech modes.
This paper provides acoustic correlates of intonation in whispered, semi-whispered and normal speech modes. In particular, it investigates correlates of utterance-final rising intonation in polar questions and falling intonation in statements. The paper does not only examine properties of vowels but also properties of the following voiceless consonant clusters. For the purpose of this study 2592 items produced by 16 native speakers of Polish were analysed. The results point to differences in spectral properties of both utterance-final vowels and consonants where falling intonation in statements contrasts with rising intonation in polar questions. Regarding the consonants, questions are produced with higher peaks, intensity, COG and STD values as well as smaller skewness and kurtosis values. Some spectral differences of consonants, including spectral slopes, are more distinguishable for questions versus statements in the whispered speech mode than in other speech modes. The more pronounced role of these cues in whispered speech suggests their compensatory function for the fundamental frequency, which is present in phonated speech. In summary, the study shows that speakers produce intended intonation patterns by varying the choice of cues as well as their magnitude in dependence on both (i) speech modes and (ii) intonation patterns.

Intonational Aspects of Imperatives in Mexican Spanish
This paper sheds new light on the intonation of imperatives in Mexican Spanish. Results from a production experiment based on scripted speech show that imperative sentences have two different nuclear configurations depending on the position of the imperative verb (VI): (i) (L+)H* L% with VI in sentence-final position, and (ii) L* L% with VI in non-final position. The pitch accent on VI in non-final position is characterized by a late peak (L+>H*). However, if the sentence is uttered with some sort of emphasis, the nuclear configuration in the non-final context can also be rising. While these results partly confirm claims made concerning the nuclear configuration in De-la-Mota et al. (2010), they contradict the findings in Willis (2002), who attested strong pitch accent variation on VI.

The acquisition of English lexical stress by Cantonese-English bilingual children at 2;06 and 3;0
This study investigates the acquisition of English lexical stress by Cantonese-English bilingual children at the age of 2;06 and 3;0 respectively, comparing them with the English monolingual peers. Research on early bilingual phonological acquisition often focuses on segmental level. Few studies are available when it concerns prosodic features, especially in children speaking non-Indo-European languages. This study

examines an important prosodic feature, lexical stress, in Cantonese-English bilingual children. The results showed that there is delayed acquisition of English lexical stress among the bilingual children, as reflected in less contrastive syllable duration and peak F0, possibly due to a lack of lexical stress in Cantonese, a typical syllable-timed language. This study helps to understand the bilingual interaction of two distinctive prosodic systems, and broaden our knowledge about early bilingual prosodic development.

Disentangling sources of rhythmic variability between dialects
Speech rhythm is highly variable. Previous studies reported variability between languages, dialects, speakers, and labelers. Research further revealed an effect of sentence in the rhythmic characteristics of speakers of the same language. In the present study we tested whether the effect of sentence material is constant across varieties of the same language. We addressed this question by an example of analyzing rhythmic variability between eight dialects of Swiss German in three different sentences. Results showed a significant interaction for dialect*sentence for most of the tested rhythm metrics. We take this as evidence that differences between dialects are contingent upon the sentences used in the experiment. We further investigated which sources in the sentence material caused between-dialect differences in rhythm scores to vary. W e found exemplary evidence that dialect-specific phonological and morphological phenomena contained in the individual sentences are the prime suspects. Implications for future speech rhythm research are discussed.

Dialectal variation at the Prosody-Syntax interface: Evidence from Catalan and Spanish interrogatives
In this study we investigate how prosody interacts with word order in the expression of interrogativity in different varieties of two Ibero-Romance languages, Catalan and Spanish. We analyze a corpus obtained by means of the Discourse Completion Task Methodology. The collected data were prosodically and syntactically annotated and show that the absence of syntactic marking (wh-word, subject-verb inversion or subject dislocation) for questions tends to correspond to a more salient intonational marking. Thus, wh-questions favor general falling intonational patterns. By contrast, yes-no questions can be classified depending on the nuclear tone (with preference for low tones in Catalan and high tones in Spanish) and final tone (low for language varieties with subject inversion or dislocation, but optionally high for those that do not present syntactic marking in a mandatory way.

Mathieu Avanzi, George Christodoulides, Elisabeth Delais-Roussarie,
Prosodic Phrasing of SVO Sentences in French
In the literature on prosody/syntax interface, syntactic information is usually considered as playing an important role in deriving the prosodic phrasing of an utterance. NP subjects, for instance, have often been claimed to phrase independently from the VP. It has nevertheless been shown that metrical factors could have an impact on phrasing, and that NPs could be phrased in the same prosodic phrase as the VP, or that the verb could be phrased with the subject. Several methods were used to measure metrical weight: number of syllables, of prosodic words, syntactic branchingness, etc. In order to determine which factors are more important, and how the all interact, we evaluate the weight that different metrical predictors have on prosodic phrasing. This is done by analyzing the phrasing of SVO structures in 200 sentences extracted from various French corpora. From the observation of the data that were semi-automatically annotated, it appears that subjects can be phrased independently or in the same PP as the VP, and that objects are rarely isolated from the verb. The analysis reveals interesting results regarding the effect of articulation rate and number of syllables, whereas syntactic-branchingness didn't show any effect.

Michelina Savino, Andrea Bosco, Martine Grice,
Intonational cues to item position in lists: evidence from a serial recall task
Intonation can convey information about how lists are structured into groups, as well as about specific item positions within a group. In Bari Italian, this function is expressed by three different tunes a) a rising contour, signalling that the list has not yet been completed; b) a high-rising contour, marking the penultimate item, i.e. signalling that the end of the list is approaching; c) a falling contour, marking the last item, i.e. cueing the end of the sequence. In this paper we explore the effects of such intonational information on working memory. In particular, we demonstrate that when listeners are requested to recall spoken nine-digit sequences by strictly following their serial order, their performance is significantly better when lists are characterised by tunes of the type described above, compared to sequences whose items are marked by a neutral, peak accent and/or are grouped by inserting a silent pause. We also observed that recall of items marked by specific contours at positions 3, 6 and 9 is particularly enhanced at these positions, whereas in sequences also containing intonational cues to items in penultimate position (2, 5 and 8) recall of those items is not equally improved. Therefore, it appears that in serial recall of spoken sequences, even when a large number of specific intonational cues to serial positions are available, listeners can make use of only a selection of them.

Anqi Yang, Aoju Chen,
Prosodic focus-marking in Chinese four- and eight-year-olds
This study investigates how Mandarin Chinese speaking children use prosody to distinguish focus from non-focus, and focus types differing in size of constituent and contrastivity. SVO sentences were elicited from four- and eight-year-olds in a game setting. Sentence-medial verbs were acoustically analysed for both duration and pitch range in different focus conditions. The children started to use duration to differentiate focus from non-focus at the age of four. But their use of pitch range varied with age and depended on non-focus conditions (pre- vs. post-focus) and the lexical tones of the verbs. Further, the children in both age groups used pitch range but not duration to differentiate narrow focus from broad focus, and they did not differentiate contrastive narrow focus from non-contrastive narrow focus using duration or pitch range. The results indicated that Chinese children acquire the prosodic means (duration and pitch range) of marking focus in stages, and their acquisition of these two means appear to be early, compared to children speaking an intonation language, for example, Dutch.

Simone Graetzer, Janet Fletcher, John Hajek,
Prosodic effects on vowel spectra in three Australian languages
In this paper, the spectral properties of vowels in three Australian languages are examined with the aim of determining whether prosodic prominence and domain-edge effects on formant frequencies, formant variability and vowel space dispersion can be identified. It is shown that these vowel systems are sufficiently dispersed, with an anchoring of the system by the open central vowel. It is also shown that for Burarra but not for Gupapuyngu or Warlpiri there is some evidence of prosodically-driven hyper-articulation. Finally, the data indicate pre-boundary lengthening in all three languages, which in some cases appears to be associated with changes in vowel quality.

Rhythmic Correspondence between Music and Speech in English Vocal Music
This study aims to investigate the rhythmic structures of music and speech, and to find out the possible corresponding rhythmic patterns between the two domains in English vocal music. With fifteen English songs as samples, lexical stress of multi-syllabic words is compared with three musical dimensionsmetrical stress, duration, and pitch respectively. It is found that in the chosen English songs, there is a good mapping between the metrical stress of music and the lexical stress of lyrics. In addition, the duration and the pitch patterns not only generally match lexical stress patterns most of the time, but also serve to manifest the prominence of the primary lexical stress on one hand, and to reflect the weakness of the unstressed syllables on the other. Except a general good match in rhythm, this study also shows

matching differences within the three comparisons. Matching degrees vary according to different meter patterns. Moreover, pitch takes priority over duration in their respective matching with lexical stress of the lyrics. Finally, the primarily stressed syllables match duration and pitch patterns much better than the unstressed ones do. Index Terms: Musical rhythm, Speech rhythm, English songs

Speech rhythm and vowel raising in Bulgarian Judeo-Spanish
The study investigates selected prosodic characteristics of (Sofian) Bulgarian Judeo-Spanish, a diaspora variety of Spanish spoken by descendants of the Jews expelled from Spain, all of them bilingual speakers with Bulgarian as their dominant language. While exhibiting some few relics from Old Spanish on the segmental level, Judeo-Spanish shows a puzzling similarity with Bulgarian with respect to speech rhythm and vowel raising. It is shown that the two languages spoken by the bilinguals, Bulgarian and Judeo-Spanish, pattern alike in displaying almost the same rhythmic values (except for %V) and that raising of unstressed /a/ and /o/ as is typical of the variety of Bulgarian spoken in Sofia also regularly occurs in the Judeo-Spanish data. Our findings show that Judeo-Spanish is crucially influenced by Bulgarian, thus suggesting that it has largely converged toward the surrounding language on the phonological level.

Sandra Schwab, Carla V. Jara Murillo,
The role of stress perception in the assignment of written accent in Spanish
The aim of this investigation is to examine whether the adults' difficulty in placing the written accent in Spanish words is related to their ability in perceiving stress. The following variables were also taken into account in this study: the participant's education level (academic and non-academic), the stimulus lexical status (words and non-words), accentual pattern (proparoxytone, paroxytone and oxytone words) and length (2, 3 and 4 syllables). Participants performed a stress identification task and a word spelling task. Besides the effects of lexical status, education level and accentual pattern, results show an effect of the stress perception in the assignment of the written accent: stimuli with a correctly identified stress were more likely to be correctly written (i.e. with or without written accent) than the incorrectly perceived stimuli. This finding reinforces the idea that there is a relationship between prosodic and written skills.

Uwe Reichel, Alexandra Markó, Katalin Mády,
Parameterization and automatic labeling of Hungarian intonation
In Hungarian intonation research a common framework developed by Varga (2002) is to categorize the intonation within the domain of accent groups by character contours. We propose a linear parameterization of a subset of these contours derived from polynomial stylization. These parameters were used to train classification trees and support vector machines for contour prediction. Parameter extraction and training was carried out on the original F0 contours of spontaneous speech data as well as on three differently normalized variants suppressing fundamental frequency level and range effects. The highest accuracies were obtained for classification trees and F0 residuals after midline subtraction, but the overall performances were rather poor. Nevertheless, a significant improvement of the results was achieved by a Hidden Markov model to predict the correct label sequence from the partly erroneous classification output.

Local and global convergence in the temporal domain in Polish task-oriented dialogue
Conversational parties tend to mutually adapt their communicative behaviour in a number of dimensions, from the level of physical aspects of speech signal and gesture, utterance properties, up to the level of mental representations. In the present study, an attempt is made to track the process of convergence in the temporal domain both as a global tendency and a local phenomenon. The material under study consists of two sets of task-oriented dialogues recorded with or without eye contact (telephone conversations) between the speakers. All the recordings were segmented into syllables and analysed in terms of speech rate and nPVI for each speaker as well as for the correlations between the speakers in each pair. Global convergence tendencies were proven to be weak but some influence of dialogue settings and gender was

found. The results seem to support the hypotheses that the alignment-related processes remain under the influence of many factors related to the dialogue flow and cannot be modelled as simply incremental.

Beatriz Raposo de Medeiros, Fred Cummins,
Speech and song synchronization: A comparative study
Does synchronization among speakers or singers require the presence of a beat? Is an implied underlying pulse or meter relevant? We set out to explore synchronization among speakers and singers as they speak or sing a variety of texts. We compare metrically strong nursery rhymes with non-metered prose. We compare singing in genres with two very different types of rhythm (samba and rock), and we compare sung and spoken versions of texts. In each case, we ask whether the rhythmic qualities of the texts facilitate synchronization. The metrical structure of the nursery rhyme does not facilitate synchronization compared to prose, while the simple beat of rock music does help. Further comparisons are provided in the text.

Accentual phrases in Slovak and Hungarian
Languages with primarily delimitative function of word stress commonly make use of accentual phrases (APs) in their intonational phonology (e.g. Tamil or French). Slovak and Hungarian are genetically unrelated but geographically close languages with word-initial lexical stress. In this paper we compared the stylised f0 of single accent groups (AGs) with the f0 level pattern of the entire intonational phrase (IP) to test if AGs are relevant for the intonational phonology of Slovak and Hungarian. Steep f0 slopes with a recurring pattern (rising or falling) and large deviations from IP level patterns were interpreted as evidence for the autonomy of the AG in the given language. The results suggest that Hungarian is indeed a language in which accent groups form a unit on their own, however, such evidence was not found for Slovak.

Nicole Dehé,
Final devoicing of /l/ in Reykjavík Icelandic
Icelandic has a phonological process which devoices sonorants after voiced segments in domain-final position, but to date the category of the relevant domain and potential further factors affecting it have not been identified. The present paper studies final devoicing of /l/, by which /l/ is realized as the voiceless lateral fricative [ɬ] in domain-final position. It reports on the results of an experimental reading study designed to test the exact environments of this process and the implications for a prosodic hierarchy for Icelandic. The results suggest that devoicing of /l/ is bound by the prosodic utterance. All instances of /l/ were devoiced in utterance final position. Within the utterance, final devoicing is optional, but the frequency of its application reflects the syntactic and prosodic hierarchy such that it is most frequent at a clause/an IP-boundary, significantly less frequent at a syntactic XP-edge and it almost never occurs within a syntactic XP.

Scott Lee,
The Realiziation of French Rising Intonation by Native Speakers of American English
This study examines the acquisition of French intonational rises by adult native speakers of American English. Production data were gathered using a discourse completion task and a storytelling task from eight American college students beginning a semester-long study abroad program in Southern France. Results suggest that speakers struggled with two particular aspects of French intonation: the grouping of words into Accentual Phrases, and the phonetic realization of phrase-final rises. In particular, the probability distribution for the alignment of the late L elbow was bimodal for L2 speakers but unimodal for L1 speakers, suggesting the use in the learner speech of two distinct tonal patterns instead of the single French LH*. Mean values for overall pitch range and the scaling of continuative rises were significantly

lower and less variable than French L1 values as well.

Monosyllabic Lexical Pitch Contrasts in Norwegian
This paper examines the lexical tonal accent contrast in monosyllabic words in the Trondersk dialect of Norwegian. The results of a production experiment in which speakers produced the unmarked accent and the circumflex accent showed that the tonal distinction is characterized by a difference in f0 maximum, f0 height at onset, f0 minimum and its timing, and height of the final Accent Phrase H tone. The presence of the tonal accent contrast on monosyllabic words is unusual among dialects of Norwegian and Swedish.

Taiwanese Tone Recognition Using Fractionalized Curve-fitting of Prosodic Features
In this paper, we examined different methods of modeling prosodic features of tones, and their effects on a speaker-independent Taiwanese tone recognition system. Tones can be modeled either by plain or curve-fitted features. Plain features represent the original curve faithfully using pitch values, while curve-fitted features can be thought of as an approximation to the values using mathematical functions, such as a Legendre polynomial. In addition, durational information of tones was also proven effective in previous researches. Thus, we proposed a new approach of modeling Taiwanese tones using curve-fitted features extracted from fractions of the pitch curve, along with duration as an additional prosodic feature. Our experimental results showed that using these features in an SVM classifier could substantially improve the accuracy of tone recognition in Taiwanese. Besides, we provided an empirical perspective for theoretic studies on tonal neutralization.

Comparison of Pitch Range and Pitch Variation in Slavic and Germanic Languages
This study presents the results of a large-scale comparison of various measures of pitch range and pitch variation in two Slavic (Bulgarian and Polish) and two Germanic(German and British English) languages. The productions of twenty two speakers per language (eleven male and eleven female) in two different tasks (read passages and number sets) are compared. Significant differences between the language groups have been found: German and English speakers use lower pitch maxima, narrower pitch span and generally less variable pitch than Bulgarian and Polish speakers. These findings support the hypothesis that particular linguistic communities tend to be characterized by particular pitch profiles.

3.2.34 p.781

Philippe Martin,
Silent reading and prosodic structure constraints
Silent reading of written texts involves necessarily a process of subvocalization, i.e. the presence of a voice reading the text in the head of the reader speaking to her/himself. This process includes not only the sequences of syllables corresponding to the written material, but also sentence intonation. Since subvocalization cannot be eliminated other than by changing the status of each word into a pictographic function (as it may be the case for a STOP road panel sign), it is argued here that sentence intonation is essential to language comprehension, and more specifically to the conversion of sequences of syllables into higher order linguistic units (corresponding to accent phrases AP in the Autosegmental-Metrical model). Consequently, reading and in particular silent reading is constrained by the same rules than the prosodic structure in general, and specifically to the minimal duration of accent phrases. This minimal value, occurring when AP's contain only one syllable, is about 250 ms, a value which corresponds to the minimal period value of Delta brain waves. Therefore this AP minimal duration limits also the maximal number of AP that could be processed in silent reading, i.e. about 240 per minute, which corresponds to the maximal number of words per minutes experts in fast reading can process while keeping a reasonable

level of comprehension, i.e. about 800 wpm.

Emma Valtersson, Francisco Torreira,
Rising intonation in spontaneous French: how well can continuation statements and polar questions be distinguished?
This study investigates whether a clear distinction can be made between the prosody of continuation statements and polar questions in conversational French, which are both typically produced with final rising intonation. We show that the two utterance types can be distinguished over chance level by several pitch, duration, and intensity cues. However, given the substantial amount of phonetic overlap and the nature of the observed differences between the two utterance types (i.e. overall F0 scaling, final intensity drop and degree of final lengthening), we propose that variability in the phonetic detail of intonation rises in French is due to the effects of interactional factors (e.g. turn-taking context, type of speech act) rather than to the existence of two distinct rising intonation contour types in this language.

Ludger Paschen,
Intonation and focus marking in Ulyap Kabardian
This paper presents a pilot study that aims at establishing a model for the intonation of Ulyap Kabardian in the ToBI framework. On the basis of data gathered during a field trip in 2012, it is suggested that four/three pitch accents and three boundary tones are needed to describe intonation in four communicative contexts. Additionally, it is shown that for focus marking in Ulyap Kabardian questions, a stress shifting rule dislocates word stress to a prosodically determined position. This shift rule is extraordinary in that it is insensitive to stress clashes. From a cross-linguistic perspective, the intonation system of Ulyap Kabardian bears a higher resemblance to the system of one of the Kabardian dialects spoken in Turkey than to Russian, the principal contact language.

Intonation-Based Classification of Language Proficiency Using FDA
State-of-the-art pronunciation tutoring (CAPT) systems are based on ASR technology. Consequently, they can provide a distinguished learning feedback which is focused on phonetic features and the positions of articulation errors. In contrast with the relative success with segmental errors, the acquisition and assessment of second language (L2) prosody is still a challenging problem. Although prosodic parameters like f0 contour or duration measures are usually displayed, the consequential evaluation components are generally missing. Considering the strong variation in speech data, functional data analysis (FDA) is a useful concept which statistically analyses interrelations between principal components (e.g., given accentuation) and their contribution to superimposed forms (e.g., resulting f0 contour). This article describes baseline processing and preliminary results of a pilot study on the intonation-based proficiency classification of German by using FDA methods. The experimental part contains the FDA-based classification results compared to a perceptual classification by German natives.

Tonal allophony in Vietnamese: Evidence from task-oriented dialogues
In this paper we investigate the behaviour of the lexical rising tone (SAC) in disyllabic sequences in the Northern variety of Vietnamese. Results from task-oriented dialogues show that this rising tone (SAC), when occurring before the lexical high-level tone (NGANG), can be realised as low level or falling, resembling a different tone in the language (HUYEN). This is the case word-internally and within noun phrases. Two further observations give us an indication that a sandhi process could be developing: (a) this variation is not found in sequences across a larger juncture, and (b) the SAC tone does not undergo this change before other tones.

Nina Grønnum,
Laryngealization or Pitch Accent - the Case of Danish Stød
According to recent proposals Danish stød is the phonetic manifestation of a HL tonal pattern compressed within one syllable, making the stød/non-stød distinction a special case of the more general tonal word accent distinction in Swedish and Norwegian. This review of the relevant aspects of Danish stød and intonation demonstrates that (1) such a tonal representation of stød is contradicted by the phonetic reality. (2) Stød is distributed in words according to roughly the same principles across regional varieties of Danish, but tonal patterns are highly variable. (3) Word accents in Swedish and Norwegian are associated exclusively with stressed syllables, whereas stød occurs also in less than fully stressed syllables, devoid of autonomous pitch movements. (4) A word in Swedish and Norwegian can have one pitch accent only, but Danish words may have more than one stød.

Ann Bailey,
Intonational Phonology of Cuban Spanish: A Preliminary AM Model
The present study proposes a preliminary model of intonational phonology for Cuban Spanish in the framework of Autosegmental-Metrical phonology. Data from controlled and semi-spontaneous speech were used to establish the boundary tones and pitch accents which are contrastive in this variety of Spanish. It was found that Cuban Spanish shares various tonal categories with both the Pan Spanish ToBI (Tones and Break Indices) and other Caribbean Island Spanish dialects (Puerto Rican and Dominican), but differ from these dialects in how those pitch accents and boundary tones are used to convey meaning. Cuban Spanish shares its primary prenuclear pitch accents and nuclear contours for imperative statement and narrow focus with the Pan Sp_ToBI, but shares the nuclear contours for broad focus, vocative, and wh-questions with Puerto Rican Spanish. Similar to the other Caribbean Island Spanish varieties, the Cuban Spanish boundary tone inventory consists of a subset of the attested boundary tones found in the Pan Sp_ToBI, and all three Caribbean varieties share low boundary tones in non-wh questions, a marker of Caribbean Spanish speech.

Modeling of a rise-fall intonation pattern in the language of young Paris speakers
Intonation seems to be one of the major cues for identifying youth language in the Paris region. As part of a large-scale corpus-based analysis, this paper attempts to model a high-low final prosodic pattern, considered to be representative of a Paris working-class suburbs accent. Comparison with the emphatic high-low prosodic pattern, well-known in general French, will provide the opportunity for sociolinguistic insights. The ethnic hypothesis is dismissed in favor of a context-bound and interaction-sensitive interpretation.

Topic and Focus Intonation in Argentinean Porteño
This paper investigates the intonation of topics and focus in Argentinean Porteño. We have found that whereas tonal alignment is phonetically conditioned, pitch height and duration constitute the main cues to express various types of focus in declarative and interrogative sentences; at least four intonational categories seem to be used by our speakers and the relevance of a register feature is discussed. As for topics, they are marked by special tunes that depend on the type of sentence; in particular, the topic tune in questions is the opposite of those found in declaratives.

Analysis of Prosodic and Rhetorical Structural Influence on Pause Duration in Chinese Reading Texts
This paper investigates factors that influence pause duration in Chinese reading texts through examining

the stress degree in pre-pausal and post-pausal positions and the rhetorical structure in discourse as a whole. The RSTTool is used in diagramming the rhetorical structures of the texts. The recordings, extracted from the ASCCD corpus, are further analyzed acoustically and statistically by applying Praat and R. The statistical analysis results show that the stress degree in both pre- and post-pausal positions has a significant impact on pause duration. Moreover, the nuclearity in both positions have also been shown to have a remarkable influence. Specifically, the nucleus in pre-pausal and satellite in post-pausal positions can significantly lengthen the pause duration.

Irina Nesterenko,
Statistical and temporal properties of prosodic phrasing in French conversational speech
Our study investigates prosodic phrasing in a corpus of French conversational speech. We looked at statistical and temporal properties of prosodic constituents, which were previously identified within laboratory phonology paradigm. Prosodic annotation of our corpus implements two-level hierarchical model distinguishing major prosodic units (Intonational Phrases, IPs) and minor prosodic units (Accentual Phrases, AP). Both temporal data and distribution of the number of APs in an IP evidence the global tendency to produce shorter units in conversation. Moreover, Intonational phrases containing no more than two Accentual phrases cover 80% of the data. We discuss the implication of these results for both phonological studies of the constraints on prosodic phrasing and oral document tagging.

Intonational Patterns of Telephone Numbers In Brazilian Portuguese
The main purpose of this study was to identify intonational patterns of a quite common type of numeric grouping in Brazilian Portuguese: the one associated with telephone numbers. To this aim, 30 samples of spoken telephone numbers, read aloud by 85 native speakers of Brazilian Portuguese were analysed. The description of their intonation contour was observed by using Momel/Intsint [1] and ProsodyPro [2] scripts for Praat (version 5.3.53) [3], through a semi-automatic analysis of pitch variations in numeric groupings that form the telephone numbers. The results show a pattern of intonation and numeric grouping strategy that are sufficient enough to prosodically characterize different types of spoken telephone numbers in Brazilian Portuguese.

Simone Falk, Elena Maslow,
Song and speech prosody influences VOT in stuttering and non-stuttering adolescents
Since a long time, it is known that singing helps persons who stutter to produce their utterances more fluently. The prosodic characteristics of spoken and sung utterances differ considerably in their rhythmic and tonal structure. Therefore, it has been proposed that song prosody helps stutterers to improve their rhythmic planning of verbal material [1]. In order to investigate this idea, we examined temporal aspects, namely Voice Onset Time (henceforth, VOT) of voiceless plosives, in sung and spoken utterances of young German stutterers and non-stuttering controls. VOT tends to be reduced in song compared to speech. We expected a more important reduction in the stuttering group as voice onset timing should be facilitated in song compared to speech. Eight stuttering adolescents and eight normal fluent peers read and sang an altered version of Happy Birthday with test words containing the three voiceless stops /p/, /t/, /k/. Results showed that stuttering as well as non-stuttering adolescents reduced VOT during singing compared to speech. In contrast, only adolescents who stutter were less variable in their VOT production in song compared to speech. Additional analyses indicated further group differences in vowel duration following the stop consonant. These findings suggest that young stutterers benefit from sung prosody in their timing abilities.

Stefanie Jannedy, Melanie Weirich,
Some aspects on individual speaking style features in Hood German
Multiethnic urban German (Hood German) as spoken by adolescents in Berlin differs in several significant ways from more standard varieties of Berlin German. It is characterized by a variety of morpho-syntactic

alternations and phonetic variants uncommon to the regional standard spoken in Berlin. Previous quantitative corpus analyses have shown that overall speakers of the multiethnic youth style German have a strong tendency to centralize /ɔɪ/ compared to speakers rendering the local regional standard. This paper now summarizes this centralization tendency and investigates auditory salient realizations of variation by individuals which show tendencies towards a hiatus in the diphthong /ɔɪ/, breaking the nucleus and the off glide. Moreover, there are other prosodic and segmental co-occurring features in the speech of some adolescents which are displayed since it is suspected that some of these may be(come) markers of Hood German.

Katarina Bartkova, Mathilde Dargnat,
Automatic extraction of prosodic patterns Cross linguistic study on laboratory data
The goal of our study is to use an automatic approach to extract the general prosodic tendency of the speech signal conveyed by the F0 pattern and the syllable duration. The speech signal is prosodically annotated by an automatic prosodic transcriber and then prosodic patterns are extracted from this annotation. The pertinence of the pattern extraction is tested here on laboratory data containing isolated sentences in French and English uttered by native and non-native speakers. An analysis of the extracted parameters allows observing how the prosody of the sentences is defined by their shared syntactic structures and to what extend are the prosodic features used by the two languages different or similar. It appears from the analyzed data that such an automatic prosodic parameter processing can yield relevant information for a cross-linguistic study of the prosody.

Listening for sound, listening for meaning: Task effects on prosodic transcription
The perception of prosodic structure (phrasal prominences and boundaries) may depend in part on acoustic information present in the signal and in part on meaning based on syntactic, semantic and pragmatic factors. Listeners may also be able to weigh acoustics and meaning to different degrees. We test naïve subjects' marking of prominences and boundaries in spontaneous American English under three different conditions, all of which involve listening to audio recordings and marking prominences and boundaries on a transcript. The three conditions differ in the instructions that transcribers were given. In one condition, subjects were instructed to transcribe prominence and boundaries based on meaning criteria, in a second condition they were told to transcribe based on criteria of acoustic salience. A third condition had more general instructions, without explicit reference to either meaning or acoustic perception. Our results show that subjects perform differently when focusing on meaning and on acoustics, especially for prominence marking, where many different words are selected as prominent under the two tasks. Boundary marking is more similar under the two instructions, with acoustic criteria resulting in a higher frequency of boundaries, but with boundaries marked largely on the same words in both tasks. When given non-specific instructions, performance was much more similar to that obtained under acoustic-based instructions. We report on agreement rates within and across conditions. This study has implications for models of prosody perception and the methodology of prosodic transcription.

Acoustic-Prosodic Characteristics of Sleepy Speech - Between Performance and Interpretation
When we address speaker states like sleepiness, two partly competing interests can be observed: within both applications and engineering approaches, we aim at utmost performance in terms of classification or regression accuracy - which normally means using a very large feature vector and a brute forcing approach. The other interest is interpretation: we want to know what tells apart atypical (here: sleepy) speech from typical (here: non-sleepy) speech, i.e., their respective feature characteristics. Both interests cannot be served at the same time. In this paper, we preselect a small number of easily interpretable acoustic-prosodic features modelling spectrum and prosody, based on the literature and on the general idea of sleepiness being characterised by relaxation. Performance obtained with these single features and this small feature vector is compared with the performance obtained with a very large feature vector; moreover, we discuss to which extent the features chosen model relaxation as sleepiness characteristic.

Hyperarticulation in Lombard speech: A preliminary study
Over the last century researchers collected a considerable amount of data reflecting properties of the Lombard speech, i.e., speech in a loud environment. The documented phenomena include effects on intensity, fundamental frequency, spectral tilt, speech rate and articulationm. Relatively little attention has been paid to the effects on relative extent of movement of individual articulators. In an attempt to fill in this gap we present a preliminary analysis of EMA data collected in increasing levels of babble noise. We introduce HH-index as a measure of overall relative activity of articulators. Our results indicate a non-linearity of the effect of noise on articulatory movement and quantitatively different effects on the movement extent for different groups of articulators. The effects of noise are compared with those brought out by other techniques for eliciting articulatory variation. We also discuss possible application of Lombard speech as an elicitation paradigm for studies of hyperarticulation.

3.4.5 p.874

Susanne Schötz, Joost van de Weijer,
A Study of Human Perception of Intonation in Domestic Cat Meows
This study examined human listeners' ability to classify domestic cat vocalisations (meows) recorded in two different contexts; during feeding time (food related meows) and while waiting to visit a veterinarian

(vet related meows). A pitch analysis showed a tendency for food related meows to have rising F0 contours, while vet related meows tended to have more falling F0 contours. 30 listeners judged twelve meows (six of each context) in a perception test. Classification accuracy was significantly above chance, and listeners who had reported previous experience with cats performed significantly better than inexperienced listeners. Moreover, the two food related meows with the highest classification accuracy showed clear rising F0 contours, while clear falling F0 contours characterised the two vet related meows that received the highest classification accuracy. Listeners also reported that some meows were very easy to classify, while others were more difficult. Taken together, these results suggest that cats may use different intonation patterns in their vocal interaction with humans, and that humans are able to identify the vocalisations based on intonation.

Chunyue Zhu, Toshiyuki Sadanobu,
Observation of so-called "pursed-lip" and "curled-lip" utterances in Japanese, using video and MRI images
The Japanese language includes utterances described by the idioms "speaking with pursed lips" and "speaking with curled lips." This study employs video and MRI imaging to examine the articulatory characteristics of these utterances ("utterances P" and "utterances C", respectively) by comparing their articulation with that of "unmarked" utterances ("utterances U"). Through doing so, we arrive at the following four conclusions: (1) For the articulation of utterance P, the lips are projected outward, and rounded by expanding in the vertical direction and narrowing in the horizontal direction. (2) For the articulation of utterance C, curling the lips is not an absolute requirement. The articulation of utterance C is similar with that of utterance P in that the lips are projected outward and rounded. (3) Utterances P and C differ in two points: (a) Lips projection accompanies the lower jaw projection only in utterances P; (b) Lips in utterance P is wider than those in utterance C. (4) The shapes the lips make in utterance P, utterance C, and utterance U can be described as a circle, a horizontal rectangle, and a horizontal oval, respectively. (5) There are many facts that contradict the accepted theory that "Rounding the lips causes both lips to project outward. In reaction to this movement, the surface of the tongue is pushed toward the rear" (Koizumi 1989).

Prosodic Cues to Monolingual versus Code-switching Sentences in English and Spanish
Code-switching offers an interesting methodology to examine what happens when two linguistic systems come into contact. In the present study two experiments were conducted to see if (1) listeners are able to anticipate code-switches in speech-in-noise, and (2) prosodic cues are present in the signal to warn of an upcoming code-switch. A speech-in-noise perception experiment with early Spanish-English bilinguals found that listeners are able to accurately identify words in code-switching sentences with the same accuracy as in monolingual sentences, even in highly degraded listening conditions. We then analyzed the stimuli used in the perception experiment, and found that the speaker does use different prosodic contours for code-switching productions as compared to monolingual productions. We propose that listeners use these code-switching specific prosodic contours to anticipate code-switches, and thus ease processing costs in word identification.

4.1.2 p.890

Simon Ritter, Timo B. Roettger,
Speakers modulate noise-induced pitch according to intonational context
Recent studies have shown that speakers systematically modulate properties of voiceless segments according to intonational context. More specifically, in the absence of fundamental frequency (F0), speakers appear to adjust the Center of Gravity (CoG) and the intensity of voiceless fricatives to convey the impression of pitch. In line with these findings, the present production study extends earlier work and investigates noise-induced properties of fricatives, modulated by the intonation context. It is shown for German that the mean CoG and intensity of intended contours with a high boundary tone are higher than those produced for intended contours with a low boundary tone. Furthermore, looking at the development of CoG and intensity over the time course of the fricative, the trajectories corresponding to the boundary tones differ in intercept and slope, i.e. reveal a steeper fall in case of a corresponding falling tone.

Albert Rilliard, Donna Erickson, Takaaki Shochi, Joõ Moraes,
US English attitudinal prosody performances in L1 and L2 speakers
Expressive behavior linked to paralinguistic meanings finds grounds in codes proposed as universals, as well as in culture-specific conventions. This study observes performances in such kinds of attitudinal prosody for USA English, produced by L1 and L2 speakers. The results show that the observed variance is linked to individual competence, to the linguistic context, and to the cultural background of the speakers. They also show that the code used to express a given speech act, code learned in the L1 language by L2 speakers of English, may be used in their L2 language. For some of these expressions, L2 speakers received higher scores than L1 speakers, suggesting that expressions conventionalized in a foreign language, are adequately fulfilling not-conventionalized expressions in the L1 culture.

András Beke, György Szaszák, Viola Váradi,
An Automatic Hierarchical Multiple Level Phrase segmentation approach for Spontaneous speech
The present paper investigates automatic prosodic phrasing of spontaneous speech: a two-step segmentation technique is presented, based on unsupervised learning. In the first step, the Intonational Phrases (IP) are detected automatically based on speech energy, spectral centroid and a double-thresholding technique. In the second step, Phonological Phrases (PP) are identified within the IPs. As acoustic features, F0, overall energy and vowel duration are investigated. An adaptive thresholding method is used based on Kullback-Leibler divergence computed in an autocorrelative manner for the feature streams. For Hungarian spontaneous speech, a phrasing accuracy of over 80% can be reached when comparing to a hand-labelled reference phrasing. It is found that in Hungarian sponatenous speech, F0 and energy play an essential role in IP level phrasing, whereas PP level phrasing is most effective using F0 related features alone. Vowel durations are shown not to contribute to prosodic phrasing in Hungarian. Although the evaluation targets the Hungarian language, the applied method is universal and can be easily adapted for other languages. Index Terms: speech synthesis, unit selection, joint costs.

Effects of auditory, visual and gestural input on the perceptual learning of tones
Research has shown that audio-visual speech information facilitates second language (L2) speech learning, yet multiple input modalities including co-speech gestures show mixed results. While L2 learners may benefit from additional channels of input for processing challenging L2 sounds, multiple resources may also be inhibitory if learners experience excessive cognitive load. The present study examines the use of metaphoric hand gestures in training English perceivers to identify Mandarin tones. Native Mandarin speakers produced tonal stimuli with simultaneous hand gestures mimicking pitch contours in space. The English participants were trained to identify Mandarin tones in one of four modalities: audio-only, (AO), audio-visual (AV, speaker voice and face), audio-gesture (AG, speaker voice and hand gestures) and audio-visual-gesture (AVG). Results show significant improvements in tone identification from pre-

to post-training tests across all four training groups, demonstrating that gestural as well as visual articulatory information may facilitate tone perception. However, further analyses with individual tones reveal some group differences. Most noticeably, the AVG group had a slower learning curve during training compared to the other trainee groups for Tone 4, the least accurately identified tone, indicating a negative effect of multiple input modalities on the perception of difficult L2 sounds. In contrast, for Tones 2 and 3, the AG group revealed slower learning effects compared to the AV group, presumably because of the similar gestural trajectories for these two tones, which made the gestural input less distinct. Overall, the results suggest a positive role of gestures in tone identification, one that may also be constrained by phonetic and cognitive demands.

Céline De Looze, Daniel Hirst,
The OMe (Octave-Median) scale: a natural scale for speech melody.
Fundamental frequency, the primary acoustic correlate of speech melody, is generally analysed and displayed using a linear scale (Hertz) or a logarithmic one, generally in semitones and usually offset to an arbitrary reference level such as 100 Hz. In this paper we argue that a more natural scale for analysing speech is the OME (Octave-MEdian) scale, using the octave (o) as the basic unit, offset to the median value of the speaker's range. We present results showing that a reasonable estimate of a speaker's pitch range can be obtained directly from the median.

P-centre Position in Natural Two-Syllable Czech Words
The ability to lock motor activity oscillator with external acoustic events is typical of various forms of human behaviour. Previous research showed that the beginning of an action is not necessarily the beginning of the rhythmic phase and led to the concept of p-centres. We present an experiment with 18 natural two-syllable Czech words spoken in synchrony with metronome beats by 18 subjects. Complexity of the consonantal onset and the type of coda together with distinctive phonological vowel length were carefully controlled to reveal a complex but comprehensible relationship between the word structure and phase locking.

Correlation between prosody and epistemic bias of negative polar interrogatives in Japanese
The study investigates the correlation between prosodic patterns and epistemic bias observed in Japanese negative polar interrogatives, with special attention given to the perceptual and functional aspects of the correlation. The result of a naturalness rating test and a comprehension test demonstrate that listeners perceive the matching interrogative-answer pairs more natural, compared to the conflicting pairs. Also, it is revealed that the prosodic patterns successfully guide listeners to identify the epistemic bias of negative polar interrogatives.

L2 production of Estonian quantity degrees
The Estonian quantity system involves three contrastive patterns referred to as short (Q1), long (Q2)

and overlong (Q3) quantity degrees. Our previous studies have shown that for L2 learners the distinction between Q2 and Q3 is a difficult task in both production and perception. While Q1 and Q2 structures are always distinguished in the orthography, this is not the case in most Q2 and Q3 words excluding the words with plosives between first and second syllable vowels. Thus, the orthography might be the reason for the use of the same production pattern for both Q2 and Q3. The current paper studies the role of L2 orthographic input on the L2 production of Estonian quantity degrees by two groups of subjects with different language backgrounds: Finnish and Russian. The material used in the study involves word structures with and without orthographic manifestation of quantity contrasts. The results confirm the role of Estonian orthography on the L2 pronunciation, however, the two L2 subject groups show different prosodic patterns.

Rachel Steindel Burdin,
Variation in list intonation in American Jewish English
Yiddish-influenced intonation has been previously noted as a potential defining characteristic of American Jewish English, and list intonation was identified as a possible area of differentiation. However, apart from remarks in general descriptions of Standard American English (SAE) prosody, a systematic study of list intonation has not been conducted in SAE. In this study, lists were defined, and extracted from sociolinguistic interviews with Jewish women with varying degrees of exposure to Yiddish. The lists were then ToBI annotated. Speakers from different language backgrounds differed significantly in their use of contours, boundary tones and pitch accents on list items, with speakers with less exposure to Yiddish using more of the standard English contour (H* H-L%) than speakers with more exposure to Yiddish. Yiddish bilinguals were more likely to use a rise fall contour (L+H* L-L%), fewer H-L% boundary tones and H* pitch accents, and more rising pitch accents (L+H* and L*+H) than non-bilinguals. In addition, speakers of all language backgrounds used a variety of list intonations, showing the need for more systematic study into the uses and meanings, social and otherwise, of list intonations.

Is Syllable Stress Information Robust for ASR in Adverse Conditions?
This paper presents a study on the robustness of stress information for automatic speech recognition in the presence of noise. The syllable stress, extracted from the speech signal, was integrated in the recognition process by means of a previously proposed decoding method. Experiments were conducted for several signal-to-noise ratio conditions and the results show that stress information is robust in the presence of medium to low noise. This was found to be true both when syllable boundary information was used for stress detection and when this information was not available. Furthermore, the obtained relative improvement increased with a decrease in signal quality, indicating that the stressed parts of the signal can be considered islands of reliability.

Bettina Braun, Muna Pohl, Katharina Zahner,
Speech segmentation is modulated by peak alignment: Evidence from German 10-month-olds
In two headturn preference experiments, we tested whether German infants' segmentation strategies are

sensitive to the position of a pitch peak relative to the stressed syllable. Specifically, we compared target words with early-peak accents (where the pitch peak is early with respect to the stressed syllable, i.e. H+L* accents) and medial-peak accent (where the pitch peak is aligned with the stressed syllable, i.e. H* accents). Such differences in accent type signal mostly pragmatic distinctions, such as the difference between new and recoverable information. We familiarized infants with target words with one of the two intonation conditions that were embedded in sentences. We measured looking times to lists of trochaic part-words that were embedded in target words or were novel to them. Results showed an effect of familiarity only in the medial-peak condition, suggesting that infants at 10 months of age are very sensitive to pitch information for segmenting running speech.

Hae-Sung Jeon,
The Perception of Korean Boundary Tones by First and Second Language Speakers
This paper reports an experiment which investigated the perception of prosody in Korean or non-word utterances by native Korean speakers and English learners of Korean. Listeners rated the degrees of positivity and excitement of resynthesized utterances with different pitch ranges and durations. The results revealed no significant differences between the two groups of listeners. The variations in pitch range and duration had systematic effects on the ratings. However, the interactions between various factors suggest that the mapping between prosodic shapes and their paralinguistic meaning is not straightforward.

The distribution of pitch patterns and communicative types in speech-chunks preceding pauses and gaps
This paper describes the distribution of pitch patterns and communicative types in the interpausal units (IPUs) preceding pause or gap silences extracted from a corpus of spontaneous speech as part of our work towards automatic prediction of turn-taking in dialogue interaction. IPUs preceding speaker change ('Gaps') and IPUs preceding silence where the same speaker continues talking ('Pauses') were selected in the course of automatic extraction of pause/gap silences in dyadic dialogue interactions. A listening test was conducted to estab-lish 'human predictable' pause/gap data sets which were sub-sequently manually annotated in terms of pitch patterns and communicative types. Overall, the Gaps and Pauses subsets show differentiation in terms of both their communicative types and pitch tunes. Declaratives and Questions are mainly found in Gaps, whereas in Pauses we mainly find Hesitations and Incomplete Declaratives. Gaps are generally characterised by falling or rising pitch patterns, whereas in Pauses a large proportion of speech samples are realised with level pitch. Classification experiments reveal strong discrimination of pauses and gaps for both prosodic and functional annotation labels.

Holly S.H. Fung, Peggy P.K. Mok,
Realization of Narrow Focus in Hong Kong English declarativesa Pilot Study
Narrow focus, i.e., focus on one word, is realized differently in native English and Cantonese. While it is signaled primarily by on-focus F0 changes such as F0 range expansion in English, it is marked essentially by lengthening of duration in Cantonese. Another difference is the pitch of the post-focus elements. While native English demonstrates post-focus F0 compression, Cantonese shows no significant post-focus pitch change. To investigate how narrow focus is realized in Hong Kong English (HKE), an emergent variety of English spoken by native speakers of Cantonese in Hong Kong, a controlled production experiment was conducted with 8 HKE speakers. Results showed that while the HKE speakers did realize foci with significant on-focus F0 range expansion, they exhibited no post-focus compression.

David Abelman, Robert Clark,
Altering speech synthesis prosody through real time natural gestural control
This paper investigates the usage of natural gestural controls to alter synthesised speech prosody in

real time (for example, recognising a one-handed beat as a cue to emphasise a certain word in a synthesised sentence). A user's gestures are recognised using a Microsoft Kinect sensor, and synthesised speech prosody is altered through a series of hand-crafted rules running through a modified HTS engine (pHTS, developed at Université de Mons). Two sets of preliminary experiments are carried out. Firstly, it is shown that users can control the device to a moderate level of accuracy, though this is projected to improve further as the system is refined. Secondly, it is shown that the prosody of the altered output is significantly preferred to that of the baseline pHTS synthesis. Future work is recommended to focus on learning gestural and prosodic rules from data, and in using an updated version of the underlying pHTS engine. The reader is encouraged to watch a short video demonstration of the work at http://tinyurl.com/gesture-prosody.

Xiaoluan Liu, Yi Xu,

Body size projection by voice quality in emotional speechEvidence from Mandarin Chinese

This study attempts to extend the line of research on using body size projection theory to account for emotional speech. It is predicted by the theory that anger is expressed by projecting a large body size with low pitch, rough voice and long vocal tract; happiness is expressed by projecting a small body size with high pitch, breathy voice and short vocal tract. Ten native speakers of Mandarin with drama training background recorded sentences in happy, angry, disgust and neutral emotions. We used multiple measurements to assess voice quality, formant dispersion (as an indicator of vocal tract length) and pitch. The results show clear support for the body size projection theory in voice quality, with anger and disgust associated with pressed and rough voice while happiness with breathy voice. But the results of formant dispersion and pitch demonstrate no clear directions. While the study is the first to show clear speech production support for the body size projection theory with voice quality data, the equivocal results of formant and pitch call for improvement in method of emotion elicitation in the laboratory.

Jan Michalsky,

Scaling of Final Rises in German Questions and Statements

Although certain intonation contours occur more frequently with German questions than with German statements, there is evidence that the semantics of intonational phonology operates on a more abstract level [1][2][3][4]. Hence, it is unlikely that there are pitch patterns in German that are exclusively used in interrogatives. Rather, intonational signaling of interrogativity can be regarded as resulting from the interaction between tonal and phonetic features. The tonal structure provides abstract semantic features, which are modified by paralinguistic features through phonetic realization [5]. This paper deals with the question which phonetic features may serve as cues to interrogativity in German. We report a reading task that was designed to elicit utterances that have phonologically identical nuclear rising pitch contours but differed by pragmatic function, serving either as a question or a statement. The observed absolute and relative scaling of nuclear and prenuclear tonal targets suggests that questions differ from statements by larger f0 excursions of nuclear rising contours, whereas the scaling of prenuclear accents does not substantially contribute to the expression of interrogativity. We conclude that phonetic cues to interrogativity in German are mainly realized through scaling and are restricted to the nuclear part of the intonational phrase.

Grace Kuo,

Processing Prosodic Boundaries in Natural and Filtered Speech

The prosody of an utterance can carry information that is critically important to understand the meaning of a sentence. In addition, previous studies have shown that listeners are able to detect major prosodic boundaries in their native language in stimuli whose segmental information has been removed, such as low-pass filtered [1][2] and hummed speech [2][3][5]. The present boundary strength rating study is conducted on native and non-native speakers to Taiwanese and Swedish, in an attempt to observe native and non-native speakers' accuracy in judging the upcoming boundary size in natural and filtered speech. 36 Taiwanese and American English speakers were recruited for the rating task whose stimuli consisted of Taiwanese and Swedish utterances from three prosodic boundary types (word boundary, phrase/tone sandhi group boundary, and Intonation Phrase boundary). In Experiment 1, participants rated the

upcoming boundary strength on a slider for filtered speech stimuli. In Experiment 2, they rated the boundary strength for natural speech stimuli. The results show that both non-native speakers could accurately predict the upcoming prosodic boundary type in both natural and filtered speech. The acoustic analyses of duration, f0 range, f0 median, spectral tilt, and harmonics-to-noise ratio reveal that non-native speakers use these prosodic cues to make their judgment, however, they put different emphasis on different cues when they were presented with stimuli of different qualities (natural vs. filtered) and lengths.

Malin Svensson Lundmark,
Constant Tonal Alignment in Swedish Word Accent II
Studies on accentual tonal alignment of intonation languages suggest that L in rising (LH) pre-nuclear accents anchors with a specific point in the segmental string, while the timing of H varies. This study investigates if lexical accents, too, exhibit a constant alignment by testing the South Swedish word Accent II. When under the strain of tempo variability the L-target was found not to be anchored with syllable onset. The results were not fully conclusive regarding H, but no clear evidence was found against anchoring of H, which could mean that H is an important phonological event in Accent II, while L is not.

Antonio Origlia, Francesco Cutugno,
A simplified version of the OpS algorithm for pitch stylization
In this work we present a new version of our previously published Optimal Stylization (OpS) algorithm for pitch stylization. Here we give a better perceptual representation of the pitch curve for linguistics research. While the OpS algorithm produced good stylizations for naive listeners, when deployed in a prosodic analysis tool, we observed that, under specific conditions, important details were missed in the stylized curve to an expert's ear. Changes introduced in the dynamic tonal perception model to solve these problems resulted in a simpler and more robust model. We show how the new version of the OpS algorithm is able to recover these situations while not significantly altering the original OpS curves.

Interpersonal factors affecting tones of question-type utterances in Japanese
The purpose of this paper is to clarify the interpersonal factors affecting phrase final tones of question-type utterances in Japanese daily conversations. We extracted question-type utterances ending with final particles from our dialogue speech database and classified them into two categories according to the degree of information request. Prosodic features were then analyzed by focusing on phrase final F0 movement and pitch reset. Analysis results indicated that F0 rising and falling degrees increase when the speaker express a close attitude to the dialogue partner, such as in conversations among family members and infant-directed speech. In addition, the presence of pitch reset in the phrase final was found to have functions of relieving the speaker's tension, when the dialogue partners have distant relationship.

George Christodoulides, Cédric Lenglet,
Prosodic correlates of perceived quality and fluency in simultaneous interpreting
This study explores the relationship between prosodic features specific to simultaneous interpreting and listeners' perception of the fluency and accuracy of interpreting, as well as their comprehension of the source speech. Two groups of participants (47 subject experts and 40 non-experts) listened to a 20-minute lecture in German, along with its interpretation into French under two conditions (the actual interpretation, or a read-aloud rendition of the same text by the same interpreter) and answered comprehension and rating questions. The prosodic features of the two conditions were analysed, confirming differences regarding the temporal organisation of speech, disfluencies, pitch register and the interface between prosody and syntax. Our results suggest that interpreting-specific prosodic features affect the perception of fluency, which in turn affects the perception of accuracy; however the impact on listeners who enjoy relevant contextual knowledge is less pronounced.

Rasmus Dall, Junichi Yamagishi, Simon King,
Rating Naturalness in Speech Synthesis: The Effect of Style and Expectation
In this paper we present evidence that speech produced spontaneously in a conversation is considered more natural than read prompts. We also explore the relationship between participant's expectations of the speech style under evaluation and their actual ratings. In successive listening tests subjects are presented with either spontaneously produced, read aloud or written sentences, and are asked to rate the naturalness of each sentence with either instructions toward conversational, reading or general naturalness. It was found that, when presented with spontaneous or read aloud speech, participants consistently rated spontaneous speech more natural - even when asked to rate naturalness in the reading case. Presented with only text, participants generally preferred transcriptions of spontaneous utterances, except when asked to evaluate naturalness in terms of reading aloud. This has implications for the application of MOS-scale naturalness ratings in Speech Synthesis, and potentially on the type of data suitable for use both in general TTS, dialogue systems and specifically in Conversational TTS, in which the goal is to reproduce speech as it is produced in a spontaneous conversational setting.

Hao Liu, Yi Xu,
A Simplified Method of Learning Underlying Articulatory Pitch Target
Previous research has shown that parameters of the quantitative Target Approximation model (qTA) proposed by Prom-on and Xu can be directly extracted from natural speech with high accuracy through analysis-by-synthesis implemented in PENTAtrainers. While this may raise the possibility that PENTAtrainers actually simulate natural acquisition of prosody production, it is questionable that the human brain actually replicates the full articulatory mechanics represented by qTA in order to learn and control prosody production. In this paper we explore if a much simpler function can be used to extract at least some of the qTA parameters. We first managed to reduce the number of qTA parameters from three to two by evaluating their relative sensitivity. We then tested a pursuit function that learns only pitch target height and slope. Using a corpus of Mandarin utterances varying in lexical tone and focus, we show that parameters learned by the pursuit function can be used in qTA synthesis to generate F0 contours closely resembling those generated with parameters learned with qTA-based analysis-by-synthesis, with the advantage of having a much simpler learning algorithm. These results suggest that it is possible to learn articulatory control parameters for prosody without fully replicating the mechanical process itself.

Maria Del Mar Vanrell, Meghan E. Armstrong, Pilar Prieto,
The role of prosody in the encoding of evidentiality
The overarching goal of this paper is to advance on the understanding of how evidential meanings are expressed in natural languages. Specifically, we aimed to investigate what type of meaning was encoded in yes-no questions through the combination of the question particle (QP) que 'that' and the nuclear intonational pattern L+H* L% in Majorcan Catalan yes-no questions (i.e., Que és un llibre? L+H* L% 'QP-It's a book?'), and to understand any temporal information that might be encoded through this construction. Several complementary research methods were used to address our question: the Discourse Completion Task, an acceptability task and a multiple-choice questionnaire. The results show that three types of information are encoded in QP que_L+H* L% questions: sentence modality, inference based on direct evidence and immediacy of the evidence.

Prosody in Swiss French Accents: Investigation using Analysis by Synthesis
It is very common for a language to have different dialects or accents. The different pronunciations of the same words is one of the reasons for the different accents, in the same language. Swiss French accents have similar pronunciation to standard French, but noticeable differences in prosody. In this paper we investigate the use of standard French synthetic acoustic parameters combined with Swiss French prosody in order to evaluate the importance of prosody in modelling Swiss French accents. We use speech synthesis techniques to produce standard French pronunciation with Swiss French duration and intonation. Subjective evaluation to rate the degree of Swiss accent was conducted and showed that prosody modification alone reduces perceived difference between original Swiss accented speech and standard French coupled with original duration and intonation by 29%.

Hierarchical stress generation with Fujisaki model in expressive speech synthesis
This paper introduces a hierarchical stress generation for expressive speech synthesis. In the previous study, we proposed a novel hierarchical Mandarin stress modeling method, and the text-based stress prediction experiments demonstrates a reliable stress assignment can be obtained from textual features. However, the stress model should be further verified to be an effective and efficient prosody model in a Text-to-Speech system. In this work, Fujisaki model known as an ideal global representation of prosody is adopted to construct the pitch contours. To illustrate the effect of stress model, the Fujisaki model parameters are automatically predicted by the textural feature with and without stress information. The synthetic speech sounds more natural than that without stress modeling. The RMSE of the pitch contour and the feature importance analysis also show stress information can improve the pitch modeling. This work offers a promising method to accurate pitch modeling for Mandarin expressive speech synthesis.

Frank Zimmerer, Jeanin Jügler, Bistra Andreeva, Bernd Möbius, Jürgen Trouvain,
Too cautious to vary more? A comparison of pitch variation in native and non-native productions of French and German speakers.
This article presents preliminary results indicating that speakers have a different pitch range when they speak a foreign language compared to the pitch variation that occurs when they speak their native language. To this end, a learner corpus with French and German speakers was analyzed. Results suggest that speakers indeed produce a smaller pitch range in the respective L2. This is true for both groups of native speakers. A possible explanation for this finding is that speakers are less confident in their productions, therefore, they concentrate more on segments and words and subsequently refrain from realizing pitch range more native-like. For language teaching, the results suggest that learners should be trained extensively on the more pronounced use of pitch in the foreign language.

Selection of Training Data for HMM-based Speech Synthesis from Prosodic Features - Use of Generation Process Model of Fundamental Frequency Contours
-Generation process model of fundamental frequency (F0) contours is ideal to represent global movements of F0's keeping a clear relation with back-grounding linguistic information of utterances. Using the model, improvements of HMM-based speech synthesis are expected. A new method is developed to cope with erroneous F0's of utterances included in HMM training corpus. F0 extraction errors not only cause wrong F0's, but also degrade segmental features of synthetic speech, since they affect the over-all accuracy of speech analysis. The method is to exclude speech segments from HMM training, where extracted F0's are largely different from those generated by the generation process model. Experiments on speech synthesis showed a clear improvement in synthetic speech quality when phoneme-base exclusion is conducted with a properly selected threshold.

SVR vs MLP for Phone Duration Modelling in HMM-based Speech Synthesis
In this paper we investigate external phone duration models (PDMs) for improving the quality of synthetic speech in hidden Markov model (HMM)-based speech synthesis. Support Vector Regression (SVR) and Multilayer Perceptron (MLP) were used for this task. SVR and MLP PDMs were compared with the explicit duration modelling of hidden semi-Markov models (HSMMs). Experiments done on an American English database showed the SVR outperforming the MLP and HSMM duration modelling on objective and subjective evaluation. In the objective test, SVR managed to outperform MLP and HSMM models achieving 15.3% and 25.09% relative improvement in terms of root mean square error (RMSE) respectively. Moreover, in the subjective evaluation test, on synthesized speech, the SVR model was preferred over the MLP and HSMMmodels, achieving a preference score of 35.93% and 56.30%, respectively.

Tone Modeling Using Stress Information for HMM-Based Thai Speech Synthesis
This paper describes a modeling technique of Thai tones for HMM-based speech synthesis. Tones are important prosodic features for tonal language including Thai because the phonetically same words but with different tones give different meanings. Although there have been several approaches to improving tone correctness of synthetic speech by considering tone types, another significant factor, stress, was not used explicitly for prosody modeling. We incorporate stress/unstress information into the framework of the HMM-based speech synthesis. Objective and subjective evaluation results show that the use of stress information improves the performance in Thai tone modeling.

Understanding the significance of different components of mimicry speech
Voice conversion systems aim at finding a transformation function using statistical models. Mimicry/ Voice imitation is a natural voice transformation technique which sounds convincing to the listeners. It thus seems advisable to study the transformation used by human beings who perform mimicry. The objective of this study is to examine the various components of speech that are modified during voice imitation. To transform a given speech utterance to sound like that of a target utterance, the process needs to be understood at both production and perception level. In this paper the importance of source and system parameters and also the significance of different components of speech that contribute to the perception of imitation are studied. A flexible analysis-synthesis tool is used to modify the features of natural utterance and convert it to imitated utterance. Perceptual studies are carried out to understand if the modified features contribute to imitation. The results show that a combination of features is varied by the imitator to achieve imitation and they vary depending on the target speaker.

The Cartoon Task Exploring Auditory-Visual Prosody in Dialogs
This paper introduces and evaluates a collaborative task designed to elicit auditory-visual dialogs. The task was based on the viewing of two versions of the same cartoon film that was edited so that in order to reconstruct the story information from two incomplete versions must be shared in a consecutive fashion. The aim of this design was to elicit a relatively balanced dialog between the two participants as the story is pieced together from the beginning to the end. The current paper describes the production of a corpus consisting of audio, video and motion capture data from 22 pairs of Australian English speaking participants, and presents results on turn-distribution and raw prosodic features. Our analysis showed that the task could produce relatively balanced dialogs although this was not the case for all pairs. Analysis of raw prosodic features did not suggest that convergence occurred over the conversation, but replicated earlier findings of similarity between partners as compared to others.

Peggy P.K. Mok, Holly S.H. Fung, Jingwen Li,
A preliminary study on the prosody of broadcast news in Hong Kong Cantonese
Broadcast news is a distinctive register. Previous studies only provided some general descriptions of the prosodic features in broadcast news but with few concrete data. Most of them were also on English news. This study investigated the prosodic features of Cantonese TV broadcast news using acoustic data. Speech using the same materials from two groups was compared: eight Hong Kong professional TV news anchors, and a control group consisting of eight university students. The results show clear differences between the two groups in terms of speech rate, pitch range and variability of syllable duration (speech rhythm). It was found that the news anchors spoke significantly faster than the control group, also with an enlarged pitch range. They also produced more variability in syllable duration. There is clearly more prosodic variation in the news register than ordinary speech. Finally, we provide some possible reasons for these features, as well as directions for future studies.

Elisabeth Delais-Roussarie, Ingo Feldhausen,
Variation in Prosodic Boundary Strength: a study on dislocated XPs in French
Three independently motivated types of information are usually assumed to influence prosodic boundary placement and to play a role in their relative strength: the morpho-syntactic structure, the information structure and the metrical complexity. The phonetic realization associated with the different boundary types (in particular IP and ip) is also assumed to vary. Based on data of clitic left-dislocations in French, we argue here that differences in the relative strength of the prosodic boundary occurring at the end of the dislocated XP (i.e. an intermediate (ip) or an intonational phrase (IP) boundary) cannot be derived in a straightforward manner from these three types of information. In a production experiment, where the syntactic and information structure were controlled, while the metrical complexity was varied, it appeared that the strength of the boundary occurring at the right edge of the dislocated object NP displayed a high degree of variability. In addition, the results indicate a lack of correlation between metrical complexity and boundary strength. The results lead us to argue that a sort of phonological neutralization occurs in certain textual contexts. This neutralization does not allow for distinguishing between intermediate and intonational phrase boundaries in all cases.

Prosodic chunking algorithm for dictation with the use of speech synthesis
The aim of this paper is to present an algorithm that automatically segment a text in prosodic chunks for a dictation by conforming to the rules and procedures used in real settings to dictate a text to primary school children. A better understanding and modeling of these rules and procedures is crucial to develop robust automatic tools that could be used in autonomy by children to improve their spelling skills through dictation with the use of speech synthesis. The different steps used to derive the prosodic chunks from a given text will be explained through concrete examples. The proposal made here relies on the analysis of a corpus of 10 dictations given to children in French and French Canadian elementary schools, and more precisely during their first three years in elementary school (i.e., cycle 2 in the French school system). The phrasing observed in the data is described. It is thus simplified in order to develop an algorithm that automatically generates prosodic chunks from texts.

Within- and Between-Speaker Variability of Parameters Expressing Short-Term Voice Quality
This study focuses on short-term acoustic correlates of voice quality. It assesses the within-speaker stability (across different speaking styles) and between-speaker variability of measurements which compare the amplitudes of various spectral events H1*-H2*, H2*-H4*, H1*-A1*, H1*-A2* and H1*-A3*. Although speakers do differ with regard to the compactness of the parameters in read and spontaneous speaking styles, the parameters H1*-H2*, H1*-A1* and H1*-A2* appear both considerably stable for one speaker

in different speaking styles and efficient in between-speaker comparisons. Though not directly applicable in forensic settings, these glottal parameters outperformed vowel formants in classification using LDA.

Bénédicte Grandon, Hiyon Yoo,
Do Korean L2 learners have a "foreign accent" when they speak French? Production and perception experiments on rhythm and intonation
French and Korean are two languages with similar prosodic characteristics as far as rhythm and intonation are concerned. In this paper, we present the results of production and perception tests where we describe the prosodic characteristics of Korean L2 learners of French. The aim is to analyze the impression of "foreign accent" for two prosodic components (intonation and rhythm) of speech produced by Korean L2 learners of French and the perception of this "accent" by native listeners of French (L1). We show that the productions of Korean learners and French native speakers present minor differences but that they do no translate into cues for determining clearly the presence of a "foreign accent".

Linda Garami, Anett Ragó, Ferenc Honbolygó, Valéria Csépe,
Prosodic processing in the first year of life: an ERP study
From early months of life prosody has a prominent contribution to segmentation: prosodic boundaries overlap with syntactic ones and facilitate the extraction of syntactic regularities both at word and at phrase level. Therefore, the long-term representation of rhythmic features of the native language, especially the stress templates derived from regularities are assumed to play a particular role in pre-lexical processing. We examined the nature of early stress representation in a language with a fixed stress pattern in an electrophysiological experiment (acoustic passive odd-ball paradigm, 10 month-olds: 28 infants; 6 month-olds: 21 infants, 400 items, deviant: p=20%) using bi-syllabic Hungarian pseudo-words to follow how prosodic features contribute to processing saliency and how word stress templates based on regularities may emerge. We used legally and illegally stressed stimulus both in standard and deviant positions in separate conditions. In the legal standard condition two mismatch responses (MMRs) temporally synchronized to each syllable could be recorded. On the contrary, in the illegal standard condition no significant response was found. It seems that language environment influences the processing of speech prosody and the MMR correlates of word stress processing are related both to saliency and to stress templates emerging during the first year of life.

The Inadequacy of Rhythm Metrics to Quantify L2 Suprasegmental Characteristics
The study investigated the L2 speech rhythm of Chinese English speakers (L1 = Mandarin) using the metrics of deltaV, deltaC, %V, VarcoV, VarcoC, rPVI-C and nPVI-V. Five native speakers of American English and Mandarin were recruited to record five sentences in English. In addition, the Chinese speakers also recorded five Mandarin sentences. One-way ANOVAs were conducted to see if significant differences exist on each of the metrics among L1 English, L2 English and L1 Mandarin. Results show that the two L1's are categorically distinct on all metrics, conforming to the perceptually distinct rhythmicities of English and Mandarin. However, no significant differences were found between L1 and L2 English which have different intuitive rhythmicities, suggesting that the metrics are inadequate to capture the suprasegmental details that give the final make-up of speech rhythm.Finally, new directions of speech rhythm research and new applications of the rhythm metrics are sketched.

Pitch range declination and reset in turn-taking organisation
In this paper, we investigate how pitch range declination and reset contribute to turn-taking organisation. We (i) investigate the effect of the unit position in a turn on its pitch range as well as (ii) compare the difference in pitch range between consecutive units that are separated by a gap vs. a pause. We also (iii) test the effect of the number of speech units in a turn as well as the turn duration on the peak height

at the beginning of the turn. Our results suggest a pitch range declination trend between the Initial and Median speech units of a turn but a violation of this declination for the Final units of the turn. Consequently, the difference in two consecutive units' pitch range is found larger at pauses than at gaps. Our results also show that the higher the number of speech units in a turn or the longer the turn, the higher the peak height. Our findings particularly reveal that the distance between the pitch range level and its upper limit may be a salient cue in projecting the end of a turn. We discuss our findings along the debate on Projection and Reaction theories and that of Hard vs. Soft pre-planning of speech production, and address how these findings may be useful for human-machine interactions.

Towards Automatic Extraction of Prosodic Patterns for Speech Synthesis
This paper deals with the adaptation of AuToBI annotation for speech synthesis purposes. AuToBI is a tool that automatically detects and classifies the standard ToBI labels for American English. AuToBI annotation is performed word-by-word. However, a labeling of intonation patterns at the intonational phrase level is essential for the detection of the correlation between theme/rheme (thematicity) and prosody and also much more appropriate for speech synthesis applications that use various layers of linguistic annotation (syntax, semantic, information, and prosody structures), such that if used in speech synthesis applications, AuToBI's output would require a post-processing stage of the extracted labels. We present a procedure that includes an initial AuToBI annotation and the adaptation of the AuToBI output to a phrase-based annotation, following a set of determined rules. A further analysis of the correspondence between prosodic patterns and themacity structures is used to validate the results.

Automatic Detection of Filled Pauses and Lengthenings in the Spontaneous Russian Speech
During automatic speech processing a number of problems appear, and among them there are such as speech variation and different kinds of speech disfluences. In this article an algorithm for automatic detection of the most frequent of them (filled pauses and sound lengthenings) based on the analysis of their acoustical parameters is presented. The method of formant analysis was used to detect voiced hesitation phenomena and a method of band-filtering was used to detect unvoiced hesitation phenomena. For the experiments on filled pauses and lengthenings detection a specially collected corpus of spontaneous Russian map-task and appointment-task dialogs was used. The accuracy of voiced filled pauses and lengthening detection was 82%. And accuracy of detection of unvoiced fricative lengthening was 66%.

Prosodic analysis of the speech of a child with cochlear implant
According to previous studies [1,6], acoustic and perceptual analysis can be considered useful clinical tools to investigate the speech characteristics of hearing impaired children (HIC). This research aimed at describing the perceptual and acoustic correlates of the speech samples from a HI and user of CI child (within the chronological age range of 5 years and 1 month and 7 years and 1 month), through the vocal quality and voice dynamics descriptions in two different moments. The speech samples were collected during speech therapy sessions. The perceptual analysis of the vocal quality was based on the Vocal Profile Analysis Scheme for Brazilian Portuguese (BP-VPAS - Camargo &Madureira, 2008). The recorded corpus was analyzed through the ExpressionEvaluator script (Barbosa, 2009) ran by Praat software v5.2.10. The measures, which were automatically extracted, comprised the fundamental frequency f0, first f0 derivative, intensity, spectral slope and long-term mean spectrum. The correlations found between the acoustic and perceptual data proved relevant for rehabilitation processes.

Structural and Prosodic Correlates of Prominence in Free Word Order Language Discourse
Production and perception experiments with native speakers of Russian, a free word order language, show

that prosody and change in word order are used to mark discourse-prominent constituents. Concurrent application of these cues to prominence is possible, as evident from distinctively higher f0 and intensity maxima, and duration values associated with ex- situ words, as well as their higher visibility in discourse. Distinctive acoustic-prosodic realization of ex-situ words may cue their relatively high informational load and discourse prominence, as well as (redundantly) signal that the word is left- or right-dislocated.

Segmental Influences on the Perception of Pitch Accent Scaling in English
In both tone and intonation systems, segmental context is known to influence production and perception of target F0 contours in various ways. Many languages, for example, prefer to realize critical F0 events during maximally sonorous intervals, either by varying the timing of pitch movements, or by virtue of distributional limitations on certain contour types. Current analytic practice, by contrast, routinely ignores segmental backdrop when estimating the perceptual efficacy of putative cues, such as F0 turning points, to tone scaling and timing patterns. Results of the perception study presented here argue that pitch accent scaling is best modeled using a weighted average of F0 sampled over a defined region of interest, and that individual sample weights are determined in part by the sonority of the segments from which they are taken. That is, samples from lower sonority segments contribute less to integrated scaling percepts than those from higher sonority segments. This model, called TCoG-F(requency), accounts for crosslinguistic tonal timing and distribution patterns in the literature, and underscores the danger of analyzing tonal phenomena completely apart from the segments that express them.

Intonational phonology in Bengali and English infant-directed speech
We examined the phonetics and phonology of intonation of infant-directed speech (IDS) and non-IDS in story-reading in two typologically-divergent languages, English and Bengali. In addition to finding an increase in f0 range and variability in IDS, replicating previous work on IDS prosody, we found novel evidence that f0 manipulations in IDS are constrained by intonational phonology. Speakers in both languages used an increased proportion of tonal elements with higher tonal targets and more turning points in IDS, within the language-specific intonational grammar. The tonal elements showing increased use in IDS also were associated with marking topic and focus. Thus, phonetic changes in IDS may in part be induced by speakers' choices of phonological tonal elements, which in turn may be connected with choices about marking discourse structure.

Hemispheric lateralization of sentence intonation in left handed subjects with typical and atypical language lateralization: an fMRI study
Introduction: Prosody (as the melody of speech) is an important component of human social interactions. More specifically, linguistic prosody conveys meaning of speech through syllable, word, or sentence level stress and intonation. In the modern neuroimaging era the hemispheric representation of sentence intonation is widely investigated. Most of these studies suggest bilateral activations predominantly in the perisylvian language areas and in the subdominant homologues. However, there are some inconsistencies about the hemispheric representation and lateralization of linguistic prosody. These inconsistencies could be due to the lack of attention on the language lateralization of the subjects. Aims: The present study aims to investigate the hemispheric representation and lateralization of linguistic prosody with a

sentence intonation task in two groups of left handed subjects with typical and atypical language lateralization. Functional MRI was used to test the assumption that - according to the functional lateralization hypothesis - the representation of sentence intonation is predominantly lateralized within the language dominant hemisphere and the lateralization of sentence intonation is associated with language lateralization in both groups. Methods: Left handers were examined to create two groups of subjects with typical and atypical language lateralization. In all, 32 healthy subjects were evaluated with a standard verbal fluency task with fMRI in order to assess functional hemispheric language lateralization. In our final investigation the atypical group consisted of 8 subjects with right hemispheric language dominance (LI<-0.2) and the typical group also consisted of 8 subjects with left hemispheric language dominance (LI>0.2). Sentence intonation task was utilized to test linguistic prosody skills with fMRI. 49 pairs of sentences (18 pairs of neutral-neutral sentences, 10 pairs of interrogative-interrogative sentences, and 1 pair of interrogative-neutral sentence) were presented with an event-related design. Sentences were matched in terms of syntactic structure, semantic complexity and length and all were affectively neutral. In the fMRI data analysis interrogative pairs were compared to neutral pairs. Results: One of the main findings of our study is that subjects with both typical and atypical language lateralization activated the middle temporal gyrus (MTG) on the right side. The activation of the MTG on the right hemisphere is classically associated with the encoding of prosodic information. Furthermore, both groups recruited the frontal language areas only in the language-dominant hemisphere. Moreover, between-group comparison showed significantly stronger activations in subjects with typical language lateralization only in left sided language areas: pars triangularis of the inferior frontal gyrus, the superior frontal gyrus and the inferior parietal lobule. Conclusion: This finding is in accordance with the functional lateralization hypothesis of prosody, and suggests a correlation between linguistic prosody lateralization and language lateralization.

The acquisition of multimodal cues to disbelief

In this study, we examine how 3-, 4-, and 5-year-old Catalan-acquiring children are able to make use of the audio (intonational) and visual (facial gesture) modalities in the comprehension of speaker disbelief, as well as the role of a child's developing Theory of Mind. Our results suggest that in this case, facial gesture provides children with scaffolding for linguistic meaning. In addition, those children that passed a false belief task tended to perform better on the comprehension task in general. We discuss the implications of these findings for the study of intonational development.

Amalia Arvaniti, Mary Baltazani, Stella Gryllia,

The pragmatic interpretation of intonation in Greek wh-questions

We experimentally investigated the pragmatics of two melodies commonly used with Greek wh-questions, L*H L-!H%, described as the default, and LH* L-L% considered less frequent and polite. We tested two hypotheses: (a) the !H%-ending melody is associated with information-seeking questions, while the L%-ending melody is pragmatically more flexible and thus appropriate also for non-information-seeking wh-questions expressing bias; (b) the !H%-ending melody, being more polite, is more appropriate for female talkers, all else being equal. In Experiment 1, comprehenders rated !H-ending and L%-ending versions of the same questions for politeness and appropriateness for the context in which they were heard (which favored either information-seeking or "biased" wh-questions). In Experiment 2, comprehenders heard the same questions and chose between two follow-up responses, one providing information, the other addressing the bias of the wh-question. Comprehenders rated !H%-ending questions more appropriate than L%-ending questions and judged the !H%-ending questions of female talkers more polite. They also chose information-providing answers more frequently after !H%- than L%-ending questions, but the preference was higher for female talkers and depended on comprehender gender. The results argue in favor of a compositional view of intonational meaning which depends not only on the tune but also on context, broadly construed.

Pablo Arantes, Anders Eriksson,

Temporal stability of long term measures of fundamental frequency

We investigated long-term mean, median and base value of F0 to estimate how long it takes for their variability to stabilize. Change point analysis was used to locate stabilization points. In one experiment

stabilization points were calculated in recordings of the same text spoken in 26 languages. Average stabilization points are 5 seconds for base value and 10 seconds for mean and median. Variance after the stabilization point was reduced around 40 times for mean and median and more than 100 times for the base value. In other experiment, four speakers read each two different texts. Stabilization points for the same speaker across the texts do not exactly coincide as would be ideally expected. Average point dislocation is 2.5 seconds for the base value, 3.4 for the median and 9.5 for the mean. After stabilization, individual differences in the three measures obtained from the two texts are on average 2% on average. Present results show that stabilization points in long-term measures of F0 occur earlier than suggested in the previous literature..

4.3 Friday Session Three

2pm - 3:30pm : 4-3-plenary (1+3 presentations)

4.3.1 KeyNote 4

Anne Cutler - Invited Keynote:

Aspects of the suprasegmental structure of speech are famously subject to speaker choice. There is no obligatory location for accent in a sentence such as "She didn't run home"; speakers may say "SHE didn't run home" or "She DIDN'T run home" or "She didn't RUN home" or "She didn't run HOME", with different resulting inferences in each case. But do listeners also have any degree of choice in the auditory processing of this dimension of speech? This presentation will argue that they do, and support the argument with evidence from laboratory studies of spoken-word recognition, of semantic structure computation in spoken sentences, and of the processing of delexicalised prosodic signals.

4.3.2 p.1154

Meredith Brown, Laura Dilley, Michael Tanenhaus,
Probabilistic prosody: Effects of relative speech rate on perception of (a) word(s) several syllables earlier
Speech perception depends on the ability to rapidly accommodate considerable variability in speech rate. We present results from two eye-tracking experiments indicating that listeners use context speech rate to generate, maintain, and update probabilistic hypotheses about the timing and number of constituents in upcoming speech. Participants heard utterances containing polysyllabic nouns preceded by indefinite articles and followed by [s]-initial words (e.g. ...saw a raccoon slowly...). We altered the speech rate of the indefinite article and of the [s] with respect to surrounding context, manipulating the likelihood that the item would be perceived as singular (a raccoon) vs. plural (raccoons). Shorter indefinite articles elicited higher proportions of fixations to plural target pictures than longer articles both before and after the processing of [s], demonstrating that listeners made rapid use of prosodic cues to the presence or absence of the article. Importantly, fixations were also influenced by the duration of [s] relative to context speech rate. These findings suggest that listeners maintain and update provisional speech-rate hypotheses across multiple morphophonemic units. We interpret these results with respect to probabilistic approaches to spoken language understanding.

4.3.3 p.1159

Jill C. Thorson, James L. Morgan,
The role of intonation in early word recognition and learning
The motivation for our study is to investigate how English-acquiring toddlers are guided by the mapping between intonation and information structure during on-line reference resolution and in novel word learning tasks. We ask whether specific pitch movements (deaccented, monotonal, bitonal) more systematically predict patterns of attention and subsequent novel word learning abilities depending on the referring or learning condition (new, given, contrastive). Experiment 1 examines the attentional patterns of 18-month-old toddlers when referents are either new or given in the discourse, and carry one of the three pitch accent types. Contrary to previous work, results show increased attention to the target in the deaccented condition if the referent is new to the discourse. Also, both monotonal and bitonal pitch movements direct attention to the target even when the target is given. Thus, pitch type interacts with information structure in directing toddler attention. Experiment 2 tests two-year-olds in a novel word

learning task, varying pitch type and contrastiveness during learning. Preliminary results show that learning is aided when the novel word is introduced in contrast to a previous referent. Together, these two experiments demonstrate the role of pitch type and information structure in guiding attention and aiding early word learning.

4.3.4 p.1164

Rory Turnbull, Adam J. Royer, Kiwako Ito, Shari R. Speer,
Prominence perception in and out of context
The perception of prosodic prominence is known to be influenced by several distinct factors. In this study, we investigated the role of context, both global and local, in the prominence judgements of naïve listeners. Monolingual English listeners marked where they heard prominence on pairs of two-word phrases (e.g. *blue ball*, *green drum*). Stimuli varied in whether or not the first phrase implied a contrastive focus on the second phrase. We found clear evidence of a hierarchy of prominence across pitch accent types: L+H* >H* >!H* >unaccented. Additionally, we found that contrast status only affected prominence markings when the participants were made explicitly aware of the discourse context and were instructed to imagine themselves physically present to observe the conversation. This effect of global context suggests that information structure cannot be reliably interpreted in the absence of an established discourse context. Taken together, these results suggest that naive listeners are sensitive to prominence differences at levels corresponding to categorical annotations. Perception of a word's relative prominence was consistently influenced by phonetic and phonological factors, while pragmatic factors (such as contrast-evoking context) required more elaborate plausibility manipulations in order to affect prominence perception.

Cue-based analysis of speech: implications for prosodic labelling systems

Over the past few decades it has become clear that an adequate account of systematic context-driven variation in word forms requires representations below the level of the abstract symbolic phoneme or even the allophone. One proposal for this sub-allophonic level of description is in terms of feature cues, such as the cues to articulator-free features and articulator-bound features proposed by Halle (1992) and by Stevens (2002), also assumed in the concept of enhancing cues in Stevens and Keyser (2010), Keyser and Stevens (2006) and Stevens, Keyser and Kawasaki (1986). This proposal of a level of representation of discrete feature cues, along with continuous-valued cue parameters, has the potential to bridge the gap between abstract symbolic categories of the phonology and the concrete spatial and temporal specifications that drive the articulatory-acoustic implementation of word forms in continuous communicative speech. Such an approach suggests that phonetic transcription might benefit from a focus on capturing the individual cues to feature contrasts that are realized in the speech signal. Does this approach to understanding phonetic variation in word forms have implications for prosodic labelling? We will explore this possibility, taking as our point of departure Arbisi-Kelm's (2006) proposal for labelling the separate correlates of prosodic disfluency in stuttered speech, and adapted by Brugos and Shattuck-Hufnagel (2012) for prosodic disfluencies in utterances produced by typical speakers. Our hypothesis is that variation in cue selection and cue parameter values is systematically governed by context, and that cue-level transcription may be needed to capture systematicity in the phonetic implementation of prosodic phonology as well as of lexical phonology.

Abstract

Entrainment is the propensity of speakers to begin behaving like one another in conversation. We identify evidence of entrainment in a number of acoustic and prosodic dimensions in conversational speech of Standard American English speakers and Mandarin Chinese speakers. We compare entrainment in the Columbia Games Corpus and the Tongji Games Corpus and find similar patterns of global and local entrainment in both. Differences appear primarily in global convergence.
Index Terms: prosody, entrainment, discourse

1. Introduction

Entrainment — also known as *adaptation*, *accommodation*, or *alignment* — occurs in many dimensions of human-human conversation as people begin to act similarly to one another. This process is critical to humans' assessment of dialogue success and overall quality and to their evaluation of conversational partners [1, 2]. In a study of entrainment on gesture and facial expression, [3] found that subjects displayed strong unintentional entrainment and that greater entrainment led them to report liking their partner more and believing the interaction was progressing more smoothly. [4] found that degree of entrainment in lexical and syntactic repetitions occurring in just the first five minutes of a dialogue significantly predicted task success in studies of the HCRC Map Task Corpus.

In previous research on acoustic-prosodic indicators of entrainment ([5, 6, 7]), we found considerable evidence of entrainment in the Columbia Games Corpus. In this paper we examine cross-language and cross-cultural entrainment.[1] We compare results from our previous experiments on Standard American English (SAE) conversations to entrainment in Mandarin Chinese (MC) conversations collected in a similar setting in the Tongji Games Corpus. We compare entrainment in pitch, loudness, and speaking rate over all speakers and in female, male, and mixed-gender dialogue pairs.

Entrainment has been studied at the conversation level or at the turn level. At the conversation level, there may be evidence of an overall coordination of behavior despite local variation; at the turn level there may be turn-by-turn coordination, in which speakers closely match their partner's previous turn. Entrainment may also be measured in different ways, in terms of *similarity* over either level, *synchrony*, as behavior varies in tandem, although absolute values of features may be different, or *convergence*, as behaviors become more similar over time.

[1]Our previous findings on the Columbia Games Corpus are presented here for comparison and contrast with the new findings on the Tongji Games Corpus.

Our goal is to identify where subjects from these different language groups show evidence of each of these aspects of entrainment at the global and local levels. In Section 2 we describe the corpora we compare. In Section 3 we describe the acoustic and prosodic features we examined. In Section 4 we compare MC and SAE speaker entrainment at the global or conversational level. In Section 5 we make similar comparisons at the local or turn-by-turn level. In Section 7 we discuss our results and describe future research.

2. Corpora

2.1. Columbia Games Corpus

The SAE experiments in this work were conducted on the Columbia Games Corpus [8], a corpus of spontaneous, task-oriented speech between pairs of strangers. The corpus comprises twelve dyadic conversations elicited from thirteen native speakers of SAE (six female, seven male). Each pair of subjects played a set of computer games that required them to cooperate to achieve a mutual goal. Subjects were recorded in a sound-proof booth on laptops with a curtain between them. Neither could see the other's screen. In the Cards games, one speaker (the information *giver*) described the cards she saw on her screen, and her partner (the *follower*) attempted to match them to the cards on his screen. In the Objects games, one speaker (the *giver*) described the location of an object on her screen, and her partner (the *follower*) attempted to place the corresponding object in exactly the same location on his own screen. For each game, participants received points based on how exact a match was; they later were paid for each point. Each of the twelve sessions consists of two Cards games and one Objects game. Each session, on average, contains 45 minutes of dialogue. On average, each Cards game took 7.7 minutes, and each Objects game took 21.5 minutes. In total, the corpus consists of approximately nine hours of recorded dialogue. It has been orthographically transcribed and annotated with prosodic and turn-taking labels.

2.2. Tongji Games Corpus

The MC experiments in this study were conducted on theTongji Games Corpus. The corpus contains approximately 12 hours of spontaneous, task-oriented conversations between pairs of subjects comprising 115 conversations averaging 6 minutes between 70 pairs of speakers (40 female, 30 male). Subjects were randomly selected from university students with a National Mandarin Test Certificate level 2, with a grade of A or above to increase the likelihood that the Mandarin spoken in the corpus is standard. Recordings were made in a sound-proof

booth on laptops with a curtain between participants so that neither could see the other's screen. Two games were used to elicit spontaneous speech in the collection of the corpus. In the Picture Ordering game, one subject, the information *giver*, gave the other, the *follower*, instructions for ordering a set of 18 cards. When the task was completed, the same pair switched roles and repeated the task. In the Picture Classifying game, each pair worked together to classify 18 pictures into several categories by discussing each picture. Seventeen pairs played the Picture Ordering game; 39 pairs played the Picture Classification game; and 14 pairs played both games. The corpus was segmented automatically using SPPAS [9]. The automatic segments were manually checked and orthographically transcribed. Turns were identified by two PhD students specializing in Conversation Analysis.

3. Features and units of analysis

The smallest unit of analysis in this work is the *inter-pausal unit*, or IPU, defined as a pause-free segment of speech from a single speaker. A *turn* is defined as a maximal sequence of IPUs from a single speaker. For the SAE speakers 50ms was used as the minimal pause length and 80ms was used for the MC speakers, based upon the average length of stop gaps in each corpus. Each game conversation in the Tongji Corpus is also divided into 18 tasks, each of which involves the placing or classification of a single card. For our analysis, we include one randomly chosen conversation from each of the 70 speaker pairs for a total of 70 conversations among 99 speakers, since some speakers participated more than once with different partners. We compare seven acoustic-prosodic features in our comparison: intensity min, intensity mean, intensity max, f0 min, f0 mean, f0 max, and speaking rate (syllables/second). All seven were extracted from each IPU using Praat ([10]). We compare results from the MC subjects with our previous experiments on SAE speakers ([6, 7]), in which we looked at intensity mean, intensity max, f0 mean, f0 max, jitter, shimmer, noise-to-harmonics ratio (NHR), and speaking rate.

4. Global entrainment

We begin our analysis by considering entrainment globally, to see whether speakers are similar with respect to a given feature at the conversation level. We first look for evidence of global similarity, using a method proposed in [6]. For each speaker, we compute a *partner* similarity and a *non-partner* similarity. The first is the negated absolute difference between the two partners' values. The second is the negated absolute difference between a speaker and the averaged values for the non-partner speakers in the corpus. For the MC study, the non-partners are restricted to those of the same gender and conversational role (information giver or receiver) as the partner. If partner similarities are larger than the non-partner similarities for a given feature, we conclude that the speakers entrain on that feature. Using this method, we previously showed ([6]) that speakers of SAE showed evidence of *global* entrainment for intensity mean, intensity max, f0 max, and speaking rate. That is, for these four features, speakers were more similar to their partners than to the speakers in the corpus with whom they were never paired. For intensity mean and max, they were also more similar to their partners' speech than they were to the speech that they produced themselves in conversation with a different interlocutor.

Our comparison shows (Table 1) the same pattern for MC speakers as for SAE speakers. Speakers in the Tongji Games Corpus were significantly more similar to their partners than to their non-partners in intensity mean, intensity max, f0 max, and speaking rate. That is, for all four features that show evidence of entrainment in SAE, speakers of MC show evidence of entrainment as well. As in the SAE study, we found no evidence of global entrainment on f0 mean. The MC subjects also showed no evidence of entrainment for intensity min or f0 min, which the SAE study did not consider.

Table 1: *T-tests for global similarity in Mandarin Chinese.*

Feature	t	df	p	MC	SAE
Intensity mean	-5.05	98	0.0	✓*	✓
Intensity max	-5.13	98	0.0	✓	✓
Intensity min	-1.16	98	0.25	x	–
F0 mean	0.67	98	0.51	x	x
F0 max	-3.44	98	0.001	✓	✓
F0 min	0.45	98	0.65	x	–
Speaking rate	-7.99	98	0.0	✓	✓

* A checkmark indicates differences are significant for a language.

4.1. Global convergence

While global similarity takes a static view of entrainment, global convergence measures entrainment dynamically, to see whether speakers increase in similarity as the conversation progresses. In our study of entrainment in SAE, we divided each conversation into two parts. If for a given feature the similarity between speaker averages in the second part was greater than their similarity in the first part, we concluded that the speakers displayed convergence on that feature. We further experimented by splitting the first *game* in each session in half (each session in the Games Corpus consists of three games) and then with splitting the entire session in half. We found that intensity mean, shimmer, and NHR were more similar in the second half of the first game than in the first, and that shimmer and NHR, which do not show evidence of entrainment when computed over an entire session, are more similar between partner than between non-partners when computed over the second half alone ($p < 0.0001$). When we compared similarity features across halves of an entire session, we found that pitch mean and jitter were more similar in the second half. We found no evidence of convergence on f0 max or speaking rate in SAE.

In the Tongji Games Corpus, each conversation consists of 18 sections, each of which involves the placement or description of a single card. We compared partner differences over the first nine sections with those in the second nine. We also compared partner differences in the first section with those in the last. The analysis in this section is over 66 conversations; four were omitted because they were missing speech from one of the interlocutors for one or more of the 18 sections. We found that intensity mean and max were significantly more *different* in the second halves of the conversations; no other significant differences were found. We therefore cannot conclude that MC speakers globally converge on any of the features we examined.

5. Local entrainment

Our domain of entrainment in the previous section is global – across the whole conversation. That is, overall, we can say that speakers are similar to each other – more similar than they are to people with whom they are not speaking – but they may not be similar locally: a pair of speakers may fluctuate around similar

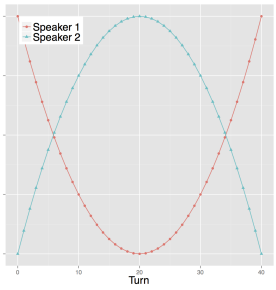

Figure 1: *Speakers entraining locally but not globally.*

means for a feature but diverge widely at any given point. Figure 1 illustrates such a case. The speakers' means are identical, but the distance between them at most points in time is large.

We test for local similarity entrainment by comparing the distance between adjacent IPUs at turn exchanges. If, for a given feature, adjacent IPUs are more similar than non-adjacent IPUs, we conclude that speakers entrain *locally* on that feature, irrespective of their *global* similarity. Consider a conversation comprised of turns $0...n$. For turn i, uttered by speaker A, we calculate the *adjacent* distance as the distance between the initial IPU in turn i, and the final IPU in turn $i-1$, spoken by B. The *non-adjacent* distance is the distance between the turn i's initial IPU and the final IPUs in ten other randomly chosen turns uttered by B. In our study of entrainment in the Columbia Games Corpus, we found evidence of *local* entrainment for every feature we examined using this method. Table 2 shows the results of our comparisons between the adjacent and non-adjacent distances for MC compared with previous results for SAE; t-test values are for MC; checkmarks indicate where the difference is significant for the language. Our results show

Table 2: *T-tests for local similarity in Mandarin Chinese.*

Feature	t	df	p	MC	SAE
Intensity mean	-3.72	69	0.001	✓*	✓
Intensity max	-4.16	69	0.001	✓	✓
Intensity min	0.75	69	0.458	x	–
F0 mean	1.28	69	0.205	x	✓
F0 max	0.81	69	0.419	x	✓
F0 min	-0.17	69	0.986	x	–
Speaking rate	-3.61	69	0.001	✓	✓

* A checkmark indicates differences are significant for a language.

that in MC conversations showing evidence of *global* entrainment, speakers tend to entrain *locally* on intensity mean, intensity max, and speaking rate. This pattern is consistent with our results for *global* entrainment, which was evident in our data for those three features but also for f0 max. However, in contrast to our results for global entrainment, which showed entrainment on the same features as SAE, we did not see evidence of local entrainment on f0 mean or max, while all features displayed local entrainment in SAE.

5.1. Local synchrony

Another way of measuring entrainment is by studying whether speakers' behavior changes in synchrony. Measuring the Pearson's correlation between two sets of values, proposed by [11], captures the dynamics of turn-by-turn synchronous matching between interlocutors to see whether speakers' values vary together even if they are not similar. In our SAE study we found significant correlations between adjacent IPUs for all features ($p \approx 0$). However, correlations for most features were weak ($\gamma < 3$). Intensity mean and max were moderately correlated between adjacent IPUs ($\gamma = 0.50, 0.47$).

To reduce the degree of computation for local synchrony and convergence, we computed the MC correlations over only 30 conversations out of the 70 for which we examined global entrainment, randomly selecting ten conversations each from female-female, male-male, and mixed-gender pairs. We found much stronger correlations between adjacent IPUs in the MC conversations (Table 3). The most noticeable difference between the two languages is that, in SAE, correlations between f0 features in adjacent IPUs are weak, while in MC, they are among the strongest. This may reflect that fact that pitch plays a dual role in a tonal language, conveying both lexical and pragmatic information. Additionally, it is interesting to note the pattern similarities: the correlations for means, both intensity and f0, are slightly stronger than the correlations for maximums, and the correlation for speaking rate is the lowest correlation in both languages, though far more so in MC.

Table 3: *Pearson's correlation between adjacent IPUs. ($p \approx 0$ for all results except MC speaking rate)*

Feature	γ MC	γ SAE
Intensity mean	0.63	0.50
Intensity max	0.55	0.47
Intensity min	0.31	–
F0 mean	0.66	0.28
F0 max	0.61	0.18
F0 min	0.63	–
Speaking rate	-0.048	0.15

5.2. Local convergence

For another view of local entrainment, we look at whether entrainment increases over time: whether speakers *converge* locally. As before, we calculate the difference between adjacent IPUs at turn exchanges (the *adjacent* distance). We then correlate this distance with time. A negative correlation constitutes evidence that the distance between partners at turn exchanges decreases with time. In our SAE study, we found negative correlations between adjacent distance and time for pitch mean and max ($\gamma = -0.06, -0.05; p = 4.6e-11, 4.9e-08$). However, these correlations, although highly significant, are also extremely low.

Using the same 30 MC conversations as in the previous section, we numbered all the turns in each conversation and correlated the adjacent distances for each feature with the turn indices (Table 4). For our MC corpus, the negative correlations between adjacent differences and time are about four times as strong as correlations for the SAE corpus, although still only moderate. As with SAE, we see significant local convergence for pitch mean and max, as well as for intensity min and f0 min, which the SAE study did not consider. Speaking rate, however, shows *divergence*.

6. Entrainment and gender

Several theories of entrainment predict that females will entrain to a greater degree than males. The male dominance hypothesis asserts that differences in speech between males and females can be attributed to women's subordinate social status. Speech

Table 4: *Pearson's correlation between adjacent differences and turn index in Mandarin Chinese.*

Feature	γ	p	MC	SAE
Intensity mean	0.028	0295	x	x
Intensity max	0.022	0.418	x	x
Intensity min	-0.086	0.001	✓*	–
F0 mean	-0.218	0.0	✓	✓
F0 max	-0.238	0.0	✓	✓
F0 min	-0.193	0.0	✓	–
Speaking rate	0.128	0.0	x**	x

* A checkmark indicates differences are significant for a language.
** Displays divergence.

Accommodation Theory ([12]) claims that when a power imbalance exists between interlocutors, the less dominant or powerful speaker will converge more. However, [13] found that these theories failed to explain results of their observations of convergence and divergence in same- and mixed-gender dyads. Alternatively, [3] posits that the perception-behavior link is the mechanism behind entrainment. Thus, women should entrain more than men, regardless of the gender of their conversational partner, because women are known to have greater perceptual sensitivity to vocal characteristics. [14] explained their finding that female speakers were perceived to accommodate more in a shadowing task than male speakers in this way. [15], on the other hand, found that female pairs were *less* similar to each other than male pairs, and concluded that functions outside the domain of perception appear to be influencing the degree of phonetic convergence.

For SAE, we found ([7]) that female-male pairs entrained on every feature examined; in addition, the degree of entrainment on intensity mean and max was greatest for female-male pairs. Male pairs showed the least evidence of entrainment, entraining only on intensity mean, intensity max, and syllables per second, supporting the hypothesis that entrainment is less prevalent among males. Their degree of entrainment on these features was also lower than that displayed by female or mixed-gender pairs. Female pairs entrained on all features except pitch mean, pitch max, and jitter.

The Tongji Games Corpus includes 23 female-female conversations, 17 male-male, and 30 mixed-gender. As in Section 4, and as in [7], we compared *partner* differences – the differences in feature values between interlocutors – with *non-partner* differences – differences in feature values between each speaker and the averaged values with all speakers of her partner's gender and role with whom she is never partnered. Our results are shown in Table 5. Again, the similarity in pattern to

Table 5: *Evidence of global entrainment by gender group.*

Feature	FF		MM		MF	
	MC	SAE	MC	SAE	MC	SAE
Intensity mean	✓	✓	x	✓	✓	✓
Intensity max	✓	✓	x	✓	✓	✓
Intensity min	x	–	x	–	x	–
F0 mean	x	x	x	x	✓	✓
F0 max	x	x	x	x	✓	✓
F0 min	x	–	x	–	x	–
Speaking rate	✓	✓	✓	✓	✓	✓

our results for SAE is striking. We find that mixed-gender pairs entrain on the greatest number of features, and male pairs on the least. As for SAE, the most consistent results are for intensity mean, intensity max, and speaking rate, although all gender groups entrained on these in SAE, and male pairs entrain only on speaking rate in MC.

In addition to the number of features entrained on, we are also interested in the degree of entrainment exhibited by each gender group. We compare each group's *partner* similarities, normalized by the *non-partner* similarities to control for the overall within-group similarity. We compare the strength of entrainment on intensity mean, intensity max, and speaking rate, the three features that show the most evidence of entrainment among all three gender groups. For SAE, we found that entrainment on intensity mean and max was strongest for mixed-gender pairs and weakest for male pairs; the strength of entrainment on speaking rate followed this pattern but the differences only approached significance ($p = 0.08$). For MC, the differences in entrainment strength were significant between all three groups for all three features (Intensity mean: $F = 3.13, p = 0.048$; intensity max: $F = 3.73, p = 0.028$; speaking rate: $F = 5.10, p = 0.008$). A post-hoc test revealed that entrainment on intensity mean and max was weakest for male pairs, while entrainment on speaking rate was weakest for mixed-gender pairs. While for SAE, we concluded that entrainment is both strongest and most prevalent in mixed-gender pairs, for MC we can only conclude that it is most prevalent in mixed-gender pairs, but not necessarily strongest.

7. Discussion and Future Research

The truly striking finding presented in this paper that entrainment in pitch, intensity and speaking rate appears to be generally very similar in SAE and in MC. We have presented evidence that MC speakers entrain globally in similarity of values for the three main aspects of prosody: duration, pitch and intensity. However, unlike SAE speakers, they show no evidence of global convergence on any feature. Locally, they entrain in similarity of values on intensity and speaking rate and in synchrony on intensity and pitch. They converge locally on intensity min and all f0 features, and diverge on pitch. The prominence of intensity among these results – it is the only feature for which there is evidence of entrainment for all three local measures – is something we observed in SAE as well.

When we examine entrainment behavior among different gender groups, we find that, as for SAE, entrainment is most prevalent in mixed-gender pairs and least prevalent among male pairs. Also as for SAE, all gender groups entrain most consistently on intensity and speaking rate. However, we did not find that entrainment was strongest among MC mixed-gender pairs, as we did for SAE.

The similarity of our findings for Columbia and the Tongji Games Corpora supports not only the view that entrainment is a cross-cultural phenomenon but provides evidence that members of different language groups entrain in similar ways. In future work, we will focus on individual differences in entrainment behavior, analyzing the patterns of which features speakers entrain and converge on, both globally and locally. We will also examine how conversational role affects entrainment behavior.

Speaker Movement Correlates with Prosodic Indicators of Engagement

Rob Voigt, Robert J. Podesva, Dan Jurafsky

Abstract

Recent research on multimodal prosody has begun to identify associations between discrete body movements and categorical acoustic prosodic events such as pitch accents and boundaries. We propose to generalize this work to understand more about continuous prosodic phenomena distributed over a phrase - like those indicative of speaker engagement - and how they covary with bodily movements. We introduce *movement amplitude*, a new vision-based metric for estimating continuous body movements over time from video by quantifying frame-to-frame visual changes. Application of this automatic metric to a collection of video monologues demonstrates that speakers move more during phrases in which their pitch and intensity are higher and more variable. These findings offer further evidence for the relationship between acoustic and visual prosody, and suggest a previously unreported quantitative connection between raw bodily movement and speaker engagement.

Index Terms: acoustic prosody, visual prosody, movement, gesture, speech-gesture interface, automatic methods

1. Introduction

Gesture and movement are fundamental and ubiquitous parts of the human communicative system, but are traditionally understudied phenomena in linguistics. In recent years, interest in the study of multi-modal communication and the connection between speech prosody and "visual prosody" has increased, and empirical evidence has begun to convincingly demonstrate the co-articulatory nature of "gestures and language [as] one system" (McNeill 1992).

For instance, Jannedy and Mendoza-Denton (2006) investigate gesture's role in structuring spoken discourse, showing evidence for the co-occurrence of pitch accents and gestural apices. Krahmer and Swerts (2007) show that even independent of pitch accents, the production of "visual beats" has an effect on the prosodic realization and prominence of the co-occurring speech. Gibbon (2011) demonstrates rhythmic matching between the acoustic and physical beat rhythms in drum-accompanied storytelling in the Ega language. Loehr (2012) confirms findings of temporal synchrony, showing that gestural phrases align with intermediate phrases.

Beyond overt gestures, substantial evidence supports the connection between other kinds of "visual prosody" and speech. Guaïtella et al. (2009) track rapid eyebrow movements in dialogue, and demonstrate their connection with turn-taking in interaction. Cvejic et al. (2010) use facial optical markers in motion capture recordings; in their data, speakers exhibit greater movement during prosodically focused words, even for non-articulatory features such as eyebrow and head movement. Walker (2012) explores "trail-off" conjunctions, showing that speakers and listeners in interaction use visible features such as dropped gaze to signal "disengagement."

Studies in speech perception further demonstrate the important communicative functions of gesture and movement. Munhall et al. (2004) record and recreate 3D models of head movement in talk, finding that subjects are able to correctly identify more syllables when the speech is accompanied by 3D models of natural head movements as compared with distorted or absent models. Scarborough et al. (2009) obtain forced-choice judgments of lexical and phrasal stress from subjects shown video data with the audio track removed; they show that phrasal stress is more easily perceived by subjects than lexical stress. Rilliard et al. (2009) give results for French and Japanese suggesting visual information helps listeners disambiguate "social affects" that are less clear in the audio signal alone.

In spite of this progress, major methodological impediments remain. A principled analysis of gesture in experimental settings requires complex and time-consuming human annotation, commonly based on one of several existing annotation schemes. These include interval annotation of "gesture units" and "gesture phrases" based on written transcripts (Kendon 2004); expressivity annotations on parameters such as "fluidity," "spatial expansion," and "repetitivity" (Chafai et al. 2006); and keyframe-based manual posing of animated 3D characters (Kipp et al. 2007). Though their descriptive power is high, these schemes share the property that they require huge amounts of time and effort from highly-trained human annotators. As a result, existing linguistic studies of gestural prosody necessarily operate on extremely small data sets: for example, Jannedy and Mendoza-Denton (2006) perform their analyses on 130 seconds of videorecorded speech data; Loehr (2012) on speech events from four separate speakers totalling 164 seconds of data.

Analyses of movement pose their own unique difficulties: mainly, raw movement is difficult or impossible to annotate by hand; tools for facial or motion tracking must be used, and this equipment is likely to be expensive or invasive. We therefore know little about the theoretically important relation between affective measures of speaker engagement and the embodied expression that takes form in movement.

This work is aimed at addressing these problems. We introduce a new method for automatically measuring movement magnitude and variance from video data, and apply it to a corpus of single-speaker YouTube videos, extracting acoustic and movement measurements for each phrase in the data. We then investigate the relationship between our proposed movement measure and several prosodic features indicative of engagement including pitch, pitch variance, intensity, and intensity variance (Liscombe, Venditti, and Hirschberg 2003; Mairesse et al. 2007; Gravano et al. 2011; McFarland et al. 2013).

We hypothesize that increased movement amplitude will be predictive of higher values in these acoustic categories. That is, during phrases in which speakers are engaged, excited, and moving more, they will use a correspondingly higher pitch and intensity as well as greater variance in their pitch and intensity.

2. Methods

In this work, we propose a pipeline of fully automatic, replicable annotation for the analysis of visual and acoustic prosody on single-speaker videorecorded data.

2.1. Data

Web-based video streaming services are an increasingly culturally significant tool for communication. YouTube alone reports more than 100 hours of video uploaded per minute[1], of which a significant portion is certainly linguistic in nature - conversations, vlogs, lectures, and so on. Existing work has begun to use YouTube to investigate multi-modal sentiment (Wöllmer et al. 2013) and sociolinguistic aspects of identity construction (Chun 2013), but this data source remains vastly underutilized.

As we describe in Section 2.4, our new proposed "movement amplitude" measure operates on raw video data, without the need for additional equipment at recording time. This makes it useful for the analysis of movement in YouTube data, which has the significant benefit of replicability: since users who post videos explicitly open them to the public, researchers can apply new methods and test new hypotheses on existing datasets without confronting issues of subject confidentiality.

In this study, we focus on the connection between acoustic and visual prosody in a single, narrowly-defined genre of YouTube videos: the "First Day of School" vlog. In such videos students speak into their cameras to describe their experiences in their first day starting or returning to school. This is a productive genre, with a search for "first day of school vlog" on YouTube returning nearly 1.3 million results.

We collect 14 such videos from different speakers, resulting in a total of 95 minutes of footage. The speakers all fit the most commonly represented demographic in such videos: female high-school-aged students from the United States. We use *pafy*[2] to download 360p-quality mp4-encoded versions of each video. Each video consists of a single speaker seated against a static background. We cut each video to a section of continuous speech, removing introductory and closing title cards.

A first application of our methodology to this dataset is interesting and appropriate for several reasons. The videos were found "in the wild," naturally uploaded by the speaker outside of an experimental context. They are linguistically and gesturally interesting; the speakers are in general very animated and performative, communicating directly to their peer group in discussing social expectations, classes, relationships, and so on.

2.2. Automatic Identification of PBUs

We need to extract prosodic units for our analysis; we use pause-bounded units (PBUs), automatically identified with a simple heuristic algorithm using the silence detection function in *Praat* (Boersma and Weenink 2013).[3]

We write a *Praat* script that runs an intensity analysis on the audio track of a given videorecording, then identifies silent and sounding intervals with a minimum duration of one-tenth of a second. We begin with a silence threshold of -30.0 dB and calculate the average length of the phrases thus identified. If the phrases have an average length of greater than two seconds, we increase our silence threshold by +3.0 dB and re-extract, continuing to do so until they average below two seconds in length. Our two-second length threshold is derived from an average length calculation on hand-annotated PBUs from a separate set of interactional data.

2.3. Acoustic Features

Following prior work on prosodic engagement, we extract fundamental frequency (henceforth "pitch") and intensity features for each automatically-identified pause-bounded unit in our dataset. We use a *Praat* script to calculate eight acoustic variables for each PBU: a maximum, mean, minimum, and standard deviation for both pitch and intensity.

2.4. Movement Amplitude

Here we propose a new measure for the analysis of movement in videorecorded data. The intuition behind this measure is simple. Video data consists of a series of frames, which are fundamentally images, played back at a high speed to simulate movement. In circumstances where the video camera is stationary and the background of the recorded images is relatively static, speaker movement can be quantified by measuring the difference between successive frames.

In practice, we propose a measure obtained by finding the average difference in RGB values between a given pixel and the corresponding pixel in the preceding frame, summing these values across all pixels in the image, and taking the natural log of the total. We extract video frames as uncompressed png images using the ffmpeg software package[4] and compute frame differences using the ImageChops python module from the Python Imaging Library.[5] Formally, we define the movement amplitude (MA) measured at time t in (1), with the current frame number n, an image size of width x and height y, and a function $pix_{x,y}(i)$ that returns the red, green, and blue values of a given pixel at an arbitrary frame number i:

$$\mathrm{MA}(t) = \ln \sum_{x,y} avg(|pix_{x,y}(n) - pix_{x,y}(n-1)|) \qquad (1)$$

Graphical observation of density and quartile plots of our data confirm the intuition that movement amplitude must be computed in log space. Large movements and gestures are relatively sparse compared with the continuous, generalized movements of speech, and the large variance in the number of pixels they comprise necessitates log space calculation.

Such a measure has many attractive properties. First, it is fully automatic, allowing replicable quantification of visual prosody without painstaking hand-annotation. This means it can be scaled up to provide annotation for datasets of arbitrary size with little additional effort or expense.

Secondly, like measures of acoustic prosody, it is functionally continuous, albeit at a much coarser granularity than most audio recordings. Standard audio sampling rates are 44,100 and 48,000 Hz, while standard video frame rates include 24 and 30 frames per second (FPS). We can calculate one measurement per frame, so these frame rates would allow us to extract movement amplitude samples at 24 and 30 Hz, respectively. In the 30 FPS case this provides one measurement each 33ms. In this study we show that samples extracted at this frequency are sufficient and offer meaningful data on visual prosody; however,

[1] http://www.youtube.com/yt/press/statistics.html

[2] https://pypi.python.org/pypi/pafy

[3] While PBUs provide a meaningful and computationally tractable approximate prosodic unit for this analysis, it remains an interesting task for future work to determine how they might correlate with or be related to a more theoretically principled unit such as the intonational phrase (Pierrehumbert 1980).

[4] http://ffmpeg.org

[5] http://www.pythonware.com/products/pil/

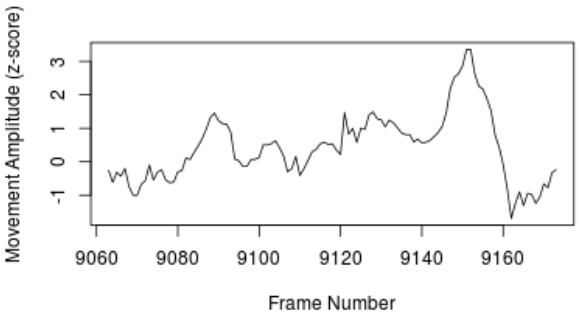

Figure 1: *Visualization of four seconds (120 frames at 30 FPS) of movement.*

the sampling rate of the movement amplitude measure could be arbitrarily scaled in proportion to the quality of the camera available to the experimenter.

Figure 1 demonstrates this continuity, showing movement amplitudes extracted from a four-second clip in our data. The peak near frame 9090, representing an MA measurement one standard deviation above the mean, encodes the combination of a speaker opening her eyes, turning her head towards the camera, and opening her mouth to say "Oh!" in recognition after a moment of thought. The significantly higher peak near frame 9155, three standard deviations above the mean, is primarily the result of a large one-handed swiping gesture.

This plot makes clear another important property of the movement amplitude measure in its current form: it encodes any and all movement, including that of the eyes, mouth, head, body, and so on. Standing up from a seated position, for example, would be recorded as a dramatic peak in MA. It also necessarily compresses 3D movement to a 2D representation in the camera's visual plane. In these ways it is substantially more coarse than any of the measures used in prior studies; however, MA quantifies overall movement in a reasonable way, as the movement of larger objects is given more weight than that of small ones. With computer vision tools such as accurate face detection, in future work this measure could also be applied to submovements to separate out, for example, facial movement as compared to body movement.

Our measure is limited by several required conditions that a recording must meet. The background of the video must be static: the functional result of this is that the contribution to the MA measurement for all pixels that show only background is negligible or absent. Additionally, all speakers in a video must be visually separable. The present study is concerned only with single-speaker video data, but in continuing work we have applied this measure to multi-speaker interactions by defining a rectangular pixel bounding region for each speaker and calculating MA for each speaker only within their region.

These conditions are limiting insofar as other techniques such as hand annotation of gesture could be applied to video footage with variable camera angles and non-static backgrounds. As discussed in Section 2.1, however, data meeting these conditions is reasonable to collect experimentally.

In processing our data we also convert MA measurements to z-scores per speaker to allow for comparable measurements in spite of differences across recording conditions such as speaker distance from the camera, color of the background and speaker clothing, and so on. As with our acoustic variables, for each video we extract an MA maximum, mean, minimum, and standard deviation for each PBU.

Figure 2: *Five-frame composite visualization of the speaker's head and facial movements as captured by movement amplitude across the first peak shown in Figure 1.*

2.5. Statistical Analysis

Automatic extraction of PBUs from our 14 videos results in 2172 observed pause-bounded units, and for each we extract prosodic features for speech and movement as described above.

To model the behavior of this data we use linear mixed-effects models as implemented in the lme4 package in R (Bates et al. 2013). We model speakers as random effects in a series of regressions predicting acoustic variables from our new movement amplitude measure, including log PBU duration in the model as a control variable. The four MA measurements (max, mean, min, and std) are highly collinear, so we use principal component analysis (PCA) for dimensionality reduction. Statistical significance is based on p-values calculated using the lmerTest package in R (Kuznetsova et al. 2013) with degrees of freedom estimated using Satterthwate's approximations.

3. Results

Dimensionality reduction with PCA on our MA measurements reveals two orthogonal components that together explain 96% of the variance in the MA data. The loadings for these two factors are seen in Table 1. Factor 1 is interpretable as overall movement, and factor 2 as variance in movement.

	Overall Movement	Movement Variance
MA Measure	*Factor 1*	*Factor 2*
max	42.1	76.4
min	73.9	-54.3
mean	52.2	19.1
std	-6.9	29.0
variance explained	64.8%	31.2%

Table 1: *Loadings of orthogonal components for movement amplitude calculated from principal components analysis.*

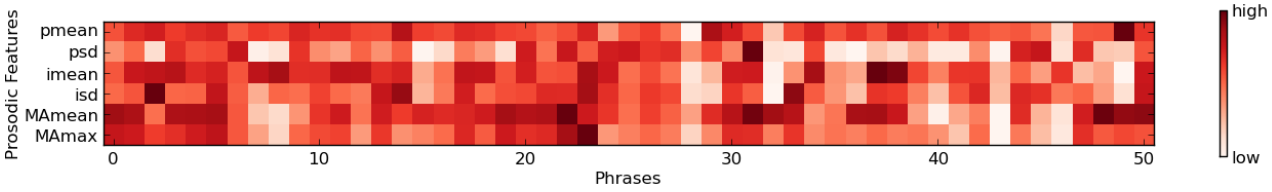

Figure 3: *Visualization of prosodic features including movement across 51 consecutive phrases from one speaker. Each vertical line of boxes represents one spoken phrase, where more deeply-shaded boxes represent higher feature values. Notice light and dark vertical banding; phrases with higher movement amplitude also have higher values for measures of acoustic prosody (and vice versa).*

The results in Table 2 show that high movement amplitude (Factor 1) has a statistically significant positive relationship with all of our acoustic variables except for intensity minimum and pitch minimum. That is, during phrases in which speakers are moving more, we can predict an increase in pitch maximum, mean, and standard deviation as well as intensity maximum, mean, and standard deviation. High movement variance (Factor 2) was not predictive of any of the acoustic features we measured. Though we ran a series of models, the results are highly significant and would survive a Bonferroni correction or any related control for multiple comparisons.

	Overall Movement	Movement Variance
Pitch	*Effect Size (Hz)*	
pmax	4.889 ***	—
pmin	—	—
pmean	2.797 ***	—
psd	0.875 **	—
Intensity	*Effect Size (dB)*	
imax	0.280 ***	—
imin	—	—
imean	0.152 **	—
isd	0.082 ***	—

Table 2: *Effect sizes for acoustic features predicted at a statistically significant level by movement amplitude in a series of mixed-effects regressions.*
$*$ *indicates* $p < 0.05$, $**$ *is* $p < 0.01$, *and* $***$ *is* $p < 0.001$.
— *indicates no significant relationship.*

To confirm these results, we also run mixed-effects regressions using speaker-scaled pitch max and min, where pitch measurements are converted to a 0-1 scale based on a speaker's overall max and min. We also calculate pitch range features per PBU, which are similarly a value between 0 and 1 calculated by subtracting the scaled pitch max from min. These models show a similar statistically significant trend: an increase of one standard deviation in our overall movement factor predicts use of 1% more of a speaker's pitch range within a given phrase.

4. Discussion

Our results build upon prior work to provide further empirical evidence for a strong connection between speech prosody and the "visual prosody" of movement and gesture. In our dataset, phrases with more overall movement were likely to have higher and more variable pitch as well as louder and more variable intensity, confirming our initial hypotheses. This finding is novel in that it adds a dimension of quantity: whereas the previous literature has found primarily temporal synchrony (i.e., the timing of pitch accents aligns with gestural apices), our results demonstrate that more movement is indicative of increased excitement in these prosodic categories.

On the other hand, movement variance - the extent to which a particular phrase had both large movements and periods of little to no movement - was not predictive of any of our acoustic features. This finding is particularly interesting in that a high movement variance would encode some well-defined fully semantic gestures. Consider, for example, a definitive pointing gesture with a pause at its apex. According to the movement amplitude measure, such a gesture would have a high MA value during the stroke and a very low value at the apex, resulting in high MA variation in the PBU during which it occurred. While the movement amplitude measure is not sufficiently fine-grained to make definitive claims in this regard, our findings are suggestive that the synchrony of gestural apices and pitch accents is predominantly temporal and local: that is, a speaker's most "extreme" gestural apices may accurately predict the timing of the immediately adjacent pitch accent, but not necessarily its magnitude with respect to that speaker's global pitch range. This hypothesis remains to be tested in detail in future work.

Additionally, this study makes several valuable methodological contributions to the multi-modal analysis of speech prosody. The newly proposed movement amplitude measure provides a replicable estimation of overall movement from raw video footage, without the need for expensive or invasive equipment at the time of filming or time-consuming annotation effort after the fact. These properties make this measure particularly attractive for the analysis of videos collected "in the wild," such as from internet video sharing sites like YouTube.

The fact that this measure, when combined with automatic extraction of approximate pause-bounded phrases as presented in this paper, is completely automatic for single speakers makes it tractable for empirically-driven sociolinguistic analyses of video data in a way that is simply infeasible by means of hand annotation alone. This paper presented statistically significant results on a narrowly-defined dataset of "First Day of School" vlog posts in order to most directly control for prosodic differences across sociolinguistic groups, but we aim to continue and expand this research. Future work will consider the possible influence of genre effects, social meaning and contextual factors such as performativity, differences in interactional or conversational speech as compared with monologues, and the influence of sociolinguistic variables such as age, gender, and dialect.

Abstract

Conversational fillers (CFs), commonly transcribed as *uh*, *um*, or *er*, typically start with a schwa-like vowel, and signal multiple social, interactive, meta-cognitive, and pragmatic functions. They also co-occur with prosodic boundaries, increase saliency of inter-word disjunctures, and participate thus in coding the prosodic structure. Contrary to these functions, CFs are assumed not to participate in the phonological system of a language. This paper uses two types of Slovak conversational speech corpora for investigating the prosodic and phonological behavior of CFs. In Slovak, the vowel inventory does not include a schwa, and word-final obstruents undergo voice assimilation that is triggered by word-initial vowels but interacts with the strength of the prosodic boundary between the two words. Our data show the propensity of CFs to neutralize word-final voicing, and function thus as prosodic breaks, but also non-negligible number of cases of CFs triggering voicing of word-final obstruents, supporting their relevance for cognitive phonology.

Index Terms: conversational fillers, Slovak, non-verbal vocalizations

1. Introduction

1.1. Conversational fillers

Conversational fillers (CFs) are vocalizations such as *uh*, *um*, or *err* that are ubiquitous in everyday speaking, and if considered words, their rates reach 2-5% of all words (e.g. [1], [2]). They convey numerous para-linguistic functions ranging from social approval [3], turn-taking management [4] and meta-cognitive processing [5], to co-creating pragmatic and discourse structures in interactions [6]. CFs are thus necessary for successful, smooth, and socially natural spontaneous conversations ([7], [8]). For illustration, CFs participate in establishing conceptual alignment between interlocutors by signaling given-new distinctions, problems with parsing or understanding preceding speech, or focusing attention on the upcoming material [9]. In this paper we focus on turn-internal CFs that most commonly signal turn-holding hesitation associated with cognitive planning and packaging information in upcoming speech material.

In addition to the frequencies and distributions of CFs, their prosody also provides useful information. For example, in turn-medial position, F0 of CFs was found to systematically correlate with the intonation of the preceding material [10]. CFs are commonly delimited by silent pauses and form thus a separate intonational phrase [2]. However, their role in prosodic chunking when integrally linked to the surrounding material is less clear. On the one hand they are perceived as increasing the salience of the disjuncture between the word that precedes and follows a CF. On the other hand, the pitch re-set, one of the typical signals of prosodic chunking between adjacent units, is very often absent between the units flanking a CF. Hence, it is not clear what role, if any, these prosodically integrated CFs play in prosodic structuring.

1.2. Slovak

Slovak is a West-Slavic language with a vowel inventory containing 5 basic vowel qualities [i, e, a, o, u], phonemic vowel duration, left-most words stress, and minimal reduction of vowel quality in unstressed syllables [11]. Fig. 1 illustrates prosodically conditioned (quantity & stress) Slovak vocalic qualities.

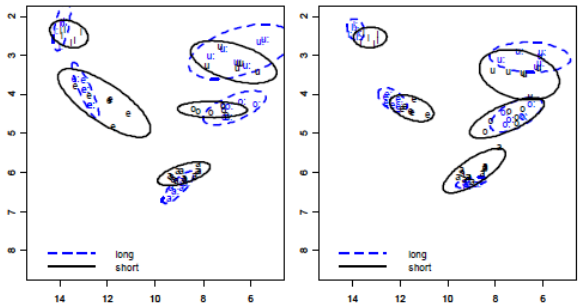

Figure 1: *Slovak vowel quality based on F1 (y-axis) and F2 (x-axis) in Bark for short (solid) and long (dashed) stressed (left) and unstressed (right) monophthongs in CVCa nonsense words from one speaker; adapted from [11].*

Slovak consonantal inventory includes 8 plosives, 4 affricates, and 8 fricatives paired for the underlying phonemic voiced-voiceless contrast. These obstruents are targets for voicing assimilation in the following way. Word-final *voiced* obstruents are *devoiced* if the following word-initial consonant is voiced or if there is a major prosodic break between the words, commonly including a silent pause. Word-final *voiceless* obstruents are *voiced* if the following word starts with a voiced segment, including a vowel, and no silent pause occurs between the two words. While consonant-triggered voicing neutralization is common, vowel-induced voicing of obstruents is rather rare, reported for example for Cracow Polish [12], a variety of another West-Slavic language. Phonetically, voicing neutralization has been found incomplete for languages such as German [13], Polish [14], or Catalan [15], but limited available experimental evidence for Slovak supports complete consonant-induced voicing neutralization across words separated by weak prosodic breaks [16].

1.3. Research questions

The majority of Slovak CFs begin with a schwa-like vowel [17]. This, together with the nature of Slovak voicing assimilation targeting word-final obstruents, offers a unique

testing ground for the role of CFs in the sound system of a language. If CFs trigger voicing of word-final voiceless obstruents, or block de-voicing of word-final voiced ones, CFs might be considered as regular words participating in the phonology of Slovak. If CFs trigger de-voicing of voiced obstruents, or block voicing of the voiceless ones, this would support their analysis as boundary signals, similarly to pauses, participating in the establishment of prosodic structuring. In this sense, CFs might be an optional modal voice boundary marker similar to pre-boundary lengthening or pitch-reset. Alternatively, CFs might be invisible and filtered out for voicing assimilations or prosodic boundary marking. Finally, we want to test if the phonetic realization of fillers, such as their initial glottalization or their duration, affects their behavior in voicing assimilation. A positive answer would be consistent with their analysis as a prosodic boundary marker.

The above questions concern the nature of CFs and their role in the Slovak sound system. A possibility of CF-triggered voicing assimilation might also shed light on the nature of the assimilation process itself. Some analyses treat word-final voicing of obstruents as a phonological phenomenon accounted for in a discrete fashion (i.e. alternations with +/- voice irrespective of the formal framework applied, e.g. [18], [19]). Other approaches employ dynamic modeling to account for both discrete and continuous nature of word-final voicing, especially in light of incomplete neutralization discussed above, e.g. [20]. Finally, some assume that voicing of word-final pre-sonorant obstruents is a purely phonetic phenomenon, e.g. [12]. Hence, if CFs trigger (or do not block) voicing of word-final obstruents preceding them, then CFs must be specified for [+voice], which then spreads to, or licences the voicing of, the preceding obstruent. Alternatively, CFs might be treated as non-linguistic entities incapable of receiving a [+voice] specification and their participation in voicing alternations would be taken as support for the phonetic nature of pre-sonorant word-final obstruent voicing.

2. Methodology

2.1. Corpora

Two corpora of conversational Slovak are analyzed in this paper. The first is a corpus of task-oriented dyadic collaborative conversations accompanying the interactive game designed to elicit dialogues and adapted from the OBJECT Games of Columbia Games Corpus [21], [17]. A pair of subjects saw images on their computer screens and without seeing each other, had to agree on the location of the target object with respect to other objects. One of the subjects (Placer) then dragged this image with the mouse on the location matching as closely as possible the location of this image on the other subject's (Describer) screen. Each session consisted of 14 such placement tasks in which the roles of the Placer and Describer were equally divided between the two players. We will refer to this corpus as *SK-Games*.

In this paper we analyze a subset of *SK-Games* including 6 sessions and totaling almost 4 hours of speech (3h, 54m) from 7 subjects (3 females 4 males; 5 subjects played the game twice with a different partner and 2 male subjects played only one game). There are 21773 words in total, out of which 763 are conversational fillers (labeled as *uh* or *mm*) [17].

The second corpus contains recordings of a courthouse TV show in which semi-professional actors play attorneys and plaintiffs and plead their cases in front of a judge. To match approximately the number of CFs of interest in first corpus (156, see 3.1), we randomly selected 188 conversational fillers following words ending in obstruents. We disregarded the cases in which the disjuncture between the word and the filler corresponded to a #4 ToBI break, that is a silent pause in most cases, focusing thus on the core cases meeting the environment of voicing assimilation. Finally, the extensive size of this corpus allowed for rough balancing of underlying voicing of obstruents. This was not done in SK-Games corpus and resulted in a strong bias toward underlyingly voiceless obstruents (110 vs. 46; see Table 2), which is partially lessened in this corpus (107 vs. 81; see Table 3). We will refer to this second corpus as *Court-TV*.

2.2. Data processing and labeling

Speech was manually transcribed including the transcription of conversational fillers. Transcripts with the audio signal were used for automatic forced alignment using the SPHINX toolkit adjusted for Slovak [22]. Three dimensions, described in Table 1, represented the core labeling effort: characterizing the articulatory activity of the vocal cords initiating the filler, voicing of the obstruent ending the word preceding the filler, and the degree of disjuncture between the filler and the preceding word within the ToBI framework [23].

Table 1. *Labeling scheme for voice assimilation types, "UR" stands for underlying representation*

Label	Dimension	Function description
M	Vocal cords	Modal voice; smooth amplitude increase
G		Glottalization
B		Burst; glottal stop with a observable burst
D	Voice assimilation	Devoicing: UR [+v] obstruent →[-v]
N		No application: UR [+v] obstruent remains [+v]
V		Voicing: UR [-v] obstruent →[+v]
K		Blocking of voicing: UR [-v] obstruent remains [-v]
1	Prosodic disjuncture	No perceivable break
2		Perceived lengthening of word-final rhyme
3		Minor break, commonly associated with tonal marking and/or small pause
4		Major break with significant silent pause between the word and the filler

Additionally, to assess the hypothesis that CFs might be invisible for the purposes of voice assimilation, for all cases with possible voicing (disjunctures 1-3) in *Court-TV*, we noted if the voicing of word-final obstruents respects the generalization described in Section 1.2 should the intervening filler be disregarded and treated as transparent. In other words, we checked the voicing agreement between the final obstruent before the CF and the initial sound of the word following the CF and labeled as respecting (1) if agreement was present or if word-final obstruent was voiceless and a silent pause followed the CF, and as not respecting (0) in the complementary cases.

Finally, the only continuous feature analyzed in this paper is CF duration that is assumed to correlate positively with the boundary strength: longer CF signal stronger prosodic boundaries. Given the uncontrolled nature of the speech in the corpora and questionable reliability of word alignment to the

signal, we employ raw duration and leave normalization effort for subsequent research.

3. Results

3.1. SK-Games corpus

The distribution of voice assimilation types in the corpus of 763 fillers is shown in Table 2. The first four rows correspond to the assimilation types based on the second dimension of Table 1, and the last row is a 'catch all' in which CFs were either preceded by sonorants or a major silent pause inhibiting the application of voicing assimilation. The second and third columns represent the underlying representation (UR) and surface form (SF) of the voicing feature respectively, and the following four columns represent ToBI's boundary indices.

Table 2. *Distribution of voice assimilation types in SK-Game corpus*

Type	UR	SF	1	2	3	4	Total
D	V+	V-	21	1	1	0	23
N	V+	V+	22	1	0	0	23
V	V-	V+	9	0	0	0	9
K	V-	V-	81	15	5	0	101
N-rest			59	40	28	480	607
Total			192	57	34	480	763

If we take the 4 most relevant categories, there are 156 cases in which a word-final obstruent is followed by a filler with a disjuncture lower than ToBI's #4 break. These cases represent the core data for evaluating the questions set in Section 1.3. There are several observations that can be made from the table. First, all possible situations can be observed (with frequency counts of more than 5), and thus any process responsible for voicing alternations potentially triggered by conversation fillers is optional and/or variable. Second, the distribution of underlyingly voiced and voiceless obstruents in this corpus (46 vs. 110) significantly deviates from the expected equal split given the same number of voiced and voiceless obstruents in Slovak ($p < 0.001$ with exact binomial calculation). The same applies to surface forms that are more likely to be voiceless than voiced (124 vs. 32). Third, the 2x2 contingency table for voiced/voiceless obstruents underlyingly and on the surface gives a significant deviation from the expected values, X^2 [1] = 32.9, $p < 0.001$. The analysis of residuals shows that D and V types are significantly under-represented while N is significantly over-represented. Seen in this way, the absence of CF-triggered voicing (K) is to be expected and retention of UR voicing occurs significantly more often than chance. However, changes in underlying specification of voicing (D & V) occur significantly less often.

The preference of voiceless obstruents before the fillers, might be triggered by the voiceless glottal stop initiating the filler. The labeling of the glottal activity shows the presence of burst (B) as extremely rare (9 cases, i.e. 1.2%) and modal voice (M) and glottalization (G) as the most frequent ones. The frequencies of M and G types varied significantly with the boundary strength; X^2 [3] = 55.6, $p < 0.001$. The analysis of residuals showed that their frequencies in the #4 break did not differ significantly but they did for the other 3 break strengths: G-tokens were more frequent for #2 and #3 breaks and less frequent for #1 breaks than M-tokens. This supports previous research in that glottalizations signal prosodic boundary.

Although the type of glottal activity varied significantly for the four assimilation types; X^2 [3] = 13.47, $p < 0.01$, only one cell – glottalization in the blocking of voicing (K) – was significantly different from the expected frequency. Surprisingly, this frequency was significantly lower than expected. This suggests that the phonetic realization of the filler (initiated with a glottal closure or without it) does not predict whether the filler triggers voicing assimilation. Additionally, modal voice was more frequent for all assimilation types, but glottalization appeared for each type as well. These observations suggest that the phonetic realization of fillers and triggering voice assimilation are not linked.

Finally, we examine CF duration as the only continuous feature of this analysis. Fig. 2 shows the data. We observe a tendency for the CFs following surface voiceless obstruents (D, K) to be longer than those following the voiced ones. A mixed models test [24] showed a weak overall effect of voicing type on CF duration (F = 3.02) and Monte-Carlo simulations revealed that the only significant pair-wise difference was between the K and N voicing types ($p = 0.003$).

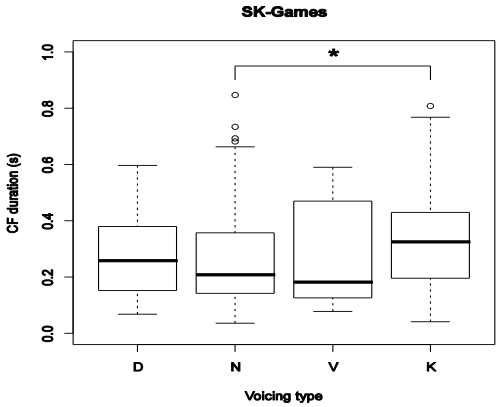

Figure 2: *Duration of conversational fillers for the four voicing types from Table 1.*

3.2. Court-TV corpus

Table 3 summarizes the behavior of fillers with respect to word-final voicing; see text above Table2 for the explanation of labels. The effect of the prosodic strength of the disjuncture corroborates the tendency of fillers to act as prosodic breaks (and either induce or not block word-final devoicing).

Table 3. *Voice assimilation types in Court-TV corpus*

Type	UR	SF	1	2	3	4	Total
D	V+	V-	59	7	4	NA	70
N	V+	V+	11	0	0	NA	11
V	V-	V+	14	0	0	NA	14
K	V-	V-	77	13	3	NA	93
Total			161	20	7	0	188

Contrary to *SK-Games*, the 2x2 contingency table for voiced/voiceless obstruents underlyingly and on the surface shows no significant deviation from the expected values; X^2 [1] = 0.1, $p = 0.92$. This corroborates a strong bias for SF [-voice] obstruents preceding a CF irrespective of their UR.

Regarding the possible interaction between word-final voicing alternations and the vocal cord activity initiating the

fillers, data in this corpus show no token with the burst, very few cases of glottalizations (N=24, i.e. 12.8%), and thus predominantly the initiation of fillers with modal voice. Moreover, all cases of glottalization occurred in tokens with surface voiceless word-final obstruents (11 for D and 13 for K types). Hence, in this corpus, the phonetic realization of the CFs reflected their phonological behavior: glottalization, assumed to reflect CF-initial voiceless glottal stop, co-occurred with devoicing of word-final obstruents resulting thus in the voicing agreement in these 24 tokens. Nevertheless, surface voiceless word-final obstruents were significantly more likely to be followed by CF initiated with regular modal voice than with glottalization (139 vs. 24). This provides additional support for CFs functioning as prosodic breaks rather than participating in phonetic voicing assimilations. Finally, the Fisher's exact test shows that the observed frequency of glottalizations for #2 and #3 breaks (combined to prevent low cell counts) is significantly greater than the expected one. This supports the observation from *SK-Games* and literature that initial glottalizations for vowel-initial words serves as one of the signals for prosodic boundaries.

As discussed in Section 2.2, the annotation of this corpus included binary coding that disregarded CFs and marked the voicing of word-final obstruents as either consistent or inconsistent with the general assimilation processes as described in Section 1.2. This served to test the hypothesis that fillers are transparent and function as neither prosodic breaks that induce devoicing nor as vowel-initial words triggering voicing. Data from this labeling suggest the rejection of this hypothesis. Disregarding CFs shows a slightly greater frequency of cases respecting the assimilation processes than those not respecting them (104 vs. 72), and exact binomial calculation shows that this split is significantly different from 88-88 split ($p = 0.019$). However, by the same token, 72 cases (41%) in which the surface word-final voicing with omitted CF did not respect typical Slovak voicing alternation is sufficient for rejecting the hypothesis. Moreover, the distribution of these two categories did not vary significantly in the four major assimilation types; $X^2[3] = 0.3$, $p = 0.96$.

Finally, Fig. 3 completes the analysis with CF durations in the similar way to Fig. 2 for *SK-Games*. Although the tendencies in the two figures are similar, a mixed-models test showed neither any overall significant effect nor any significant pair-wise comparison.

4. Discussion

The data from both corpora revealed an overwhelming tendency for surface devoicing of word-final obstruents. While *SK-Games* showed this only for underlyingly voiceless obstruents, *Court-TV* showed this trend irrespective of the underlying voicing of the word-final obstruents preceding the filler. This result supports the hypothesis that CFs function as prosodic boundary markers even if the disjuncture between a word and the following CF is minimal (ToBI's #1 break).

Regarding a possible phonetically-based explanation for the observed voicing assimilations preceding CFs, the results from both corpora reject the hypothesis that the phonetic realization of the filler, i.e. whether it is initiated with a glottal closure or without it, predicts whether the filler supports surface voicing of preceding word-final obstruents. Moreover, the data in both corpora agree with the expected function of glottalization in vowel-initial of increasing saliency of disjunctures: In both corpora, CFs initiated with glottal voice

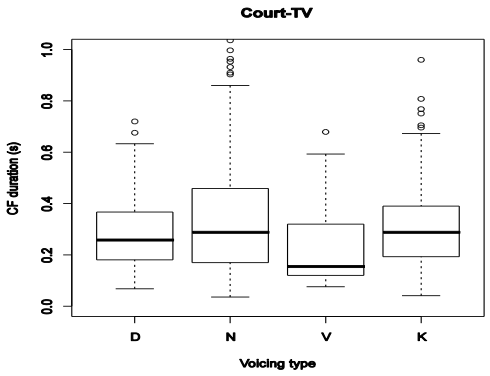

Figure 3: *Duration of conversational fillers for the four voicing types from Table 1.*

were more frequent in #2 and #3 breaks than those in #1 breaks. Interestingly, in *SK-Games*, there was no difference in the major #4 breaks, which suggests that glottalization may function as an additional boundary signal in Slovak for disjunctures of lower boundary strengths.

In spite of the overwhelming tendency for word-final devoicing before CFs, both corpora include small, but non-negligible, numbers of tokens in which CFs trigger (V), or at least do not block (N), voicing of word-final obstruents. These tokens suggest that CFs' participation in voicing assimilation cannot be completely refuted. Furthermore, following the discussion in Section 1.3, the account for these tokens require either treating CFs as 'regular' words or treating voicing assimilation as a purely phonetic process. Interestingly, further analysis of these tokens in *SK-Games* reveals that 21 out of 23 N-type tokens include prepositions like *od* and *z*, both meaning 'from'. Short Slovak prepositions (consonantal or mono-syllabic ones) tend to restructure with the following word and form a single prosodic word. The intervening surface filler and its tendency to function as a prosodic disjuncture might thus clash with the intended single prosodic word unit.

Regarding the duration of fillers, our data showed tendencies for the longer CFs to be preceded by voiceless obstruents on the surface (more so for the K type in which underlyingly voiceless consonant remains voiceless in the environment of the following CF). This observation is consistent with the analysis that CFs function as prosodic boundary markers since the longer the CF, the stronger is presumably the prosodic break signaled by this CF, and thus greater is the tendency for devoicing of word-final obstruents. However, this should be treated as a preliminary finding since CF durations were not normalized and possible silent pauses between the CF and the following words were not considered.

In sum, despite a strong bias for word-final devoicing preceding CFs, and thus their functioning as prosodic boundary markers on par with silent pauses, the hypothesis that CFs participate in voicing assimilation cannot be rejected.

5. Acknowledgements

We thank E. Cyran for inspiring discussion on Krakow Polish voicing and fillers. This research was supported by the ERDF's Research & Development Operational Programme, grant ITMS 26240220064 (RPKOM).

Abstract

The present study is intended to compare two approaches of labeling expressive corpora: auto-annotation and annotation by external lay listeners. These two methods have been applied to the semi-spontaneous emotional speech produced by Chinese learners of L2 Italian, involved in the CardTask, a mood-induction procedure that allows us to control the context of interaction, preserving the spontaneity of reactions.

The emotional responses to the stimuli presented in the task were the object of an auto-annotation session. The same samples were then administered only in the auditory mode to 20 Italian and 20 Chinese lay listeners. The results of perceptual tests have underlined some similarities and differences between both auto- and external annotation, and between the ratings given by external Italian and Chinese listeners. The labels chosen by native Italians were similar to those selected in the auto-annotation session, particularly in the case of anxiety, fear and disgust. The correspondence between the results of the two annotation methods may be ascribed to the different prosodic patterns characterizing the emotional states. The results of the annotation made by Chinese listeners show that they found it hard to give a specific emotional label to utterances produced in a second language relying solely on prosodic patterns.

Index Terms: L2 emotional speech, prosodic cues, emotion annotation methods

1. Introduction

The study of emotional speech poses many problems, both methodological and analytical. When dealing with the collection of expressive spoken corpora, the first issue to be addressed is the style of speech to analyze. According to Scherer taxonomy [1], three kinds of productions can be considered, each with some points of strength and weakness: recited, induced or spontaneous emotional speech. Other methodological problems concern the nature of the speakers involved (actors or naïf), the kind of stimulus for emotion elicitation (pictures, videos, dyadic interactions) and the linguistic materials analyzed (nonsense words, syllables, interjections, utterances) (see [2] for a review of the most common elicitation techniques).

In addition to these methodological difficulties, another issue to consider is the labeling of emotions, particularly in the case of authentic expressive speech. The most common approach is the annotation by human experts, trained to deduce labeling paradigm from theoretical hypotheses on the nature of emotions. The limits of this annotation technique, though presumed to be the most objective, have been already underlined [3]. Alternative methods used to label emotional speech are the administration of perceptual tests to naïve listeners and the auto-annotation technique, in which the speakers themselves are asked to judge their own emotional state. There is no doubt that the annotation method chosen has an impact on the labels obtained and that, in order to test the validity of emotional labels, various methods should always be combined [4].

Despite the complexities of this kind of research, the identification of acoustic correlates of emotions has been the object of many studies, both on a production and perception level (see [1], [5] for a review). A correlation between the activation dimension and the most frequently measured acoustic parameters has been demonstrated [6], [7]. High activation emotions (such as fear, joy, surprise and anger) are generally characterized by shorter pauses, a wider tonal range, higher values of F0 and intensity, and faster speech rate. Low activation emotions (for example sadness and disgust), by contrast, are vehiculated by longer pauses, a narrower tonal range, lower values of F0 and intensity, and a slower speech rate.

Moreover, cross-linguistic studies on emotional speech encoding and decoding have emphasized the role of prosodic features in the identification of different emotional categories and have indicated that specific emotional states are vehiculated by universal prosodic patterns [8], [9].

Although studies on vocal emotions have been conducted for a wide range of languages, L2 emotional speech has not yet been extensively analyzed, either from the acoustic or from the perceptual point of view. Previous researches on expressive interlanguage, carried out on learners of L2 English with different mother tongues, have focused mainly on the emotional force of swearwords, taboo words or love words, when pronounced or listened in a second language [10], [11], [12], [13]. The impact of emotional expressions in L1 and L2 has also been the object of psycho-physiological studies. Harris et al. [14], for example, monitored the skin conductance of Turkish–English bilinguals via fingertip electrodes while they were rating for pleasantness a variety of stimuli in Turkish (L1) and English (L2). The results of this study demonstrated a difference between L1 and L2 emotional forces, being more noticeable in late bilinguals [15], [16]. Harris' hypothesis, therefore, is that L1 is the language of emotional expressiveness, while L2 is that of emotional distance.

2. The study

The present study has a twofold objective: firstly it is intended to identify the acoustic features of expressive speech in L2 Italian on the basis of an auto-annotation labeling; secondly, in order to verify the effectiveness of the auto-annotation, the auto-labels are compared to those given by external Italian and Chinese listeners. To achieve this, 10 Italians and 10 Chinese learners of L2 Italian (C1 Level – CEFR [17]) were involved. They were all female, university students, aged between 18 and 23.

The high level of linguistic competence has allowed the non-native students' active participation in the task and, as a consequence, the collection of a large corpus of emotional speech in L2 Italian. The decision to recrute Chinese learners depended on the results of previous studies, according to which the expressive speech of Chinese speakers is characterized by a more moderate and restrained style than that of Italians [18].

In order to collect emotional speech, Italian and Chinese participants were involved in the CardTask, a mood-induction procedure that allows us to control the context of interaction preserving the spontaneity of reactions.

2.1. The CardTask

The CardTask is a speaking activity where a Giver and a Follower work in pairs. They sit at the same table but they cannot see each other because of the presence of a dividing panel. The Giver receives five cards; the Follower is given a deck of 25 cards. The Giver has to describe her five cards (fig. 1) and the Follower has two minutes to find each card in her deck. The Follower's task is rather difficult because the deck consists of very similar cards only differing from each other in small details (fig. 2).

Figure 1: *Giver's cards.*

Figure 2: *Examples of some cards in the Follower's deck.*

In the room there is also an experimenter, whose function is basically to ensure that the task is performed as planned and to control some disturbing unexpected events which occurred during the game [19]. The following events were designed to elicit emotional linguistic reactions in the players and to arouse five different emotions (anger, anxiety, disgust, fear and surprise):

1. at the beginning of the game, while the Follower is looking for the first card in the deck, the chronometer rings after only 20 seconds instead of the expected two minutes;
2. the experimenter pretends to find a big beetle (obviously fake) in the room;
3. the experimenter tries to leave the room but the exit door seems to be temporary locked;
4. the fifth card is not in the deck.

In this study, the CardTask game was organized in two sessions: one only involving Italian speakers, the other only Chinese participants. The interactions took place in the silent chamber of University of Naples "L'Orientale" and were videotaped.

2.2. Method

2.2.1 Acoustic analysis

In order to identify the emotional responses to the stimuli presented by the experimenter during the task, we extracted the utterances occurring in the time interval between the end of each stimulus and the resolution of the unexpected events. A total of 132 utterances of expressive speech was collected and, by means of Praat, the whole corpus was segmented and annotated in two tiers: syllables and speech runs.

For each speech portion, we measured the duration and number of syllables, the length of burst phenomena, silent and filled pauses, and the lowest and highest F0 values. We consider bursts as "very brief, discrete, non verbal expressions of affect in both face and voice triggered by clearly identifiable events" [20]. On the basis of these measures, we calculated the following indexes: articulation rate (AR) (syll/s), speech time composition (percentage of silence, disfluence, syllables and burst), and tonal range (st). Additionally, in order to highlight the F0 variations connected to the considered emotions, for every utterance we related the F0 min and max values to the lowest F0 value - the F0 floor (st) - reached by the speaker in the whole corpus.

In order to preserve the spontaneity of the interaction, we did not control the movements of the participants in the room and thus the production of background noises. For this reason we decided not to consider the intensity and voice quality features.

2.2.2 Labeling emotions

The extracted emotional speech samples, both in L1 and L2 Italian, were object of an auto-annotation session. Moreover, in order to obtain more reliable labels and to assess the perceptual effect of emotional speech in a second language, the auto-labels were compared to those given by external Italian and Chinese lay listeners (henceforth external annotation).

During the auto-annotation session, the Italian and Chinese participating in the CardTask were instructed to watch their video recordings and to annotate them with one of the six labels, the five expected emotions, plus a generic option "other". In the case of auto-annotation, the video was supposed to help the players contextualize the utterances and recall what they were feeling during the task.

As for the external annotation, since our attention was focused exclusively on the acoustic correlates of emotions in L2 and on their communicative effectiveness, the emotional utterances of Chinese speakers were administered only in the auditory form to 20 Italian and 20 Chinese listeners. They labeled the utterances following the same protocol adopted for the auto-annotation session.

In order to prevent Chinese participants from misunderstanding the relationship between the labels of emotions and referents of these labels, a native Chinese speaker, specialized in Italian language and linguistics, translated the emotion categories to their L1.

It is important to underline that the acoustic data presented in the following paragraph are organized on the basis of the auto-annotation labels.

3. Results of spectro-acoustic analysis

Figure 3 illustrates the mean values of tonal range and F0 height (register) for each emotion in L1 and L2 Italian.

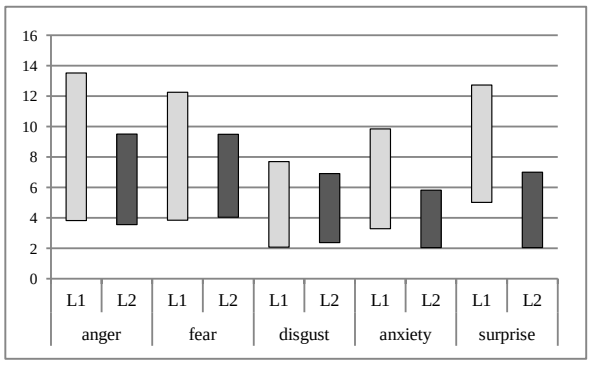

Figure 3: *Tonal Range and F0 height in L1 and L2 emotions (st).*

As the chart shows, the values regarding L1 Italian confirm the patterns for the high and low activation emotions, mentioned in the relevant literature. Of course anger, fear and surprise correlate with the highest F0 values and the widest tonal range. Anxiety, a high activation emotion as well, presents pitch height and tonal range values that are slightly lower than surprise, but higher than disgust, a low activation emotion [21].

Shifting our attention to the acoustic correlates of the emotions expressed by the Chinese subjects, it is possible to underline that the F0 values hardly match those attained by native speakers. As a matter of fact, F0 height and tonal range are quite steady in the whole corpus. The only exception is represented by anger and fear that are expressed with slightly higher values. These data seems to suggest that Chinese learners do not vary their pitch contour to distinguish different emotional states as in the case of native Italian speakers. After all, smaller pitch excursions are not only unique to L2 emotional speech, but they also represent one of the main acoustic correlates of Chinese accented Italian [22], [23].

Another parameter under study was articulation rate. Table 1 shows mean values for each emotional state in L1 and L2 Italian.

Table 1. *Articulation rate (syll/s) in L1 and L2 Italian.*

	Anger	Fear	Disgust	Anxiety	Surprise
L1 Italian	6.2	5.6	5.5	6.1	6.4
L2 Italian	5.2	5.6	4.3	4.8	4.8

Before considering AR variations in expressive speech, it is worth underlining that AR is a quite stable parameter, communicative setting being equal. With the exception of fear where L1 and L2 speakers reach the same values, in the other cases non-native utterances are produced with a slowing down of 1 or 1.5 syl/s, thus confirming the data available in the literature on foreign accented Italian [24]. The lower values of AR in L2 are essentially due to the learners' greater accuracy in uttering the single vowels and consonants. In order to reach the articulatory targets, the lengthening of syllable duration is needed, with a consequent slowing down of the speech.

Nevertheless, variations in AR do not seem to correlate with the five target emotions either in L1 or in L2. The only exception is represented by disgust in L2 Italian, whose values are particularly low (4.3 syll/s.) with respect to the whole corpus.

Figure 4 shows the composition of the utterance for each emotion in the two groups of participants.

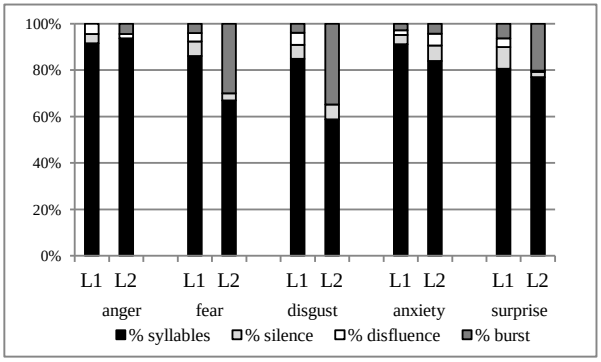

Figure 4: *Speech time composition in L1 and L2 Italian.*

In L1 Italian the percentage of syllables ranges from 85% to 95%, while in the second language it changes in the range of 60% and 93%. In the emotions that mostly differentiate L1 and L2 (fear, disgust and surprise), the bursts increase at the expense of syllable percentage. This means that when non-native speakers are not able to verbalize their emotions, bursts substitute the textual component. However, non-verbal expressions are not equally distributed between the five emotions. For example, in anger they are nearly absent, on the contrary, in disgust they represent one-third of the total time of the utterance. This datum is in line with Schröeder's findings [25]. Accordingly there are some emotions like disgust that are typically expressed by bursts, while others such as anger are not. A further observation is that in highly emotionally charged situations, L2 expressive speech is characterized by a very low percentage of disfluencies. L2 speakers rely on spontaneous and relatively universal vocal expressions to vehiculate their emotional states, instead of editing their performance with self-repairs, repetitions and substitutions. On the other hand, in L1, the percentage of disfluencies, above all in the form of lengthenings and vocalizations, is rather constant in the whole corpus. Such kind of filled pauses are typical of spontaneous speech and signal that the speaker is planning his/her speech.

4. Comparing auto- and external annotations

In order to verify the validity of labels given in the auto-annotation and to evaluate the communicative effectiveness of the selected expressive utterances in Chinese-accented Italian, we proceeded to compare the results of auto-annotation with the perceptual judgments given by external Italian and Chinese listeners. The results of the comparison underline some similarities and differences between auto- and external annotation and between the ratings given by native and non-native listeners. Tables 2 and 3 show the confusion matrices of auto- and external annotation by the two groups of listeners.

Table 2. *Confusion matrix of auto- and external annotation by Italian listeners.*

		External annotation				
		anger	fear	disgust	anxiety	surprise
Auto-annotation	anger	**29.2**	9.2	3.8	23.1	33.1
	fear	10.3	**48.3**	11.5	16.7	11.1
	disgust	5.8	25.0	**44.2**	7.7	16.3
	anxiety	6.1	14.2	2.4	**61.1**	13.4
	surprise	9.0	10.7	0.6	48.5	**28.6**

Table 3. *Confusion matrix of auto- and external annotation by Chinese listeners.*

		External annotation				
		anger	fear	disgust	anxiety	surprise
Auto-annotation	anger	**26.0**	8.0	4.0	28.0	34.0
	fear	5.6	**42.2**	8.9	8.9	34.4
	disgust	10.0	13.8	**30.0**	13.8	32.5
	anxiety	4.8	14.4	7.4	**66.7**	5.9
	surprise	9.4	9.4	6.1	47.2	**27.8**

As we can infer from the matrix of table 2, the labels chosen by the native Italians are pretty similar to those selected in the auto-annotation session by Chinese speakers, particularly in the case of anxiety, fear and disgust. The correspondence between the results of the two annotation methods may be ascribed to the specific prosodic patterns characterizing these emotional states. Anxiety is expressed by the lowest register and the narrowest tonal range. Fear and disgust are vehiculated by the same intonational patterns as in L1 Italian, though with not such marked differences. Moreover, disgust presents the lowest value of articulation rate and the widest portion of bursts. The similarities between values of F0 and articulation rate for surprise and anxiety induce listeners to confuse these two emotions. The emotional state that scores the highest percentage of mismatching between auto- and external annotations is anger, because of the considerable distance of its prosodic pattern from the model produced in L1 Italian. This result can be also explained by considering social conventions and different cultural standards in the expression of emotional states. As it has been noted in recent literature, Chinese speakers tend to inhibit the expression of emotions, which could threaten relational harmony as in the case of anger [8], [18].

The results of the annotation made by Chinese listeners show that they found it hard to give a specific emotional label to utterances produced in a second language. With the exception of anxiety, recognized by more than 60% of non-native listeners, the ratings given by Chinese subjects to the other emotions are definitely more uncertain than those expressed by Italians and more subject to random variations.

5. Conclusions

The present study had a twofold objective: firstly we intended to highlight the acoustic differences in the expression of the same emotions in L1 and L2 Italian; secondly we aimed to compare two approaches of labeling expressive corpora (auto- and external annotations) and verify the perceptual effects played by the prosodic patterns of L2 speech on native and non-native listeners.

As regards the acoustic correlates of emotional speech, the comparison between L1 and L2 confirmed Harris' hypothesis, according to which the second language is the language of emotional distance. Indeed the expressive speech of Chinese learners is characterized by a lower degree of variability in terms of F0 register and tonal range, a slowing down of articulation rate, and a different speech time composition. The reduced competence in the second language determines a lower percentage of syllable time and an increase of the burst component. During the CardTask, Chinese participants were not allowed to use their L1, the language of emotional expressiveness, but at the same time they were not able to use Italian to express their emotional states. Consequently, they tended to overcome this difficulty by relying on bursts.

As for the perceptual effectiveness of prosodic cues in the expression of emotions in L2 Italian, the data show that there is a correlation between the labels assigned by the speakers themselves in the auto-annotation and those chosen by native Italian listeners. This is particularly evident in the case of emotions characterized by similar prosodic patterns in L1 and L2 Italian (anxiety, fear and disgust). The lack of shared prosodic models, on the contrary, provokes in the listeners a high degree of uncertainty when labeling emotional states.

The random judgments given by Chinese external listeners reveal the objective difficulty of L2 learners to identify a specific emotional state in utterances produced in a second language.

Although intra- and cross-linguistic studies have already emphasized the difficulty of find coherent labels to the different emotions, this task seems to be much more demanding when analyzing emotional speech in a second language. The reason can be ascribed to the status of the L2 as the language of emotional distance, both on acoustic and perceptual levels.

In a further step of the research, we intend to extend the CardTask to learners with different mother tongues in order to verify whether the acoustic patterns characterizing the expression of emotions in L2 Italian are imputable to L1 transfer or are constrained by interlanguage development. The administration of perceptual tests to native and non-native speakers of Italian with different L1s will enable us to evaluate the extent to which the prosodic patterns and the cultural standards of the first language influence the perception of L2 emotional speech.

Further analysis of the corpus presented in this study will include a more detailed description of burst phenomena both in L1 and L2 Italian and the evaluation of the possible effect of the Chinese tonal system on the intonational features of the second language.

Socio-affective interactions between a companion robot and elderly in a Smart Home context: prosody as the main vector of the "socio-affective glue"

Yuko Sasa[1], *Véronique Aubergé*[1]

[1] LIG-lab CNRS, Grenoble University, France

Yuko.Sasa@imag.fr, Veronique.Auberge@imag.fr

Abstract

The aim of this preliminary study of feasibility is to give a glance at interactions in a Smart Home prototype between the elderly and a companion robot that is having some socio-affective language primitives as the only vector of communication. Through a Wizard of Oz platform (EmOz), a robot is introduced as an intermediary between the technological environment and some elderly who have to give vocal commands to the robot to control the Smart Home. The robot vocal productions increases progressively by adding prosodic levels: (1) no speech, (2) pure prosodic mouth noises supposed to be the "glue's" tools, (3) lexicons with supposed "glue" prosody and (4) subject's commands imitations with supposed "glue" prosody. The elderly subjects' speech behaviors confirm the hypothesis that the socio-affective "glue" effect increase towards the prosodic levels, especially for socio-isolated people.

Index Terms: socio-affective "glue", human-robot interaction, affective prosody, elderly, Smart Home.

1. Introduction

Prosody carries emotional, socio-affective and interactional information where each language has its own values [10]. This communicative information appears in different prosodic levels as in non-lexical sounds. Those can be non-phonetic sounds like grunts, affect bursts or mouth noises [20,24], phonological as fillers, mind markers or interjections [25], or onomatopoeia, widely studied in Japanese [26]. These sounds that we can consider as pure prosodic tools, were studied for specific and supposed emotional [5] and pragmatic [1] functions, as well as moods, emotions, intentions, attitudes, cognitive processes and mental states also known as "Feeling of Thinking"[14]. Moreover lexicons, sentences and paraphrases prosodic form also support various socio-affective values [29]. These cues can be extended from simple sounds to sentences produced in a same context, which have been tested in synthesis [12,15,17]. Lately, the prosody carrying this communicative information was introduced as a way to develop "socio-affective glue", terms introduced for the first time in [2]. In face-to-face interaction, the communication channel used by the speakers depends of the context and their social role, giving clues on how people have to talk to each other. Moreover, the "glue" refers to the fact that the interlocutors build dynamically their relation and adjust constantly the way they converge or not, globally changing the basic communicative channel firstly introduced by the context and their role. However, this kind of dynamic process can be more difficult to handle for some isolated-person, typically the elderly [3] but also younger person, like the Japanese hikikomori [11] or autistic people [6]. Furthermore, imitation has been studied as a basic process to create the same kind of "glue" in children language acquisition [8] or as a primitive of robots learning [23]. By the way, since the 90's, Affecting Computing and multidisciplinary communities have been focusing their work on the face-to-face interactions, especially on facial, gestural and vocal expressions using virtual agents and robots as in various studies in social computing [4,16]. It is interesting to see that when a robot is not explicitly humanoid, human creates by himself a socio-affective relationship with this device toward its « pet » stance [7]. Because all these different prosodic levels have not been studied together particularly to see their functions in the "socio-affective glue" building, our work will test them progressively thanks to a robot interacting with elderly towards gradual vocal productions: (1) no speech, (2) pure prosodic mouth noises supposed to be the "glue's" tools, (3) lexicons with supposed "glue" prosody and (4) subject's commands imitations with supposed "glue" prosody. This will be tested with a Wizard of Oz protocol in a Smart Home prototype that has been used to study speech in a natural context environment with vocal commands, including elderly speech recognition [28].

2. Methodology

First of all, this study is testing the feasibility of our protocol to observe the gradual prosody productions effect on the "socio-affective glue" develop or not between elderly who are giving Smart Home's vocal commands and a robot "controlling" this Smart Home. The spontaneous corpus briefly analyzed in this study has been collected thanks to the EMOX robot (www.awabot.com/) interacting with the elderly in a Smart Home prototype named DOMUS. A Wizard of Oz platform called EmOz [2] was developed to control both the robot and the environmental system. The Wizards followed an accurate script describing which robot vocal productions they have to use and when they need to be produced. The Wizards also controlled the Smart Home each time the subjects gave a vocal command addressed to EMOX as we told them it was the robot that controlled DOMUS. This protocol is associated to a scenario with a specific recruiting pretext we were able to play thanks to elderly's caregivers (www.bienalamaison.com). The caregivers who were accompanying the subjects during the experiment were aware of the Wizard of Oz trick and our scientific goal being the researchers accomplices.

2.1. Experimental tools

2.1.1. DOMUS, a voice commanded Smart Home

As concept of living labs [19], DOMUS is designed like a 40m^2 flat with a kitchen, a bedroom and a living room equipped with two cameras and two microphones in each room, and a shower room with a microphone. Here, we selected a few possible actions in DOMUS to propose 31 voice commands that we can simulate from a control room. E.g.*; Mettre/Eteindre la lumière (fr) – To turn on/off the light*

(en); Monter/descendre les stores (fr) - To up/down blinds; Moins/plus fort la télé (fr) - Lower/louder TV (en).

2.1.2. EMOX robot with gradual vocal productions

The EMOX robot used in this study doesn't look like a human or an animal which morphology can induce the way we picture this tool and would create artifacts that we cannot control, and so the only way to find some anthropomorphism for this robot is its speech. In primarily study we attempted to change the Fundamental Frequency (F0) of spontaneous vocal micro-expressions, without modifying the prosodic contours to find a coherent voice for the robot [22]. From this database, we selected some of non-lexical sounds as part of the robot speech (e.g. *euh, and laughs*). We also recorded extra-sounds *(see table1a*), lexicons/interjections (*see table1b*) and commands imitations (*see table1c*) all with specific prosodies that we suppose to have an effect on the "socio-affective glue". In order to have a homogeneous voice for all our stimuli, we used Voxal (www.nchsoftware.com/voicechanger), voice conversion software. For parameterization, we increased the pitch by 1.52 from the original female speaker's voice, who recorded the sounds and so the robot has got a pitched "cartoon-like voice". So the voice esthetics has a reduced anthropomorphism, as we only want to observe information on the communicative functions carried by the chosen prosodic forms. Table1 shows the 30 vocal stimuli used by EMOX. 16 other sentences (also with supposed "glue prosody") were also pre-recorded, used only if it is necessary reacting to keep the subject motivation [*e.g.: Bonjour, je suis Emox(fr)= Hello, I am Emox(en); Oui, je suis là, j'écoute(fr) =Yes, I am here, I am listening (en); Oh pardon(fr)=Oh sorry(en)*].

Sounds levels	Sounds nature	Examples of F0 contours
(a) Mouth noises	3 types of laughs		Various prosody : euh - hum1 - hum2	E.g. Hum2 	prosody 1: humhum		2 onomatopoeia « woup » (associated to up/down blinds movements)	
(b) Interjections	prosody 1 : d'accord1 - ok1 - oui1		prosody 2: d'accord2 - ok2 - oui2	
	ça va - comme ça - ça y est		voila1, voila2		ouais, oops	(c) Commands imitations	Commands in infinitive form + (b) interjections or (a) onomatopoeia	E.g. Mettre la bouilloire, voilà 
Table 1. *Emox robot stimuli types and Praat F0 contours*

2.1.3. EmOz – the Wizard of Oz Platform

In order to operate EMOX and DOMUS from the control room, we developed a Java interface associated to the robot Urbi system and the Smart Home protocols [2]. This interface is filled with buttons and each one of them controls one speech act of EMOX or one DOMUS command *(see Figure1)*. To move the robot we use a game controller so the robot can move around to follow the subjects, turn on itself, move its head (top/down, right/left) and go forward/backward. We also have the possibility to record our voice (changed through Voxal) and live play it if needed, to manage a coherent answer when the subjects' reactions were unpredictable.

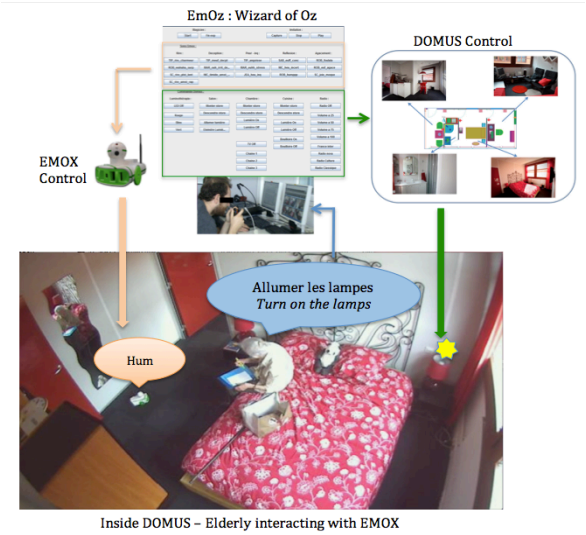

Figure1. *Scheme of EmOz wizard of Oz platform*

2.2. Experimental scenario

2.2.1. Subjects and caregivers

This study hired 4 French elderly subjects from 68 to 89 years old (one man and three women) accompanied by a caregiver/home helper they know well. The need of a helper was a criterion to select a "fragile but not sick subject", as it is difficult to find this kind of people and their degree of frailty corresponds to the scale 6 and 5 of the GIR grid [21], which is a French reference to evaluate an elderly ability. Moreover, these helpers were our accomplices, knowing the real goal of our study with the robot. Their role allowed us to reinforce the safety of the "fragile subjects". They also helped us to observe to observe the relation that the elderly had been creating with the robot. Furthermore, the helpers gave us an excuse to leave the subjects alone with the robot during one experiment step.

2.2.2. Experiment context and consent

To bring the subjects in DOMUS, we used a pretext to motivate the elderly to come, giving them a false task to do during the experiment. We did not mention the presence of the robot at first so they can interact spontaneously with it. Every subject was told to be the first participant of the experiment in order to keep a coherent scenario. In term of consent, the subjects had to sign three documents. Before the experiment we gave to the elderly a "pre-experimental consent" based on the pretext. Once they finished, they signed a "post-experimental consent" and an "image rights document" revealing the purpose of the Wizard of Oz. The helpers had their own single consent as the experimenters' accomplices.

2.2.3. Pretext of recruitment

We proposed a fake object of study to recruit the elderly. The subjects were asked to come in our Smart Home prototype because we were developing new technologies for elderly to allow them to live as long as possible in their own house, thinking of their safety and their welfare. Nevertheless we are currently not able to equip directly their home yet, so we need the subjects to come in our flat prototype. However, the problem we observed in "previous study" was that when elderly change their living environment (e.g. move into a retirement/nursing home or a hospital) they mostly have difficulties to accustom to this new place, especially when it is based on technologies. One of our "so-called hypotheses" was that if people bring some personal items (e.g. books, trinkets, decorative objects…etc.), which can be benchmarks as in Alzheimer disease, and they arrange their living environment with these items, people get used to the place more easily. Finally we asked the subjects to bring around ten items they choose and care about to come and spend some time (an hour or two) to evaluate our flat equipment, at the same time they personalize it with their own items. For their security, we asked them to be accompanied by one of their caregivers, who were also the experimenters' accomplices.

2.2.4. Experimenters roles

To play our experiment's scenario, we need two experimenter-actors interacting with the subjects:

- A "student-recruiter" who explains the pretext to the subjects and organizes the arrangement with the helper. He pretends not knowing what kind of technologies the flat is equipped with because it is his advisor who communicated with the engineering staff.
- An "engineer" who does not know the recruiter and was only asked by the student's advisor to explain how the Smart Home works. He is not aware of the study's aim.

Technically, we also needed at least two other experimenters to manipulate the EmOz platform from the control room: the first one used the java interface *(see Figure 1)* producing the EMOX vocal reactions *(in orange)* and the DOMUS commands *(in green)*. The second one was coordinating the robot movements. All these reactions were listed within a specific order regarding the voice commands that can be produced by the subjects, and these two Wizards followed this experimental script.

2.2.5. Experiment steps

The experiment scenario itself is divided into six steps:

- Step 1: the engineer welcomes the subject, the helper and the recruiter to present the Smart Home. He does not mention at this time the voice commands use and the robot is hidden. Very quickly, the helper receives a fake emergency call simulated from the control room, (before showing EMOX). The helper is asked to act like he has an urgent mission and needs to leave DOMUS for a short time, but she will come back very soon. The helper has not got any mean of transportation so the recruiter offers the ride, while the engineer explains to the elderly how the Smart Home works, waiting for their return. The helper and the recruiter use this excuse to go to the control room. Before leaving, the recruiter asks the subject to start arranging the flat with the personal items.
- Step 2: the engineer introduces EMOX to control the Smart Home. He presents a 31 commands list that can possibly be "activated". To work on a better quality speech signals, the engineer places a lapel microphone on the subject, justifying it by the fact that the robot vocal recognition system is not good enough without it. For the robot to able to recognize the subject's voice, the elderly is asked to try once all the voice commands one by one. When this training period is done, the engineer leaves the subject pretending to have some work to do.
- Step 3: It is an improvisation stage. The subject is alone with the robot, setting down his things in DOMUS.
- Step 4: After about 10 to 20 minutes, we ask the helper to go back into DOMUS and let the subject explain how the Smart Home works. If asked, the caregiver says that the recruiter was caught to talk about administrative stuffs and will return soon. EMOX does not realize the helper's commands and it only obeys to the subject.
- Step 5: When the subject has showed most of the voice commands to the helper, it is the recruiter turn to ask how DOMUS is working. If the subject himself tells something about the robot, the recruiter listens and asks about it, just out of curiosity. Nevertheless, the recruiter real task is to remind the pretext, so he starts a "fake interview" to know how the subject got used to DOMUS thanks to the items he brought.
- Step 6: During this debriefing stage, the engineer comes back and asks what the subject has thought about the voice commands technologies, without mentioning the robot at first. Here we want to know if the subject will tell about the robot and how he will talk about it. Once EMOX is evoked, we ask about the robot's voice, morphology, use, ways of speaking, functions, ability, role and personality. After this interview, the experimenters tell the real purpose of the study, revealing the Wizard of Oz tricks.

3. Discussions

3.1. The Elderly Emox Expressions Corpus

This corpus is composed by 4 experiments lasting from 1.5 to 2 hours each. For each subject, we have six videos (two per rooms) and an audio file collected by the subjects' lapel microphone. We then selected 167 interactions between EMOX and the elderly (from 43 to 52 per subject), throughout the interactions held in step 2 to 5, while the subjects: (a) are learning the commands with the engineer, (b) are alone with Emox, (c) are explaining how DOMUS and Emox work to the helper and then to the recruiter. Each interaction lasts about 10 to 50 seconds, showing a sequence of exchanges around one voice command. In this corpus, we observed two types of subjects' vocal productions of the "socio-affective glue": the commands form produced by the subjects and some of their answers after EMOX feedback. As the robot was introduced like a simple vocal commands receptor, there is no reason for the subjects to talk or ask other things to the robots. Moreover, as they had a specific list of voice commands to control DOMUS, they had no reason to produce other forms of commands as well as react to simple automation. Then, if they change their way to address their commands to EMOX or try to talk to him, we suppose that something in the robot's speech

prosody lead them to change their way to interact with it. The purpose of this for preliminaries analyses

3.2. Results

3.2.1. Debriefing global impressions

While debriefing, the main question we ask is "what opinion do you have concerning the system and the way you can control the Smart Home by voice?" (without mentioning at all the robot). For all the subjects, the first answer they gave us was: "the robot is a good company", so the technical support of the vocal commands is not mentioned first, meanwhile we introduced it in this way. Moreover, when we ask the subjects if they prefer the same commands but address directly to the Smart Home, they assert again that the robot is useful but not only: "we don't feel lonely, he talks to us". So we can say that some "socio-affective glue" was established between the robot and the elderly. We then want to know how by observing: (a) the commands form, particularly the prosody associated to them; and (b) the reactions of the subjects after EMOX feedbacks with gradual prosody levels.

3.2.2. Subjects commands tendency

During the interactions held in step 2 to 5, there are of course some variations concerning the subject's behaviors during the experiment first steps, but some common main characteristics emerged as features of the "glue" building toward different steps resumed in Figure 2: (a) declarative commands without paraphrasing; (b) the same original form commands but with a positive attitude prosody (in particular fundamental frequency arise which systematically appears at the end of the sentences, with a breathy voice); (c) commands paraphrased variations (used in synergy with a "we", illustrating the same kind of joint attention that we can observe in a mother-child dyad in an early language development context [27]) with a globally high fundamental frequency and a great arise at the end of the sentences; and finally (d) multiple prosodic focuses of support terms with a higher fundamental frequency. These phenomena are observed as well as a voice quality becoming more and more breathy. This elderly's voice quality breathiness seems to vary particularly while the robot produced a feedback based on pure prosodic vocal micro-sounds.

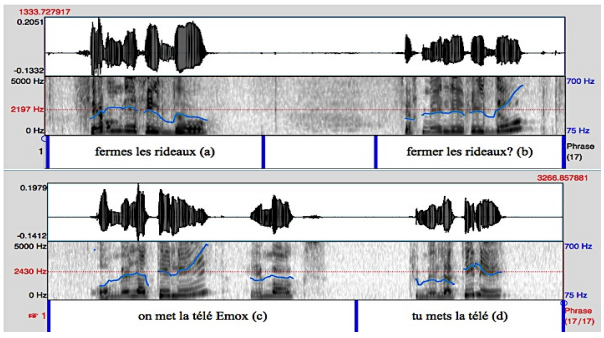

Figure 2. *Commands prosody: Praat spectrogram and F0 contours of some S1 subject's commands*

3.2.3. Subjects reactions to EMOX feedbacks

For every subject, nothing happened while there was no Emox speech reaction. The subjects just continue to read commands. But after the first appearance of pure prosodic mouth noises *(see Table1.a),* we always notice specific subjects reactions as showed in Table 2. Moreover, the voice breathiness seems to be amplified after mouth noises. Once the relation is established, the robots' lexicons and mouth noises become the base of the subjects' imitations and echolalia as answer to Emox feedbacks. This can be a clue on the degree of "glue" [13] to know when to introduce imitations that increase the "glue". The timing of EMOX's reactions and the silence duration are also an important factor in the "socio-affective glue" process that is also a major key for the interaction synchrony [9], but it also seems to be the moment that we can see if the "glue" is established. Indeed, even if EMOX (in fact the Wizards) makes mistakes or is slow, the subjects do not blame the robot but spend this response time justifying the commands, being politer or heartening it with compliments.

Types of subjects feedbacks	Quantity
Commands associated to politness and compliments	5
*Commands justifications***	13
Echolalia	10
Imitation	45
Kind repraoches	9
Mouth noises, interjections and laughs	49
*Politeness forms***	11
*Ponctual compliments***	16
Spatial proximity	28

**During silence or timelag after a vocal command

Table 2. *Subjects' reactions distribution as answer to Emox feedbacks*

4. Conclusion

The elderly's speech behaviors confirm that the effect of socio-affective "glue" increases towards the prosodic levels. This starts by the pure prosodic mouth noises that seem to be essential to initiate the relationship between the robot and a human. Once the link is created, the supposed prosodic "glue" tends to reinforce the bond through lexicons echolalia, imitations supported by a breathy voice quality. To have a cleaner corpora collection, the way to introduce the robot becomes essential as it induces the basic communication channel, where the glue is adding its effects after. To allow a precise control of the robot reactions timing and order, we need an efficient interface so the cognitive effort of the Wizard of Oz experimenter is the same as the effort the robot "seems to produce" to execute the commands. This will be one of these study perspectives, in addition to expanding this experiment with more various stimuli and subjects, on a revised and longer scenario to confirm those tendencies.

5. Acknowledgements

This work has been partially supported by the LabEx PERSYVAL-Lab (ANR-11-LABX-0025-01) and the Interabot project (Investissements d'Avenir, DGCIS) collaboration with *Awabot* (robotics) company. We thank *Bien à la Maison* company (elderly personal services) for their active participation to held the corpus. Best thanks to Tim Robert, Nicolas Bonnefond and Brigitte Meillon, for their precious technical contribution and their organization support for the experiments. Finally thanks to Leandra Batista for her advice on the results analyses and to Gilles De Biasi for his reviewing.

Abstract

Understanding of speakers' attitude is essential for establishing successful human interaction. In this paper we analyse attitude manifestations in video blogs. We describe the main features of this novel communication medium and focus our attention on its possible exploitation as a rich source of information for human-human and human-machine communication. We describe the manual annotation of attitudes and the prosodic analyses. Finally we present a preliminary automatic attitude annotation system that attains 65% accuracy.

Index Terms: video blog, prosody, attitude, automatic classification, statistical modeling, SVM.

1. Introduction

Social media is becoming a major form of interaction and of personal expression. While the popularity of content based platforms, such as web blogs, Twitter and Facebook, confirms that written text is still the major form of online interaction, new forms of expression are evolving. Conversational video blogs (in short vlogs) are becoming a widespread phenomenon of online social media, which create a huge amount of user generated content. Video blogs can be defined as personal diaries made available to the larger public in the form of self-recorded videos, where the users express themselves, their personality and share life events. They combine the best qualities of pre-recorded broadcasted speech with the naturalness of spontaneous conversations. However, at the same time, the speaker expresses himself in a de-contextualized situation, addressing an imagined audience without being influenced by the listener's reaction, as would happen in a face to face context.

Video blogs have piqued the interest of scholars in recent years. The main stream of research on vlogs involved the study of personality recognition [1, 2] and they have been widely studied with respect to non-verbal behavior and social attention. However, to our knowledge, the linguistic pragmatic aspect of this new form of expression has been given little attention. Video blogs are a unidirectional form of communication where the user intends to convey a message, an emotion or a personal opinion. In this work we are not interested in investigating personality as reflected in video blogger behavior in front of a camera, but rather the impression of what he wants to transmit at a purely pragmatic level. For this reason, we explore five attitudinal classes that appear to be representative of the videos in our corpus and analyse their prosodic characteristics. In this work we define attitude as social affective states that the video bloggers intend to transmit and we rely on the classification of attitudes in [3]. We are not interested in the inner emotion of the video blogger but in what he intends to express. Finally, we explore the predictive value of extracted prosodic cues for automatic recognition of attitudes in video blogs.
Main contributions of this work are:

- We focus on a new social media, describing the potentialities of this source of material and a qualitative analysis of its characteristics.
- We describe a novel corpus of vlogs and its manual annotation with respect to attitudes.
- We analyse prosodic features of attitude impressions in video blogs.
- We address the task of automatically predicting video bloggers' attitude impressions using multimodal nonverbal cues and machine learning techniques.

The paper is structured as follows: Section 2 describes some of the previous literature on video blogs. Section 3 outlines the characteristics of the dataset. Section 4 explains the annotation process and adaptation of the schema. Section 5 presents selection and analysis of prosodic features. Findings and results are presented in Section 6. Section 7 explains and discusses the analysis in detail. We conclude the study in Section 8.

Figure 1: Example of Video Blogs

2. Related work

Numerous studies with relevance to various fields of research have been conducted on video blog analysis. Biel et.al [1] conducted a study on recognition of the Big 5 Personality Traits

[4] of video bloggers represented through non-verbal signals. They were able to predict personality traits including Extraversion, Openness, Agreeableness, Conscientiousness and Emotional Stability from analysis of non-verbal characteristics in video blogs. Prosodic and visual feature extraction was conducted to identify labels of personality annotated by five people using Amazon Mechanical Turk. Findings suggest that speakers who demonstrate higher pitch range and higher motion activity possess Extroversion and Openness traits.

Other related work involves multimodal sentiment analysis of opinion videos among Spanish speakers on YouTube [5]. Automatic feature extraction and prediction using audio, visual and textual features were conducted to identify sentiments of the speakers. Videos were labelled according to three positive, neutral and negative sentiments. Results showed that the smile offers the best feature prediction, while number of pauses and voice intensity followed suit. Positive sentiments are indicated by increased number of smiles and pauses, whereas negative sentiments are represented by higher voice intensity.

Treating attitudes as expressions of opinions made by the speaker towards related issues during interaction with their interlocutor, Mac et.al [6] investigated audio-visual prosodic attitudes involving cross-cultural relations. Their study examines perceptions of Vietnamese and French participants in identifying attitudinal expressions in the Hanoi standard dialect. A perception test was conducted and results showed that native listeners recognised attitudes better than foreign listeners. For Admiration, however, foreign listeners were able to successfully recognise the state better than native listeners.

Analysis on prosodic characteristics in speech not only facilitates but further enhances understanding of speakers' attitudes towards a particular topic or notion [3]. Henrichsen and Allwood [3] analysed the NOMCO speech corpus containing eight dialogues by automatically extracting multimodal features to identify attitudes. A standard set of ten attitudes called the A10-based annotation was developed. Multimodal features were extracted for automatic prediction of attitude categories and results showed that attitude labels could be predicted by the trained model.

3. Video Blog Dataset

This section introduces the dataset of videos that we use throughout the paper. We first describe the data collection process and then provide a high level analysis of the contents and of the type of speech typical of video blogs.

A total of 100 video blogs were selected from the YouTube channels of four different speakers [1]. The speakers have been selected according to the following characteristics:

- Native English speaker
- American English
- Male speaker
- Aged between 18-25 years old

Among the videos of these speakers, we selected the ones with the larger number of visualizations. On average each speaker is represented by about 25 videos. The videos were downloaded using a free add-on tool for Mozilla Firefox browser [2]. The audio tracks were extracted from each video using the same tool. Annotation and labeling was conducted manually using WaveSurfer [7], as in Fig.3.1. Sample rate for all videos is set at 44100bit rate with mono sound. Total duration of the corpus is 286 minutes, and the mean duration of each video is 2.88 minutes (sd=1.09).

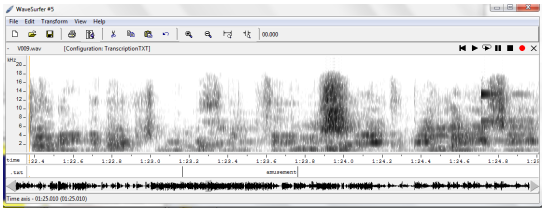

Figure 2: Annotation with Wavesurfer

3.1. Qualitative overview of the dataset

The video blogs in our dataset are typical of the video blog genre. They are pre-recorded monologues, recorded with the speaker facing the camera. They represent an expression of asynchronous communication with a delayed feedback provided by the comments of the audience, and they are usually stored in reverse chronological order. The speech is semi spontaneous. While in broadcast recordings, speech is typically prepared and scripted with a rigid format that the speaker needs to adhere to, in video blogs, the speech is more flexible. Video blogs may be characterised as prepared speech, because a substantial amount of time is given for preparation and planning prior to recording, but video bloggers do not strictly conform to the pre-written texts. As a result of this, utterances in video blogs resemble unprepared or spontaneous speech, particularly with regards to disfluencies, such as ungrammaticality, filled pauses, repetitions, repairs and false starts [8].

These two elements (the preparation of the script and the spontaneity) create a very interesting linguistic genre that preserves features of broadcast speech as well as features of natural spontaneous speech. The following is an example of video blog speech:

```
Hey guys!
If there's one thing I can't stand,
it's people who judge others.
Whether it's based on looks,
or what you heard about them, it
doesn't matter. If you don't know
the person personally, you have
no right to judge them. High
schools are the worst.
```

4. Annotation process

In the present work we are interested in analysing video blogger attitudes during the recording. In the unfolding of video blogs, the user is "playing" different roles and showing different attitudes to the audience. In order to conduct our experiments, we first labelled the corpus with respect to 5 main attitudes shown in Table 1. We base our annotation schema on the A10-set annotation identified in Henrichsen and Allwood [3].

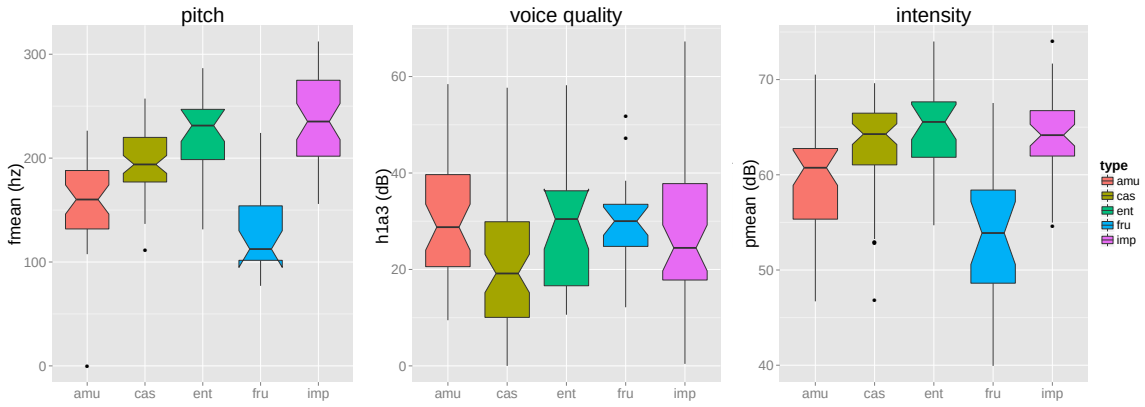

Figure 3: Pitch, voice quality and intensity distributions over the five attitude states (**amu**sement, **cas**ual, **ent**husiasm, **fru**stration, **imp**atience). The figure shows good separation in both Pitch and Intensity with clear differences in Voice Quality for Casual utterances.

The manual annotation took six weeks to complete. We annotated through several stages. A preliminary observation was devoted to understanding attitude expressions of video bloggers. After this qualitative analysis of the corpus, we selected from the A-10 the most representative attitudes for our dataset (Amusement, Impatience, Casual, Enthusiasm, Frustration). In a preliminary phase we listened to the audio files and marked segments of speaker higher activity. Subsequently, two raters were asked to label the segments using the annotation scheme presented in Table 1. Inter annotator agreement was calculated using Cohen's Kappa, and resulted in k=0.75 [9].

After labeling, the chunks' start and end times were extracted using a TCL/TK script.

Attitude	Description
Amusement	speaker laughs, chuckles
Impatience	speaker shouts, appears annoyed, harsh
Casual	speaker informally addresses the audience
Enthusiasm	speaker appears excited
Frustration	speaker appears 'defeated'

Table 1: Attitude Annotation schema

5. Feature extraction

The prosodic analysis was performed after extracting the following acoustic parameters from the video blogs audio channels, using a TCL/TK script:

- Fundamental Frequency (f0) - pitch level (high/low) [max,mean,min,median]
- Pitch target (fpct) - peak position of pitch (rising/falling)
- Voicing (fvcd) - percentage of voicing (vocal fold vibration) within each utterance
- Power/Intensity (dB) - loudness of the voice [max,mean,min,median]
- Power/Intensity movement (ppct) - peak position of power (rising/falling)
- Voice Quality (H1/a3) - tenseness of the voice (creaky/breathy) [h1h2,h1,a3] [10]
- Duration (dn) - length of the utterance (short/long)

In addition to the traditional prosodic parameters; pitch, intensity, and duration of the attitude segments, voice quality is included as a relevant acoustic parameter for communicative speech analysis. This parameter has been shown to have significant correlates with the interlocutor, speaking style and speech act [11].

5.1. Prosodic features analysis

In Table 2, we report the average and standard deviation of the prosodic values for each category. We notice that the attitudinal category Impatience shows the highest pitch and Frustration the lowest. Figure 3 (left and middle) shows the distributions of pitch and voice quality respectively. We observe that Frustration and Amusement differ significantly in terms of pitch from the other categories (lower pitch, $p<0.005$), while Casual significantly differs from the others with respect to voice quality ($p<0.005$). Impatience and Enthusiasm show similar distributions in terms of pitch, with a similar high average pitch. Figure 3 (right) shows the distributions of intensity. Again, Frustration is represented by speech with low intensity (significantly differing from the others, $p<0.005$), while, as expected, Impatience is the attitude characterised by a higher intensity. Significance was tested with a one tailed T-Test (alternative less).

6. Experiments and Results

In this section, we address the task of automatically predicting video bloggers' attitude impressions. Specifically, we were interested in assessing the prediction performances using the selected features for the annotated attitude classes. We will describe the experimental settings and present the results obtained. The study is based on the ground truth data collected (see Section 3) to evaluate classification performance; a user study focusing on the subjective assessment of the quality of the automatically extracted annotations is planned as future work.

We conducted our experiments using the data collection described in Section 4 in a 16 dimensional feature matrix. With the two different features sets as in Table 2, we trained a Support Vector Machine (SVM) with radial basis function (Gaussian) kernel as the classifier for the 5 attitude categories. We used a 10-fold cross validation approach to evaluate the trained model. We evaluated different feature sets:

Feature set ALL: All 16 features described in Table 2.

Type	fmean	fmed	fmax	fmin	fpct	fvcd	pmean	pmed	pmax	pmin	ppct	h1h2	h1a3	h1	a3	dn
Amused	162.97 *(36.09)*	172.24 *(50.94)*	228.04 *(59.84)*	103.01 *(30.43)*	0.43 *(0.25)*	0.55 *(0.19)*	59.86 *(5.75)*	60.51 *(5.88)*	75.37 *(5.38)*	36.71 *(10.43)*	0.49 *(0.27)*	6.49 *(4.74)*	30.00 *(12.17)*	-25.28 *(9.53)*	-55.28 *(5.81)*	1.07 *(0.31)*
Impatient	234.39 *(39.72)*	242.39 *(49.92)*	311.76 *(47.04)*	139.05 *(44.12)*	0.43 *(0.27)*	0.61 *(0.16)*	64.09 *(4.13)*	66.05 *(3.99)*	77.90 *(2.67)*	36.48 *(13.09)*	0.38 *(0.25)*	6.00 *(6.34)*	27.96 *(14.88)*	-26.06 *(11.18)*	-54.03 *(7.41)*	1.26 *(0.50)*
Casual	196.14 *(32.2)*	193.97 *(30.02)*	248.40 *(43.85)*	147.33 *(40.80)*	0.26 *(0.16)*	0.73 *(0.13)*	63.23 *(4.69)*	66.75 *(3.28)*	76.60 *(2.97)*	32.08 *(15.61)*	0.32 *(0.20)*	4.34 *(4.67)*	20.65 *(15.28)*	-34.72 *(17.54)*	-55.37 *(5.53)*	0.55 *(0.16)*
Enthusiastic	220.1 *(38.65)*	242.62 *(40.23)*	310.56 *(47.55)*	115.04 *(50.65)*	0.39 *(0.28)*	0.72 *(0.18)*	64.70 *(4.7)*	66.50 *(4.51)*	79.28 *(3.08)*	35.66 *(14.28)*	0.35 *(0.24)*	6.08 *(6.74)*	29.54 *(13.54)*	-26.72 *(11.87)*	-56.27 *(6.28)*	1.20 *(0.52)*
Frustrated	124.78 *(35.15)*	136.84 *(40.16)*	175.89 *(55.96)*	86.67 *(33.09)*	0.40 *(0.30)*	0.49 *(0.23)*	53.65 *(7.32)*	54.49 *(7.24)*	70.35 *(5.64)*	30.62 *(14.80)*	0.57 *(0.26)*	3.59 *(5.02)*	29.22 *(9.81)*	-27.43 *(9.72)*	-56.64 *(4.51)*	1.27 *(0.57)*

Table 2: Mean values for each attitude category with standard deviation in brackets

Feature set SEL$_1$: Select only the features that are not highly correlated (with Pearson's correlation coefficient $r < 0.7$): fmean, fmin, fpct, fvcd, pmean, ppct, h1h2, h1a3, h1, a3, dn. A correlation study of the feature set revealed that some of the features are highly correlated (correlation coefficient $r > 0.7$ with $p < 0.01$ in T-test). Only one of the features in the highly correlated feature pairs was selected and a new 11 dimensional feature set: SEL$_1$ was generated.

Table 3 shows the results of 10-fold cross validation SVMs with the different feature sets.

Feature Set	Accuracy
ALL	61.85
SEL$_1$	**65.46**

Table 3: Results for the different feature sets.

Results show that the feature set selected after removing the highly correlated features attained the best prediction accuracy. This result has also been compared with other feature set experiments by reducing the threshold of r to 0.65 or increasing to 0.75. SEL$_1$ resulted to be the feature set showing better prediction performance with a 65.46% accuracy rate.

7. Discussion

Understanding of speakers' attitude is not only essential for establishing successful human-human interaction, but could significantly contribute to the development of a robust system for human-robot interaction. Video blogs, spontaneous and intimate conversations, represent a rich source of natural attitude expressions.

We have reported the prosodic analyses of a collection of video blogs, for a better understanding of the acoustic dynamics behind five different attitudes including Amusement, Enthusiasm, Casual, Impatience and Frustration. Pitch and intensity show a strong discriminative value, and voice quality emerges as a feature characterising Casual friendly talk. We also investigate the predictive performance of prosodic cues and results from the automatic classification experiments show a prediction accuracy of 65.46%.

Although preliminary, results of this work are in line with [3]. In building conversational agents, attitude management (recognition and synthesis) is a key aspect. Given the sensitivity of conversational partners to an inadequate attitude response, attitude recognition is required to be reliable and robust. We believe that the combination of three main prosodic components such as pitch, intensity and voice quality can provide a robust attitude classification. In order to create a natural and spontaneous interaction, a conversational agent should also be able to synthesise the prosodic dynamics representative of the different attitudes. Our study goes in the direction of a better understanding of these dynamics.

8. Conclusion

In this paper we have explored attitude manifestations in video blogs. We have described the main features of this novel communication medium and focused attention on its possible exploitation as a rich source of information in human communication. We have presented a novel corpus of video blogs, its collection and annotation according to five attitudes, and analysed the main prosodic features characterising these classes. Finally we have presented a machine learning approach for the automatic detection of attitudes in video blogs and reported its preliminary results. Future work will be dedicated to extending the corpus and the annotations, and to exploring other feature selection approaches such as Principal Component Analysis.

Abstract

To understand how emotional prosody is processed in Mandarin Chinese and whether it differentiates from that of other languages, we conducted a perceptual-acoustic study on a set of Chinese vocal emotional stimuli and examined how they were perceived and acoustically characterized, in comparison with four other languages, English, Arabic, German, and Hindi, reported by Pell et al. [1]. Chinese pseudo-utterances spoken in seven emotions (anger, disgust, fear, sadness, happiness, pleasant surprise, and neutrality) were first identified by a group of native Mandarin speakers in a seven forced choice task, and then subjected to acoustic analyses. Results revealed that among the seven emotions, neutrality, anger, sadness, and fear tended to be recognized most accurately. Acoustic analysis demonstrated the importance of three acoustic parameters (f0 mean, f0 range, and speech rate) in characterizing vocal emotions in Mandarin. Both the perceptual and acoustic characteristics are highly similar, although not identical, to that observed by Pell et al. [1] in English, Arabic, German, and Hindi, indicating a set of universal principles in vocal emotion communication across languages.

Index Terms: Mandarin Chinese, emotional prosody, perceptual-acoustic, cross-language

1. Introduction

Humans can efficiently understand each other's emotions from speech cues without any visual information available, in cases such as telephone conversations. The vocal features of speech, including variations in pitch, loudness, speech rate, etc., which are considered as 'emotional prosody', are a universal means to communicate emotions used by speakers from different language backgrounds [2], [3].

Existing cross-language studies of emotional prosody have reported that listeners can successfully recognize the meaning of vocal emotions in a foreign language, but always with an "out-group" disadvantage (i.e., lower accuracy than that of their native language), suggesting that there is a set of shared properties encoding emotions across languages but on the other hand, discrepancies across languages exist and exposure to vocal emotions in a specific language plays a role (e.g., [4]-[6]). Acoustic studies have also demonstrated a number of consistent tendencies in the acoustic features of vocal emotions across languages (e.g., [1], [2], [7]). Thus, it will be important and interesting to further clarify the extent to which there exists a set of universal perceptual-acoustic characteristics shared across languages in vocal emotion communication, based on direct comparisons of data from different language groups.

However, the previous literature have mostly focused on Indo-European languages, while little is known about how vocal emotions are communicated in other major languages such as Mandarin Chinese. Mandarin is a Sino-Tibetan language which is spoken by more than a billion people around the world and diverges in fundamental ways from Indo-European languages (e.g., [8]-[12]). So far, little work has been done to systematically explore the perceptual-acoustic features of emotional prosody in Mandarin, with direct comparisons with other languages. By employing a well-established database of vocal emotional stimuli in Mandarin [13], this study aims to provide evidence on the perceptual-acoustic features of Chinese vocal emotions; by qualitatively comparing these data directly with four languages from different linguistic families (English, Arabic, German, and Hindi) that were examined in one of our previous studies [1], this study will shed light on to what extent there are central tendencies in how discrete emotions are communicated vocally across different languages and cultures.

To ensure the comparability of our data with that of the previous study, identical procedures of testing and analyses were adopted as those of Pell et al. [1]. In particular, emotionally-inflected "pseudo-sentences" in Mandarin (e.g., *她在一个门文上走亮*) were recognized by native Mandarin speakers in a seven-option forced-choice identification task and then subjected to acoustic analysis. Pseudo-sentences are composed of pseudo content words conjoined by real function words, rendering them meaningless but resembling the phonetic-segmental and supra-segmental properties of the target language; they have been used effectively in the literature investigating the perception of vocal tones independent of the linguistic-semantic content (e.g., [1], [5], [14]). Based on the evidence that many languages share perceptual-acoustic properties of discrete emotions, it is hypothesized that Chinese vocal emotions will show similar perceptual-acoustic patterns as those found in the four languages in comparison [1], although unique variations may also be observed.

2. Method

2.1. Participants

Twenty-four native Mandarin speakers (12 female, 12 male) with a mean age of 25.5 ± 3.3 years were recruited for the perception study. They were all students from China who learned Mandarin from birth, lived in China until at least 18 years of age, had been away from China for less than two years, and spoke English as a second language. Each participant gave written consent for the testing was compensated $10 CAD per hour for their participation.

2.2. Materials and procedure

Eight-hundred and seventy four Chinese pseudo-utterances spoken by 4 native Mandarin speakers (2 male, 2 female) in 7 emotion categories (anger, disgust, fear, sadness, happiness,

pleasant surprise, and neutrality), were adopted from a validated database of Chinese vocal emotional stimuli [13]. In the perceptual study, the 874 utterances were randomly combined and divided into four blocks which were presented by Superlab presentation software (Cedrus, USA) in two testing sessions, two blocks during each session. During the testing, each utterance was played once over headphones at consistent comfortable listening level, for which the participants identified which emotion was being expressed from a list of the seven categories presented on the computer screen by clicking the mouse. All participants received practice trials prior to the first block and frequent breaks during each session. All instructions were conducted in Mandarin.

2.3. Analyses

2.3.1. Perceptual-acoustic analyses

Identical perceptual-acoustic analyses were conducted as those of the study of Pell et al. [1]. For the perceptual data, the recognition rates of each of the 7 emotion categories were calculated. Acoustic analysis was performed on the 874 items and focused on three acoustic parameters that are widely employed in the literature: mean fundamental frequency (f0Mean, in Hertz), fundamental frequency range (f0Range, in Hertz), and speech rate (SpRate, in syllables per second). The values of mean f0, maximum f0, minimum f0, and utterance duration for each item were obtained in Praat [15], based on which the three parameters were calculated. Following Pell et al. [1], in order to correct for differences in a speaker's mean voice pitch and expressive range, all f0 measures (mean f0, maximum f0, and minimum f0) were normalized in relation to the individual *resting frequency* of each speaker (i.e., the average minimum f0 value of all neutral utterances produced by that speaker, see [1] for details). Therefore, for the normalized values of f0Mean and f0Range, a value of 1 for an utterance represents a 100% increase in the speaker's resting frequency, which could be compared across speakers as a proportional value. Measures of speech rate (SpRate) were calculated by dividing the number of syllables of each utterance by the duration of that utterance, in syllables per second.

2.3.2. Statistical analysis

To evaluate whether the seven emotion categories could be differentiated both perceptually and acoustically, univariate and multivariate analysis of variance (ANOVA/MANOVA) were conducted on recognition rates and acoustic measures (f0Mean, f0Range, and SpRate), respectively. In addition, a step-wise discriminant analysis was performed on the acoustic data to explore whether the seven emotion categories could be successfully classified based on the three acoustic measures.

3. Results

3.1. Perceptual data

Emotion recognition rates were calculated for each emotion category as the target emotion hit rate (% correct). A one-way ANOVA performed on recognition rates as a function of emotion category showed a significant effect of emotion category, $F(6, 154) = 26.87$, $p < .01$. Post hoc (Tukey's HSD) comparisons revealed that neutrality (86%) was recognized most accurately, followed by anger (82%), sadness (81%), fear (80%), and happiness (70%); then disgust (67%), which is significantly lower than neutrality, anger, sadness, and fear (86%; *ps* < .01). Pleasant surprise (56%) was recognized less accurately than the other six categories (*ps* < .01). Qualitative comparisons were conducted on recognition rates between Chinese and the four languages studied by Pell et al. [1]; see Figure 1 for an illustration.

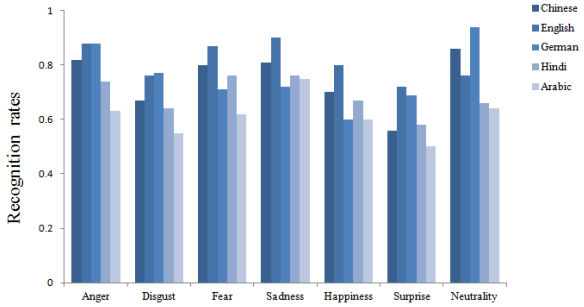

Figure 1: *Recognition rates for each emotion category of each language.*

3.2. Acoustic data

The three acoustic measures (normalized f0Mean, normalized f0Range, and SpRate) were obtained of the 874 items. To explore how the seven emotions differed in these parameters in Mandarin, a one-way MANOVA was performed on the acoustic data as a function of emotion category, with the three acoustic parameters as the dependent variables. The MANOVA indicated that the effect of emotion category on the three acoustic parameters was significant, Wilk's $\Lambda = 0.29$, $F(18, 2447) = 73.54$, $p < 0.01$. Following univariate analyses showed that the effect of emotion category was significant for f0Mean, $F(6, 867) = 106.22$, $p < 0.01$, f0Range, $F(6, 867) = 62.78$, $p < 0.01$, and SpRate, $F(6, 867) = 108.27$, $p < 0.01$. Post hoc comparisons were carried out on each acoustic parameter separately.

For f0Mean, pleasant surprise was expressed with a significantly higher f0Mean compared to all other categories (*ps* < .01), and neutrality exhibited the lowest f0Mean (*ps* < .05). Following surprise, anger and happiness yielded significantly higher f0Mean than fear (*ps* < .01), while the three emotions (surprise, anger, and happiness) showed a higher f0Mean than disgust, sadness, and neutrality (*ps* < .01). For f0Range, fewer significant differences among emotions emerged: pleasant surprise, anger, happiness, and disgust were conveyed with a significantly greater f0Range than fear, neutrality, and sadness (*ps* < .01); in addition, surprise showed a greater f0Range than disgust ($p < .01$). Finally, for SpRate, anger was expressed significantly faster than all other emotions (*ps* < .01), while disgust was produced the slowest (*ps* < .01). After anger, fear and neutrality were spoken significantly faster than happiness and sadness (*ps* < .01), while surprise and happiness also revealed a faster SpRate than sadness (*ps* < .01). Qualitative comparisons were conducted on the three acoustic parameters between Chinese and the four languages [1]. See Figure 2 an illustration.

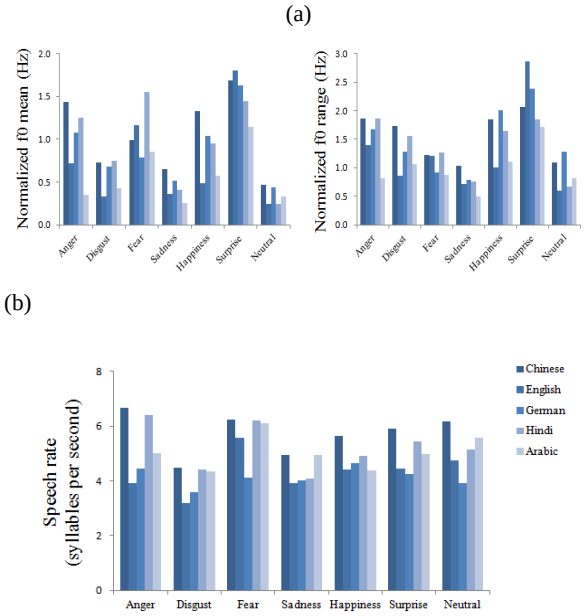

Figure 2: *(a) normalized f0 mean values for each emotion category of each language (left); normalized f0 range for each emotion category of each language (right); (b) speech rates for each emotion category of each language.*

3.3. Discriminant analysis

In order to examine how well the three acoustic parameters predicted the perceptual classification of the seven emotion categories, a discriminant analysis was performed which revealed three significant canonical functions: Function 1, $F(18, 2447) = 73.54$, $p < 0.01$; Function 2, $F(12, 1732) = 99.18$, $p < 0.01$; Function 3, $F(6, 867) = 108.27$, $p < 0.01$. Function 1 explained 55.3% of the variance and correlated significantly with f0Mean ($r = 0.80^{*}$) and SpRate ($r = 0.76^{*}$). Function 2 accounted for 38.4% of the remaining variance. Function 3 accounted for 6.3% of the remaining variance and correlated with f0Range ($r = 0.67^{*}$). This model successfully predicted the classification of the seven emotion categories at an overall rate of 49.9% (436/874), which is similar to those reported by Pell et al. [1] for English (58%), German (49%), Hindi (56%), and Arabic (53%) when the same analysis was performed.

4. Discussion

By conducting a perception study and acoustic analyses of emotional prosody in Mandarin which were identical to the methods of Pell et al. [1], our study allows direct comparison of the perceptual-acoustic features of emotional prosody among different languages; this allows certain inferences to be made about the extent to which vocal emotions display universal tendencies across languages.

The analysis of recognition rates showed expected variations among emotion categories, indicating that certain vocal emotions, e.g., neutrality, anger, sadness, and fear, were recognized more accurately than others in Mandarin, which is compatible with previous data in the four languages in comparison [1] and other languages such as Portuguese, Spanish, and Swedish [2], [7], [16]-[18]. A general advantage to recognize *negative* emotions from vocal speech cues, independent of language, is compatible with evolutionary views of emotion communication that vocal signals associated with threats, such as fear and anger, must be highly salient over long distances and across language systems to ensure human survival [19], [20]. While sadness is often considered a signal of the need for support from conspecifics and is therefore instrumental to maintain cohesion of social groups [21], [22], [23], [24], it is less clear from an evolutionary standpoint why sadness is often recognized most accurately in the vocal channel. Quite possibly, the recognition advantage of vocal sadness is due to their acoustic distinctiveness as speech unfolds, at least for expressions of 'depressed' sadness which lack acoustic variation and energy, as argued recently by Pell and Kotz [29].

Based on qualitative inspection of the perceptual data in Figure 1, it should be noted that fear demonstrated comparatively lower recognition rates in Arabic and German than in the other languages. One potential explanation is that the intensity of fear expressions across studies might be inconsistent; e.g., expressions of fear may be immediate and intense (i.e., 'panic' fear) or more sustained ('dread' fear) and these different forms appear to have distinct vocal cues [2] influencing recognition of this emotion. It seems that in Mandarin of this study and English and Hindi of the previous study, fear is more salient as intense portrayals of 'panic' fear with higher speech rate and f0 mean value.

Disgust and happiness were recognized relatively poorly in Mandarin compared to the other emotions, compatible with the four languages and previous findings (e.g., [2], [5], [7], [16]). For the case of happiness, it has been argued that instead of a unitary category of "happiness", there exist several positive emotions that share the facial expression of smile but possess distinct vocal cues (e.g., achievement/triumph, amusement, contentment, sensual pleasure, and relief), each of which could be reliably recognized through non-verbal vocalizations [25]. Given the fact that the unitary term 'happiness' has been used in the vocal emotion literature and the current study, it is possible that the distinct vocal cues were confounded with each other which led to difficulty in recognizing 'happy' vocal expressions.

In the case of disgust, it is more likely that in natural communication, this emotion is expressed predominantly by facial cues or by non-verbal vocalizations rather than through vocal inflections of the whole utterance (e.g., [7], [14], [26]). Note also that while disgust is considered one of the basic emotions in most studies, there is ongoing debate about whether disgust is either a sensory/interoceptive affect, or a socially constructed moral emotion; this raises the question of whether disgust would be associated with differentiated communicative properties like other basic emotions [27]. Pending further data, our findings do strongly suggest that vocal cues signifying disgust are highly distinct from other emotions in Mandarin and other languages, although the ability to recognize disgust based on prosodic cues tends to be problematic for many listeners [28], [29].

Finally, qualitative inspection showed that pleasant surprise yielded the lowest recognition rates among the seven emotion categories in Mandarin, replicating the observations of the four languages in the study of Pell et al. [1]. Interestingly, surprise was found to be recognized well in several other languages, e.g., Portuguese [7], Swedish [16],

Spanish [30], and Standard Basque [31]. A significant distinction is that Pell et al. [1] and the present study elicited surprise with a positive valence ("*pleasant surprise*"), whereas all other studies elicited vocal cues conveying "surprise" without a specific valence. Compared to surprise, pleasant surprise may be more easily confounded with "happiness" and more difficult to recognize. However, as all these conclusions are based on a small group of speakers and simulated speaking contexts, it is also possible that individual biases in producing certain emotions is contributing to the variation in listeners' performance on emotion identification tasks [32].

Acoustic correlates of specific emotions

Based on qualitative inspection of the acoustic data in Figure 2, the acoustic patterns of several emotions in Mandarin demonstrated a number of consistencies with those in the four languages studied by Pell et al. [1]. Specifically, sadness was conveyed with a low f0Mean, a low f0Range (i.e., reduced variation in f0), and a slow speech rate; disgust exhibited a low f0Mean, moderate f0Range, and the slowest speech rate, whereas pleasant surprise exhibited the highest f0Mean, the largest f0Range, and a moderate speech rate. In addition, neutral speech displayed a relatively low f0Mean, narrow f0Range, and a moderate speech rate (see also [5], [7], [17], [33]-[37]). The fact that many vocal emotions are encoded acoustically in similar ways, irrespective of the language, is consistent with the idea that emotional communication is constrained to a large extent by biological factors and share a set of universal properties across languages [38].

Qualitative comparison across languages also showed greater acoustic variability in certain emotions. For example, exemplars of fear in Mandarin exhibited a moderate f0Mean whereas fear exhibited a much higher f0Mean than other emotions in English, Hindi, and Arabic in the study of Pell et al. [1]. Anger exhibited a high f0Mean whereas f0 values of anger were comparatively lower in Arabic, English, German [1]. As noted earlier, these different acoustic patterns observed of fear and anger across languages are likely to reflect two types of the target emotion. Specifically, for the case of fear, it was suggested that higher f0Mean values characterized "panic fear" while low f0Mean values characterized "sustained fear" (e.g., [2], [5]). Similarly, for anger, higher f0Mean values tend to depict hot anger (i.e., rage or intense frustration), while moderate or low f0 values tend to depict cold anger (i.e., threat; [2], [5], [39]). The possibility that speakers from different cultural-linguistic backgrounds arrive at different interpretations of the labels "fear" and "anger" that influence how they display these emotions vocally could partly explain the acoustic discrepancies observed in f0 values of these two emotions across languages.

Happiness in Mandarin was spoken with a moderate f0Mean, a moderate f0Range, and a moderate speech rate in comparison with the other emotions, whereas this emotion showed a faster speech rate than all other emotions in German [1], and much higher f0 values in Portuguese [7] and Spanish [30]. As discussed earlier, the inconsistent acoustic patterns may be due to the existence of different types of positive emotions rather than a unitary category of happiness, which were associated with different constellations of acoustic features [40]. Therefore, the "happy" expressions in the current study and the literature may actually be a mixture of these different patterns of acoustic cues, which result in discrepant results across languages. Another explanation for the acoustic variability of happiness involves different functions of negative and positive emotions. While the communication of negative emotions such as fear and anger may reflect biologically-driven responses to threat that are signaled to conspecifics in similar ways across language groups, the communication of positive emotions, which facilitate cohesion and affiliation within group, may be largely restricted to in-group members with whom the primary social connections are built and maintained [40]. Thus, as opposed to negative emotions, expressions of positive emotion are influenced by cultural rules and language variables to a larger extent (see [1], [40], [41]), and as such, display greater variability in how they are encoded and decoded across cultures and languages (see [42], [25]). In future studies, it is necessary to disentangle the unitary term "happiness" that has been used in the literature to elaborate the perceptual-acoustic features of distinct types of positive emotions. In addition, cross-cultural/linguistic studies are in need to further clarify the extent to which different types of negative and positive emotions are shaped by culture and language.

Despite focusing on only three acoustic parameters that are critical in emotional communication, a discriminant analysis of the perceptually validated items in Mandarin showed that combined changes in f0Mean and speech rate accounted for approximately 55% of the variance in the acoustic data across emotions. These results are compatible with the established view that a speaker's voice register and articulation rate are essential cues in communicating vocal emotions across languages (e.g., [1], [7], [18]). In total, the three parameters successfully predicted the classification of 49% of items into their perceived emotion categories, which is comparable to that found in other languages (English = 58%, German = 49%, Hindi = 56%, Arabic = 53%, Pell et al., 2009). Nonetheless, as approximately half of the items could not be classified by this small set of acoustic variables, future work will need to include measures of intensity/amplitude, voice quality, and other parameters to fully capture how listeners use acoustic cues to recognize emotion from speech prosody.

5. Conclusion

By conducting a perceptual-acoustic study on vocal emotion expressions in Mandarin Chinese and comparing the data directly with four other languages from a previous study (Pell et al., 2009), this study supplies new evidence of the perceptual-acoustic features of emotional prosody in Mandarin which exhibit many similar, although not identical, patterns to those found in Indo-European and Semitic languages studied by Pell et al. [1] as well as others (e.g., [2], [6], [7], [17], [18]). The new evidence from Mandarin Chinese, which is a Sino-Tibetan ideographic language with little similarity with other languages in the literature, implies that linguistic structure does not impact the core acoustic-perceptual features of vocal emotion expressions in fundamental ways and further strengthens the notion that vocal emotion communication is governed by 'universal' principles across different languages and cultures. Future research using stimuli from spontaneous speech of multiple speakers will further clarify the perceptual-acoustic features of emotional prosody in more natural day-to-day settings. Another interesting topic for future studies is to investigate how the variation of lexical tones of Mandarin influences the acoustic characteristics of emotional prosody in this language.

Abstract

The speaking style of an interjection contains discriminative features on its expressed intention, attitude or emotion. In the present work, we analyzed acoustic-prosodic features and the paralinguistic functions of two variations of the interjection "un", a lengthened pattern "uun" and a repeated pattern "unun", which are often found in Japanese conversational speech. Analysis results indicate that there are differences in the paralinguistic function expressed by "uun" and "unun", as well as different trends on F0 contour types according to the conveyed paralinguistic information.

Index Terms: interjections, acoustic-prosodic features, paralinguistic information, spontaneous conversational speech.

1. Introduction

In spontaneous dialogue speech, repeated "un" utterances ("unun…") or lengthened "un" utterances ("uu…n") are often used as variations of the (short/single) backchannel "un". These two patterns may cause different impressions to the interlocutor depending on the situations they are used. Therefore, in order to achieve a smooth communication between humans and machines, these two patterns should be discriminated.

In our past works, we have focused on interjections appearing in Japanese natural conversational speech, and analyzed the relationship between speaking style and the paralinguistic information (intentions, attitudes and emotions) conveyed by the interjections [1-4]. So far, several monosyllabic interjections (such as "un", "ee", "oo", "ha", "he", "ya") have been analyzed. However, utterances where interjections are repeated in sequence have not been focused.

So far, several works have been conducted regarding the interjection "un" in Japanese (including its variations in speaking styles) [1-8]. However, there are only few studies devoting attention to the functions of "unun" comparing to "un" in discourse. For example, the relations between acoustic features and functions of interjection "un" have been investigated using speech data extracted from TV drama [5]. It is mentioned that "uun" indicates "unknown information is being stored", "embarrassment" or "hesitation". In [6], it has been described that "unun" functions as a marker that the interlocutor's last utterance evoked the speaker's attention for the current conversation topic. In [7], the distribution of backchannel expressions appearing in natural conversations has been analyzed. It has been concluded that "un" is commonly used by both information providers and followers, while "unun" is only used by information followers.

Regarding F0 pattern analysis, the relationship between speaker's attitudes and F0 patterns of "un" have been analyzed in [8]. They found that mean F0 is higher when attitudes of "activation, acceptance, confidence" are expressed, while durational change structures are related with "affirmation/negation" expression. In our past works [1-4], we have shown that the tone type (rising, falling, flat tones) is useful for discriminating between functional speech acts (such as positive reactions, asking for repetition, and thinking), while voice quality features are useful for discriminating emotion expression (such as surprise, admiration, and disgust). However, the speaking styles and paralinguistic functions of "unun" utterances have not been clarified so far.

Regarding backchannel analysis in other languages, it is reported that occurrence rates and environmental location of Japanese backchannels differ from Mandarin and English [9]. It is reported that, in general, appropriate forms and timings of backchannels ("reactive tokens" in their term) show the interest for the speakers and encourage the speaker to keep talking. However, a relatively heavy usage of backchannels in Japanese provides emotional support for speakers [9]. In [10], a large variety of non-lexical tokens, mainly backchannels, uttered in English conversations was examined and the relationship between prosodic features and its meanings was reported. It was stated that duration lengthening (equivalent to "uun" in Japanese) means "amount of thought", while syllabification (equivalent to "unun") means "lack of desire to talk".

Another motivation for the present work is the generation of head motion of robots synchronized with speech utterances [11,12]. Our analysis of head motion during speech utterances has revealed that backchannels are often accompanied by nods, and a sequence of repeated backchannels, such as in "unun" are usually accompanied by multiple nods, approximately one nod per "un" repetition [11]. On the other hand, it was also found that in "uun" utterances where the speaker is thinking, a head tilting is often accompanied. Thus, in the synchronization of head motion with speech, the discrimination of these two types becomes important.

Another issue is that "unun" and "uun" utterances may have similar spectral features, so that acoustic features commonly used in speech recognition, such as MFCC (Mel-Frequency Cepstral Coefficients), would not be enough for distinguish these two patterns. Thus, acoustic analyses are conducted on spectral features and F0 contours.

2. Analysis of "unun" and "uun" utterances

2.1. Speech data

The dataset for analysis was extracted from the ATR multi-modal natural dialogue database. The database contains 65 dialogue sessions of 10 ~ 15 minutes, including 11 male speakers and 14 female speakers with ages from 10s to 60s. The conversation topics are free, including past experiences, future plans, topics about a common known person.

Firstly, a text search was conducted on the transcriptions in the database for collecting "unun" (including two or more repetitions of "un") and "uun" (including two or more repetitions of the vowel lengthening) utterances. In Japanese a vowel lengthening symbol is used for long vowels. As the transcriptions in the database were conducted by multiple

annotators, the transcription criteria might not be unified. Thus, we asked three native speakers (research assistants) to check the consistency of the transcriptions. As a result, 6% of the utterances were corrected, resulting in a total of 342 “unun”-type utterances, and 926 “uun”-type utterances.

The left panel in Fig. 1 shows the distribution of the utterance duration in “unun” and “uun” utterances. Due to a big overlap in the distributions, segmental duration cannot be used to distinguish these two utterance types. In the right panel of Fig. 1, the distribution of the number of “un” repetitions are shown for the “unun” utterances. It can be noted that the most frequent was the pattern with two repetitions (45%), followed by the pattern with three repetitions, i.e. “ununun” (32%), four repetitions (16%) and five or more repetitions (7%).

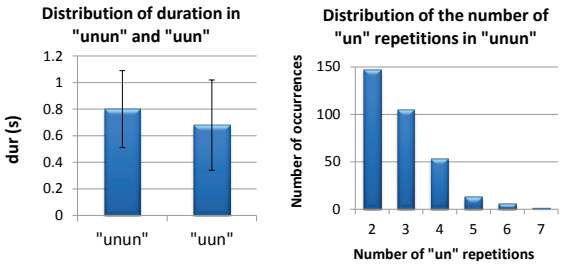

Figure 1: *Distribution of duration in “unun” and “uun” utterances (left panel). Distribution of the number of “un” repetitions in “unun” utterances (right panel).*

2.2. F0 contour type analysis

For each utterance, tone labels were annotated by the first author (which is experienced in prosody annotation), based on F0 curve displays and auditory impression. As tone categories, the following labels were used for monosyllabic utterances:

- “Fa”: falling tones
- “Ft”: flat tones
- “Rs”: rising tones
- “Rt”: pitch reset
- “FtFa”: pitch remains flat and ends with a falling tone.
- “?”: F0 cannot be observed due to vocal fry or low power.

For utterances with two or more syllables, such as in “unun”, the following labels were used:

- “FaFa”: sequence of falling tones
- “Fa_Fa”: sequence of falling tones separated by a short pause

Fig. 2 shows the distributions of different tone types in “unun” and “uun” utterances.

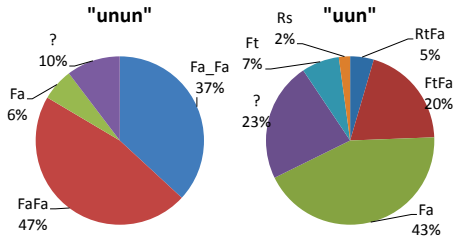

Figure 2: *Distribution of tone types in “unun” and “uun” utterances.*

Flat tones were observed in 7% and rising tones in 2% of the “uun” utterances, while such tone types were not observed in “unun” utterances.

Figs. 3 and 4 show examples of F0 contours and MFCC-smoothed spectrograms of “unun” and “uun” utterances found in our dataset.

Among the “unun” utterances, short pauses smaller than 100 ms between successive “un” syllables were found in 37% of the utterances. In this type, the F0 breaks between successive “un” syllables, being observed as a sequence of falling tones, as the example shown in Fig. 3a.

Most of the “unun” utterances appeared with the pattern without pauses between the “un” syllables (47%). Among them, we observed patterns where the nasal “n” portion is identifiable in the spectrogram and patterns where the (smoothed) spectral features do not change clearly, as the example shown in Fig. 3b. This last pattern, in particular, has little difference to the “uun” utterance spectrogram, so that the only use of spectral features (such as MFCC) would not be enough for their discrimination.

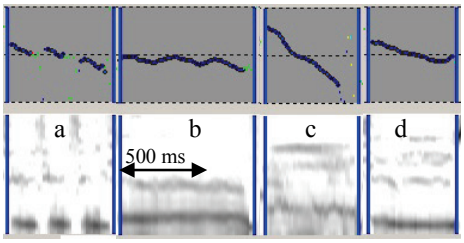

Figure 3: *Examples of F0 contours and MFCC smoothed spectrograms for “unun”. F0 is in log scale from 110Hz ~ 440Hz (center dashed line at 220 Hz); spectrogram is in mel-scale 8kHz band. a) Fa_Fa_Fa ; b) FaFaFa ; c) FaFa? (pitch reset in the second “un” is unclear) ; d) Fa (F0 up-down motion is unclear)*

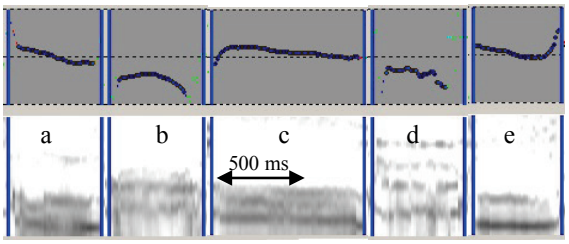

Figure 4: *Examples of F0 contours and MFCC smoothed spectrograms for “uun”. a) Fa; b) FtFa; c) RtFa; d) FtFa with laughing; e) Fa+final rising.*

The phonetic transcriptions of “unun” utterances are usually represented as /uNuN/ (where /N/ is the syllabic nasal). However, in practice, the vocal tract shape does not change much its shape, and only pitch changes upward and downward. This change in pitch is thought to be used in the perceptual distinction of “uun” and “unun” by native speakers.

Another often observed pattern was the one shown in Fig. 3c, where the pitch reset (upward F0 motion) between successive “un” syllables is not clear. Nonetheless, visually one can still observe that the gradient of the F0 contour changes between the “un” syllables.

However, utterances where the F0 resets were almost non-identifiable were also observed in 6% of the "unun" utterances, as the example shown in Fig. 3d. In such cases, the tone label "Fa" was attributed. Although no clear F0 changes can be observed, spectral changes in the /N/ portion can be observed (note that the second formant is broken in Fig. 3d). This means that "unun" utterances are not necessarily accompanied by strong upward-downward F0 changes.

On the other hand, falling tones were observed in most of the "uun" utterances (43% for Fa, and 20% for FtFa). Examples of these patterns are shown in Fig. 4a ~ c. Fig 4d shows an example of "uun" utterance accompanied by laughing, where F0 considerably fluctuates upward and downward.

2.3. Paralinguistic information analysis

Three native speakers annotated the paralinguistic information conveyed by "uun" and "unun" utterances. The paralinguistic items were attributed according to the list below, prepared based on past research on paralinguistic information annotation of interjections. The original terms in Japanese are shown in brackets.

- backchannel ("aiduchi"): "I'm listening."
- affirmation ("koutei"): "Yes, that's right."
- agreement ("dooi"): "Yes, I agree."
- denial ("hitei"): "No, that's wrong"; "No, I disagree."
- negative reaction: dissatisfaction, blame, suspicion ("hiteiteki: fuman, hinan, utagai"): "I'm not satisfied"; "I'm suspicious about"; "I can't accept immediately."
- disgust ("ken-o"): "That's disgusting."
- understanding ("rikai"): "I see", "Yes, I understand."
- admiration ("kanshin"): "I'm admired"; "I'm impressed."
- embarrassment, hesitation ("tomadoi", "chuucho", "konwaku"): "I'm embarrassed/hesitated (on how to react to your utterance)."
- thinking ("kangaechuu"): "I'm preparing my next utterance."
- sympathy, compassion, pity ("kyoukan, doujou, zannen"): "I feel the same"; "It's a pity".

The annotations were conducted by taking contextual information into account, by listening to utterance intervals of both dialogue partner voices, including five seconds before and five seconds after the target interjection part. Annotators were also allowed to include a new item, if they find the items in the list do not fit to the paralinguistic information conveyed. As a result, new labels were included:

- self-affirmation ("jiko-koutei"): affirmation-like interjection right after and directed to the speaker's own utterance.
- modest affirmation ("shoukyokuteki koutei"): affirmation-like interjection, but the speaker does not express it a straightforward manner.

The inter-annotator agreement rates (in terms of kappa values) were 0.59, 0.65 and 0.80 for each pair of annotators.

Fig. 5 shows the distributions of the paralinguistic information items for "unun" and "uun" utterances. A paralinguistic item was attributed to an utterance if two or more annotators agreed. Utterances where the number of utterances for a specific paralinguistic item was smaller than 10, or where agreement was not achieved among the annotators are included in the "others" category. Agreement was achieved in more than 90% of the "unun" utterances, and in more than 75% of the "uun" utterances.

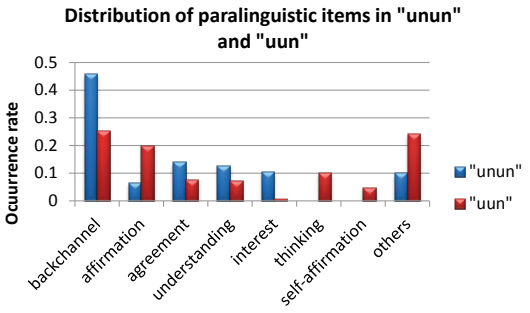

Figure 5: *Distributions of the paralinguistic information items in "unun" and "uun" utterances.*

It can be observed from Fig. 5 that both "unun" and "uun" utterances are used to express "backchannel", "affirmation", "agreement" and "understanding". However, the paralinguistic items "thinking" and "self-affirmation" were observed only in "uun" utterances, while the item "interest" was observed mainly in "unun" utterances.

Analyses were then conducted on the relationship between the tone types and the conveyed paralinguistic information.

Fig. 6 shows the distributions of the paralinguistic information items in "uun" utterances, for different tone types. The occurrence rates are normalized by the total number of utterances in each tone type, which are shown within brackets.

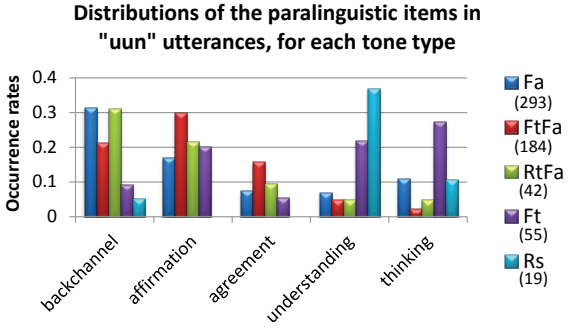

Figure 6: *Distributions of the paralinguistic information items in "uun" utterances, for different tone categories. The occurrence rates are normalized by the total number of utterances in each tone category.*

It can be observed from Fig. 6 that falling tones ("Fa" + "FtFa" + "RtFa") appear with high occurrence rates in backchannel, affirmation and agreement, flat tones ("Ft") are predominant in thinking, and rising tones ("Rs") are predominant in understanding. This is in agreement with the trends reported in past works for monosyllabic "un" utterances.

Regarding the polysyllabic "unun" utterances, no clear differences could be found between tone type and paralinguistic information, since almost all "unun" utterances have a sequence of falling tones as was shown in Section 2.2. Instead, we observed that the number of "un" repetitions could cause different impressions in the dialogue flow.

Fig. 7 shows the distributions of the paralinguistic information items in "unun" utterances, for different "un" repetition numbers (i.e., "2" for "unun", "3" for "ununun", and so on). The occurrence rates are normalized by the total number of utterances in each "un" repetition number category, which are indicated within brackets.

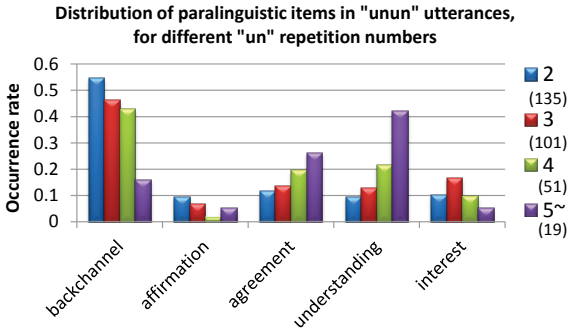

Figure 7: *Distributions of the paralinguistic information items in "unun" utterances, for different "un" repetition numbers (i.e.,"2" for "unun", "3" for "ununun", and so on). The occurrence rates are normalized by the total number of utterances in each "un" repetition number category.*

Among the "unun" utterances, it can be observed from Fig. 7 that utterances with two repetitions ("2") occur with high rates in "backchannels" (more than 50%). The utterances with more than five repetitions ("5~") can be observed with predominant occurrence rates when expressing "understanding" or "agreement". When expressing interest, number of "un" repetitions around three ("3") is found to be predominant.

Finally, from the comments from the annotators, in general, "unun" gives impression of actively pull out the interlocutor utterances by expressing interest, while "uun" gives impression of sharing the feelings of the interlocutor.

3. Discussion: Issues on the discrimination of "uun" and "unun"

For the utterances where pauses are present between successive "un" syllables or where clear spectral changes can be observed in the /N/ portion, spectral features could be used for identification of "unun" utterances. However, for other types, F0 patterns would be useful for discrimination. In this section the problems found in the discrimination of "unun" and "uun" utterances based on F0 patterns are discussed.

The upward-downward F0 motions would be one strong cue for identifying "unun" utterances. When F0 does not change, or when it moves upward and downward only once, the utterance is likely to be perceived as "uun".

However, it was shown in Fig. 4d that F0 can also move upward and downward in "uun" utterances accompanied by laughing. It would be difficult to discriminate such utterances from "unun" utterances by only using F0 range information. Further, discrimination of "unun" utterances accompanied by laughing would also be more difficult. Thus the dynamic features of F0 contours should be modeled for discriminating these features.

F0 rising in the end portion of the utterances was observed in 10% of the utterances, in 7 speakers (6 female and 1 male). Fig. 4e showed an example of "uun" utterance where the F0 rises in the end portion. This F0 rising was also observed (with less frequency) in the end portion of "unun" utterances (as in Fig. 3d), and is thought to be unconsciously produced when the vocal folds stop vibrating. As this F0 rising is not well perceived, it should be removed for tone analysis.

The "?" label was annotated in 23% of the "uun" utterances and in 10% of the "unun" utterances. Most of them were either due to low power in bad recording conditions or due to presence of vocal fry, so that F0 contours could not be obtained.

Regarding the recording conditions, in part of the database headset microphones are available, while in the other part only directional microphones on the table are available. For the table microphones, the distance to the mouth is 30 ~ 40 cm on average, so that both background air conditioner noise and the dialogue partner interference sound are strongly observed.

The problem is that "un" utterances have lower power even within the utterances of the same speaker, and their backchannel functions in dialogue make them highly probable of being overlapped with the interlocutor's utterances. Thus, the SNRs tend to become very low in "un" utterances if the microphone is not positioned close to the speaker's mouth, affecting both speech recognition and F0 extraction.

The other problem is the presence of vocal fry (or creaky phonation), where the vocal fold vibrations become irregular, so that the measured F0 would not correspond to perceived pitch contours. Vocal fry was observed mainly in 4 male subjects, where robust F0 contours could not be obtained. In such cases, the presence of short pauses between "un" utterances become more important for identification of "unun" utterances, rather than the F0 information.

4. Conclusions

We conducted analyses on acoustic-prosodic features and paralinguistic functions of "unun" and "uun" utterances, which are repeated and lengthened variations of the interjection "un", commonly appearing in conversational speech.

Analysis results indicated that both "unun" and "uun" appear in the expression of backchannels, affirmation, agreement and understanding, while "unun" appears more frequently when expressing interest, but does not appear for expressing thinking or self-affirmation, in contrast with "uun". Further, in "unun" utterances, the number of repetitions of "un" tends to be higher when expressing agreement or understanding.

Regarding the patterns of F0 contours in "unun" and "uun" utterances, it was shown that part could be discriminated by the up-down F0 movements or by spectral changes in the nasal part. However, it was also shown that utterances accompanied by laugh, final rising and vocal fry can be problematic. Future work includes evaluation of discrimination of "unun" and "uun" based on acoustic features.

Abstract

This paper presents the results of a prosodic and phonostylistic analysis based on C-PhonoGenre, an 8-hour-long spoken French corpus, consisting of 9 speaking situations and (on average) 10 speakers per situation. The corpus was automatically segmented at the phonetic, syllabic and word levels (EasyAlign), and in larger pause-separated units. Part-of-speech annotation (DisMo) and prominent syllable detection (ProsoProm) was added automatically. The corpus was also manually annotated at the syllabic level for stylistic variants, such as post-tonic schwas, liaisons, elisions, disfluencies, audible breaths and noises. Acoustic analyses (ProsoReport, DurationAnalyser) provide more than 100 micro- and macro-prosodic measures, which we correlate with the phonostylistic features and the linguistic annotation. This analysis results in a contrastive, fine-grained *prosometric* description of phono-stylistic and situational variation, over 4 situational, gradual dimensions: audience, media, preparation, and interactivity. Further statistical analysis was carried out to explore the discriminative and explanatory power of combinations of prosodic measures.

Index Terms: situational variation, prosody, classification of speaking styles

1. Introduction

General knowledge of language includes that of its variants, as demonstrated by the study of *genres* [1, 2, 3], and phono-stylistic variation is such an area [4, 5, 6]. Recent research in prosody focuses on phonostylistic situational variation in large corpora, departing from previous binary oppositions (*e.g.* read vs. spontaneous speech), or one-dimensional characterisations of style (formal vs. informal).

This paper presents a selection of global and contrasted results of an on-going research project on situation-dependent speaking styles, or *phonogenres*. It applies the semi-automated methodology of corpus description introduced in previous work [7, 8]. It analyses speaking situations by features [9, 10, 11], reduced to four main dimensions: audience, media, preparation, and interactivity; each dimension has 3 different states (see Table 1). For example, ***audience** = 1* indicates that the speaker is physically present before an audience, while ***media** = 1* indicates speech directed to an individual or a small group, yet in front of a microphone or camera (*indirect* audience). ***Preparation** = 1* indicates semi-prepared speech, situated between spontaneous and read speech. In the case of parliamentary debates, a *question* is prepared, while the *answer* is semi-prepared. ***Interactivity** = 1* indicates that the main speaker may be interrupted. For example we distinguish between dialogue interaction and broadcast sports commentaries. The corpus under study, C-PhonoGenre, is approximately 8 hours-long, and covers 9 different genres, four of which are further subdivided into *sub-genres* (based on their situational specificities).

Results show that phonogenres and sub-genres can be distinguished and characterised by the relation between situational and prosodic dimensions. Various "hidden" or unpredicted influences of situational properties on prosody also emerge. An indirect, but equally important result of this study is a corpus processing methodology, based on the co-ordinated application of several semi-automatic tools.

2. Data

C-PhonoGenre contains data from 8 speaking styles: instructional speech [DIDA]; spontaneous narration [NARR]; speeches during "Question Time" at the French parliament [PARL]; sermons [RELG]; radio press reviews [RPRW]; three kinds of sports commentary [SPOR]: rugby, basketball and football; presidential New Year's wishes [WISH] and weather forecasts [WFOR]. The average sample duration per speaker is 5:30 min.

Table 1. *Situational features by PhonoGenre*

PhonoGenre		Audience	Media	Preparation	Interaction
DIDA	Radio	1	2	2	2
	TV	0	2	2	0
	Lecture	2	0	1	0
NARR	Narration	1	0	0	2
PARL	Question	2	1	2	1
	Answer	2	1	1	1
READ	Reading	0	0	2	0
RELG	Internet mass	0	1	2	0
	Sermon on TV	2	1	2	0
RPRW	Radio press review	0	2	2	0
SPOR	Basket	0	2	0	0
	Rugby/football	1	2	0	2
WFOR	Weather forecast	0	2	2	0
WISH	Pres. New Year	0	1	2	0

For this study, we compiled a corpus including the eight speaking styles of C-PhonoGenre and the "reading" style [READ] from C-PROM-PFC [12]. Table 2 shows number of samples, syllables, words and total speech time per genre. Although [SPOR] and [RELG] contain less than 10 speakers per genre, the total amount of data renders these genres comparable with the others. On the other hand, while 10 different speakers are included under the "weather forecasts" genre [WFOR], the total speech time is 9 minutes, i.e. less than a minute per speaker.

The corpus contains recording of both female and male speakers, originating from 3 different French-speaking areas: Metropolitan France, Belgium and Switzerland [13]. We do not present findings regarding regional variation here, but the information is present in the corpus metadata and can be used for further study. Regional variation may partly explain the observed intra-genre, inter-speaker dispersion.

Table 2. *Number of recordings, syllables and words, and duration by phonogenre*

PhonoGenre	Num. samples	Duration (min)	Num. syllables	Num. words
DIDA	17	100	26 304	18 717
NARR	10	44	11 396	9 546
PARL	10	20	5 710	3 613
READ	16	36	9 932	6 648
RELG	7	54	8 726	6 141
RPRW	15	95	26 359	17 531
SPOR	5	35	7 601	5 305
WFOR	10	9	2 861	1 947
WISH	15	98	18 614	12 578
TOTAL	**105**	**491**	**117 503**	**82 026**

3. Methodology

3.1. Data processing

After manual orthographic transcription in Praat [14], we obtained a phonetic transcription as well as a segmentation of words, syllables, phones and pauses, automatically using EasyAlign [15]. Manual corrections were made to reach a high quality alignment between the segments and the speech signal. A unique annotator manually added a <*delivery*> tier in order to enhance downstream data processing. It contains four types of annotation: i) disfluencies, articulation and phonological phenomena: schwa; vowel lengthening (whether associated to hesitation or not); creaky voice; liaison and elision; ii) symbols to distinguish between complete silence, audible and less audible breaths, and mouth noises; iii) indices of paralinguistic phenomena (laugh, cough) and external sounds; iv) overlapping segments and syntactic plan interruptions. Part-of-speech tagging and multi-word unit detection was obtained automatically using DisMo [16]; this annotation is used to study the interface between speaking styles and grammar. A five-level degree of prominence for each syllable was calculated using ProsoProm [17]. Three additional tiers were automatically added: <*lex*> distinguishing between lexical and functional words; <*if*> localising initial vs. final lexical words' syllables; and <*ap*> which is an automatically generated segmentation into accentual phrases (in Mertens' sense [18], i.e. phonological words), including an annotation of the initial and final syllables of each accentual phrase. Pitch was corrected manually for the entire corpus, since the accuracy of several acoustic measures and prominence detection depend on it.

3.2. Acoustic measures

Acoustic and prosodic features were extracted for the entire corpus. Initially, ProsoGram's [18] two-step algorithm for pitch stylisation was applied: for each syllable, vocalic nuclei are detected based on intensity and voicing, and then the F0 curve on the nucleus is stylised into a static or dynamic tone, based on a perceptual glissando approach. ProsoReport [8] summarises this information, taking into account information contained in other tiers (such as <*delivery*> and <*lex*>) to produce a detailed collection of descriptive statistical measures for each corpus sample. These measures can be grouped into four main families: temporal measures (e.g. articulation rate); pitch measures (e.g. pitch register and movement); syllabic prominence measures (e.g. percentage of prominent syllables in various positions); correlational measures (e.g. percentage of accentual-group-initial prominent syllables). Additionally, DurationAnalyser [19] produced a set of statistics based on segmental information (e.g. variance coefficients for vowels or consonants, nPVI etc.). All this information was compiled for further analysis; in total, 129 prosodic descriptors for each corpus sample were retained.

4. Results

Based on the aforementioned prosodic descriptors, many results appear to be significant. We show only some of them based on the *genre* classification, then on different prosodic domains (duration, intonation and accentuation of initial and final syllables, across genres and situational features).

4.1. Results by phonogenre

The articulation ratio at the genre level sets apart WISH and RELG, reflecting that both situations are solemn. SPOR also stands out, but for another reason: the commentator has to pause while the ball moves from one player to the next. Conversely, WFOR, and to a lesser extent RPRW, show the highest articulation ratio, because of the time pressure imposed by broadcasting media.

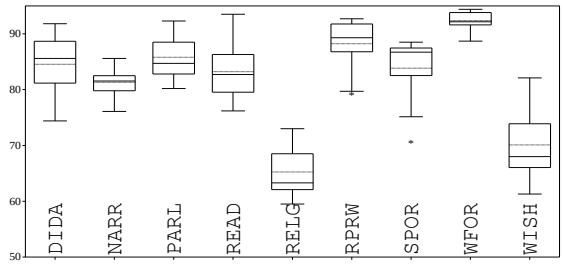

Figure 1: *Articulation ratio for the 9 phonogenres*

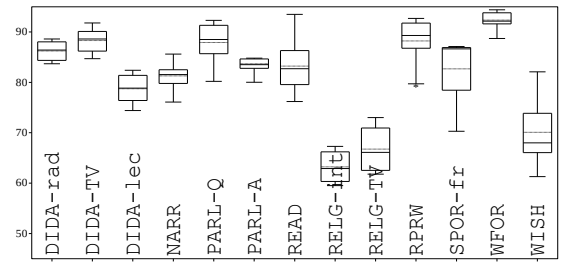

Figure 2: *Articulation ratio for the 13 sub-genres*

At the sub-genre level, articulation ratio also illustrates interesting contrasts. Parliamentary answers (PARL-A) clearly occupy more speech time than questions, because the listeners react during the answer and the speaker has to take into account this feedback. The three instructional sub-genres also show differences, mainly between the Radio and TV sub-genres. A possible explanation of this difference may be that radio samples are shorter than TV samples (DIDA-rad: approx. 3 min., DIDA-TV: 10-20 min.), as well as the fact that TV delivers images with speech, sharing time with visual flow [20]. The DIDA-lec subgenre (non-broadcast university lectures) is closer to DIDA-rad, suggesting that the media dimension is less important than the instructional one. RELG subgenres differ slightly on articulation ratio, though other prosodic measurements distinguish them much more clearly.

4.2. Segmental duration

Among the acoustic parameters based on segmental durations, the variance of vowel duration is the one exhibiting the best

discriminative power. Figure 3 is a box-plot of vowel duration variance for different sub-genres. The NARR genre detaches from others probably because of its spontaneous nature: at the syllable level, this results in frequent hesitation-related lengthening; at the discourse level, an irregular speech rate is entailed by the progressive construction of discourse. In contrast, the READ and WFOR genres have a lower variation of vowel duration, but for different reasons. READ readers are non-professionals and thus adopt a monotonous rhythm; whereas the WFOR genre has a very high speaking rate, causing a ceiling effect on vowel duration. Interesting differences occur again between in parliamentary sub-genres, showing a significantly lower variation for the answer [PARL-A] than for the question [PARL-Q], due to the increased interactivity (see 4.1).

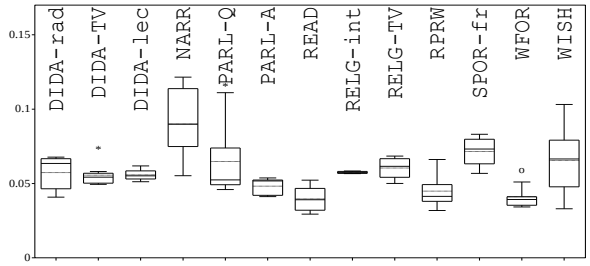

Figure 3: *Variation of vowel duration for the 13 sub-genres*

The *preparation* feature also shows a lower variation of vowel duration for prepared recordings (F(2,102)=50; p<0.001). This is explained by more lengthened hesitations in spontaneous speech. The *interactivity* feature shows similarly a greater variation (F(2,102)=31.4 p<0.001) for interactive recordings, usually the spontaneous ones (NARR, SPOR).

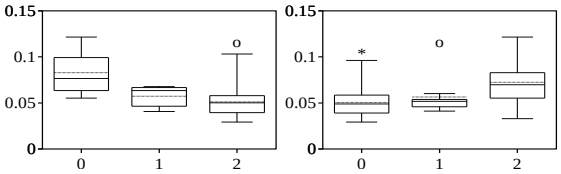

Figure 4: *Variation of vowel duration for 3 levels of preparation (left) and interactivity (right*)

4.3. Intonation

Intonational properties indicate a lower relative F0 variation for phonogenres with a larger audience (F(2,102)=10.5; p<0.001); this is surprising, as we hypothesised that public speaking would entail greater speaker involvement. However, this acoustic parameter varies according to our predictions across the media feature (F(2,102)=12.06; p<0.001).

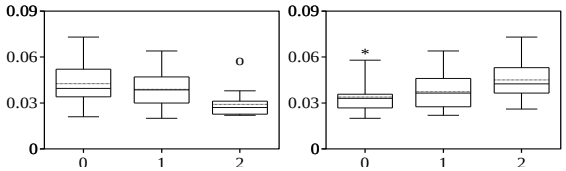

Figure 5: *Relative F0 variation for 3 degrees of situational features of audience (left) and media (right)*

4.4. Prominence in initial and final position

The study of initial and final positions of prominent syllables results in differentiating phonogenres based on their situational features.

4.4.1. Situational features

The percentage of prominent final syllables is decreasing as the phonogenre is getting more *interactive* (F(2,102)=8.88; p<0.001). This can be explained by a high score of hesitation in NARR and vowel lengthening, typical for sport commentaries SPOR (Figure 6, left).

The percentage of prominent initial syllables is getting higher if a phonogenre falls is *media*, where it is important to clearly distinguish discourse segments (Fig.6, right). The initial prominent syllables of AP shows similar results (F(2,102)=5.88; p<0.001).

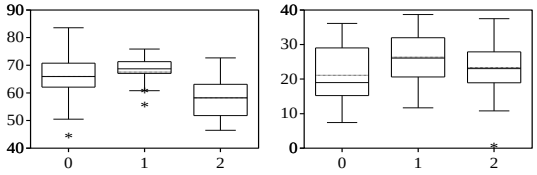

Figure 6: Percentage of prominent final syllables for interactivity (left) and percentage of prominent initial syllables for media (right) for each of the 3 degrees

The relative length of initial and final syllables of the AP varies in a significant manner across the *preparation* dimension (initial syllables F(2,102)=5.42 p<0.001; final F(2,102)=10.65 p<0.001). The variation is inverted: initial syllables of AP tend to be shorter in prepared discourse than in non-prepared, but final syllables become longer (Figure 7).

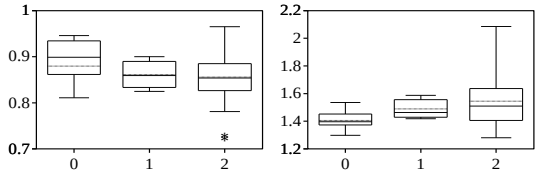

Figure 7: *Relative length of initial (left) and final (right) syllables of the AP for preparation*

The physical presence of *audience* implies lower percentage of initial prominent syllables per AP. This is the case for parliamentary speeches where one member of the house is talking directly to the government minister [PARL]; for university lectures, where teacher addresses the students [DIDA-lec], or sermons where the priest is addressing the faithful [RELG-TV] (F(2,102)=12.8; p<0.001).

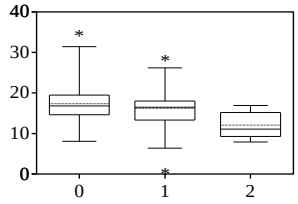

Figure 8: *Percentage of initial prominent syllables per AP for audience for each of the 3 degrees*

4.4.2. Sub-genres

Sub-genres level distribution of initial prominences (Fig. 9) partly reflects the values of situational features. Sub-genres in which an audience is present show the lowest level (PARL; DIDA-lec, RELG-TV, SPOR), whereas media ones (DIDA-rad, DIDA-TV, WFOR) show the highest level. RELG-int behaves like a media style, although it was graded as an intermediate style across the media dimension. Despite RPRW being a prototypical case of broadcast media style, it shows a low level of initial prominence. In fact, RPRW shows a high rate of prominent initial syllables of words, not of AP, which reflects the stylistic choice of marking initial syllables.

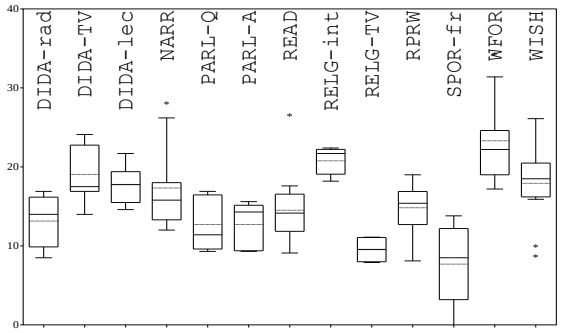

Figure 9: The distribution of the percentage of initial prominent syllables per AP for the 13 sub-genres

4.5. Principal Component Analysis

Since no unique prosodic/acoustic parameter is sufficient to clearly distinguish speaking styles, we explored a global statistical approach which finds the optimal linear combination of all parameters. A Principal Components Analysis (PCA) was thus performed, to model phonogenres and situational features with the parameters, knowing that some of them are high correlated. The first two principal components (PC) explain only 43% of the variance, while the first 8 explain 78.2%. A discriminating analysis with 8 PCs over 9 phonogenres showed that 93.3% of recordings were identified as belonging to the correct genre. Table 3 shows the percentage of correct classification decisions, over genre, sub-genre and the 4 situational features.

Table 3. *Percentage of correct classification with 8 principal components for Genre and Sub-Genre distinction as well the 4 situational features*

Genre	93.3 %
Sub-Genre	90.5 %
Audience	90 %
Media	84.8 %
Preparation	92.4 %
Interactivity	92.3 %

Figure 10 shows the distribution of the 105 speech recordings along the first two PCs. The first PC appears to be highly correlated with the articulation ratio, as the WFOR genre is clearly opposed to the genres WISH and RELG. The bottom of the figure shows the confidence ellipses for the 'media' situational feature according to the first 2 PCs with a clear distinction between semi-media (1) and media (2) condition, while the non-media (0) condition is over the first two conditions.

5. Conclusion

Our study led to two concrete outcomes: (a) a detailed methodology for future studies in *phonostylistics* and socio-phonetics, which is primarily based on automated tools and the study of prosody (an extension to other levels, e.g. the lexical level, is envisaged); and (b) a spoken corpus of high scientific value, due to its thorough multi-level annotation.

The results show that, while no single prosodic measure is sufficient to separate and classify speaking styles, a linear combination of several measures leads to a robust clustering of samples belonging to different genres. We next will explore feature selection techniques to determine which set of prosodic measures is the most relevant (instead of a PCA analysis that produces a global, but opaque, combination of measures).

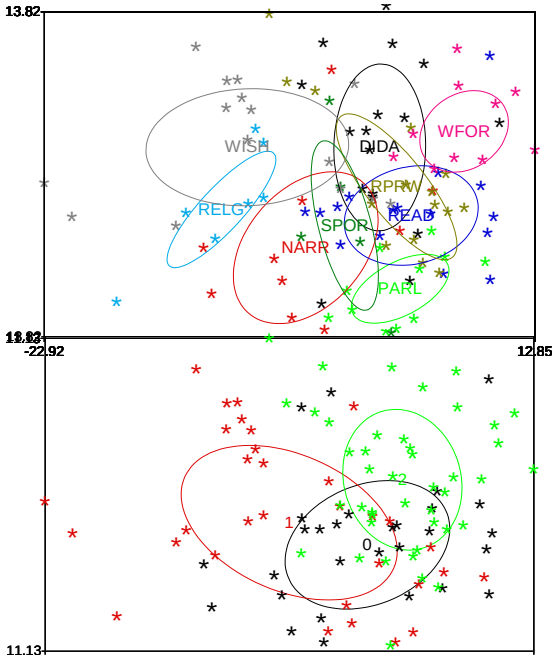

Figure 10: The 105 recordings according to the first two PC and confidence ellipses by phonogenres (top); the confidence ellipses for the media situational feature (bottom)

The study has also shown that following an iterative, adaptive procedure is necessary: while the initial, top-down approach was to select samples in order to create a balanced corpus (based on a predefined array of situational features), subsequent data analysis led to the observation that samples within a given genre could and should be further classified in *sub-genres*. Therefore, the interplay of prosodic measures and situational features gave rise to an *a posteriori* subdivision of genres (bottom-up approach) in order to ensure compact definitions and to reduce the excessive heterogeneity of some speaking situations. Results show (Fig. 1, 2, 3) that sub-genre groupings *transcend genre differences* (e.g. PARL-A and DIDA-rad, in Fig. 2), and that some of them are related to common, controlled situational features (cf. Fig. 9, DIDA-lec: non-media, public audience). They also present evidence for groupings due to unpredicted, or hidden, situational features, like "external time pressure" (cf. Fig. 1 PARL, WFOR, RPRW), "speech sequence duration", or "solemnity / ritual conventions" (RELG and WISH), that belong to the prototypical image of speaking style. The differences observed between questions and answers within the PARL genre suggest a situational feature [+ interactivity] at the sub-genre level. They reveal a prosodic reflection of a discursive (not situational) feature, namely the presence of other listeners that react to the exchange even though they do not participate in it directly. The results also indicate that several different speakers per genre must be included in the corpus for the genre-specific features to rise above individual variation.

Although some annotation steps remain manual, most of our methodology is automatic. This framework was built in a very generic way: we plan to provide additional prosodic measures and test corpora in other languages. Such research enables both verification of linguistic hypotheses and automatic genre identification. Finally, we should mention that the C-PhonoGenre corpus will be made available to the community for any other research purposes.

Abstract

This work presents a methodology used to collect some spontaneous social affect corpus and preliminary prosodic analysis of certainty and uncertainty in Brazilian Portuguese. The corpus was collected using a Wizard of Oz method (through EmOz platform). The scenario to induce certainty and uncertainty is based on the situation of a job interview, where a companion robot (Emox) is used as a trainer. The subjects were convinced to benefit from a free teaching of this "revolutionary" method to train to job interview. In this scenario the linguistic expressions are partially controlled, in order to focus the certainty/uncertainty expression mainly on paraphrasing and prosody. Data were preliminarily analyzed for audiovisual prosody: videos analysis were made regarding eyebrows, eyes, mouth and face/head movements, while audio analysis were made about acoustic prosody parameters of fundamental frequency and duration. The first results show that using EmOz within such a scenario is an efficient way to induct spontaneous but comparable speech production. Prosodic results show that fundamental frequency and duration measurements, as well as eyebrows, eyes, mouth and face/head movements are differently used in certainty and in uncertainty production in Brazilian Portuguese.

Index Terms: spontaneous attitudinal corpus acquisition, audiovisual prosody of (un)certainty, Brazilian Portuguese.

1. Introduction & theoretical background

As early noted by [1], one fundamental prosody's function is to express the speaker's affective states, such as emotions, attitudes or moods. More generally, in face to face communication the socio-affective states (intentions, attitudes, mental states) are the main cues of dialog efficiency. Here, the socio-affective prosodic expressions are assumed to be voluntary controlled and a part of the linguistic system, according to [2, 3, 4], differing in this way from emotions. In this paper we focused on two attitudes particularly relevant in dialog: *certainty* and *uncertainty*, specifically in Brazilian Portuguese (henceforth BP).

Since 15 years, many prosodic studies of BP have been focusing on the role of the prosody to express the speaker's attitudes or intentions [5, 6, 7, 8, 9]. Among the investigated attitudes in these prosodic studies we can find certainty and uncertainty, which were already studied in other languages.

Many studies held on several languages showed some similarities and differences between languages (confidence vs. doubt for French, English, Japanese, Vietnamese and Chinese [10]). More elicitated expressions were produced in some Dutch language studies [11, 12, 13, 14]: the audiovisual prosody was investigated to indicate the uncertainty degree in answers of factual questions. In these studies, the methodology for data acquisition was based on the answer to factual questions, as done in [15, 16]. The researchers (who do not show themselves to the participants at this moment) asked 40 questions to the subjects (students). Participants were recorded in audio and video (with a camera taking the participant's face). After this, the participants were asked if they would be able to recognize the answer to the same questions if they were in a multiple choice test. Subsequently, the same subjects answered the same questions in a multiple choice test. The authors' intention was to describe, through audiovisual prosody, the degree of uncertainty in each answer, measuring the Feeling of Knowing (FOK), defined as "people's ability to assess and monitor their own knowledge" [13].

Audiovisual prosodic differences between certainty and uncertainty in these studies include: i) concerning the verbal cues: the final boundary tone, where the High tone is associated to uncertainty, while the Low one is associated to certainty; the delay or the time to start the answer, longer times being linked to uncertainty; the presence of pauses, mainly filled ones (filled by 'uh', 'uhm' or 'mm'), is more frequent in uncertainty; ii) concerning the visual cues: gaze not focused and funny (marked) face, which are linked to uncertainty; presence of eyebrows movements or smiles, generally related to uncertainty [11, 12, 13, 14].

In BP, the prosody of certainty and uncertainty attitudes, as well as the prosody of other attitudes that are said to be related to them (like doubt, incredulity or obviousness) was mainly studied in acted speech. Most of these works investigate these attitudes in acted sentences, included or not in contextual situations [17, 18, 19, 20, 21]. The prosodic differences described in these attitudes concern fundamental frequency - F_0 (higher at the end of the sentence in uncertainty and doubt attitudes), intensity (stronger in certainty), duration (longer in uncertainty), and the presence of pauses and fillers (mainly in uncertainty).

For emotional prosody (involuntary production processing), some perceptive discriminations between acted and spontaneous speech were shown [22, 23]. The next step of this present study will be to compare acted and spontaneous expressions of certainty/uncertainty.

Thereby, we come to a paradox: how can we control the induction of spontaneous attitudes in order to get comparable data for several subjects, together with acted speech for the same subjects? In other words, how can we study real expressions of certainty and uncertainty attitudes on (quite) the same linguistic material? Using real interaction corpora can provide spontaneous speech, but we would not be sure that lexical items will be the same, as discussed in [24, 25]. In BP, the works investigating attitudes' prosody with spontaneous corpora [e. g. 8] had another problem: how to annotate the real productions, since even if the induction process is supposed to carry on certainty/uncertainty, it must be verified without influencing the annotation by the expected labels? To try to

solve these problems and with the aim to study certainty and uncertainty in a spontaneous comparable corpus we decided to create a job interview scenario.

2. Material and methods

2.1. Corpus

(Un)certainty occurs in many contexts of verbal interactions. One context, perhaps easier to control, would be situations where answering questions is needed. For that reason it is the kind of protocol used the most to collect data to study (un)certainty. We can find many real situations where one has to answer questions: knowledge games, job interviews, giving information and so on. To have spontaneous answers in which (un)certainty can be expressed, we chose to create a job interview scenario (rather than doing a real job interview, due to ethical reasons), in which we could also use factual questions (which answers would be comparable due to lexicon similarities). This way we were able to use two kinds of question/answer interaction.

Many studies held by the Grenoble team are based on this methodological choice (a combination of a scenario conducted by Wizard of Oz method) to induct spontaneous affective speech [23, 24, 26, 27]. The advantages of this choice were discussed in [23], and among them we can highlight the possibility to induct attitudinal production in a controlled way.

To play this scenario, we chose to use EmOz, a Wizard of Oz platform, developed at LIG laboratory [28], which works with a companion robot Emox (developed by the Awabot Company <www.awabot.com>). This choice is based on three assumptions: the small robot, whose form is neither human nor animal, cannot perform humanoid gestures, that is the anthropomorphisation and interpretation of robot movements are reduced and then all the attention can be paid to the vocal productions; the recorded sentences said by the robot could be exactly repeated in each interaction with each different subject, in the same order, to have the same stimuli for each participant; the EmOz platform allows to control the robot remotely, while the subject thinks (s)he was interacting with a(n) (intelligent) machine.

About the EmOz platform, we use Excel files (scripts) associated to the robot Urbi system through a Java interface to program the robot's actions [28]. In these files it is possible to include the robot's actions like body or head movements, sounds or a combination of sounds and movements. The sentences the robot will say are prerecorded as wave files. The platform has a protocol and an improvisation mode. In the protocol mode we have a table with all the programmed robot's actions, in order, and we can follow the sequence by just clicking each table line. In the improvisation mode we have all the scripts and sounds as clickable buttons (and we can choose the scripts which will appear as buttons and drag and drop these buttons to organize them), and finally we have a recording button to record and play sounds on the spot (See figure 1).

The job interview scenario was organized as follow: first we recruited 9 Brazilian students at Grenoble University, two men and seven women, aged from 21 to 32 years, telling them they would do a job interview with a robot that could do and analyze job interviews. This way, the subjects thought they would evaluate the robot system while the robot would train them to do job interviews. Systems like this exist or are in development [29, 30, 31], which makes our scenario credible.

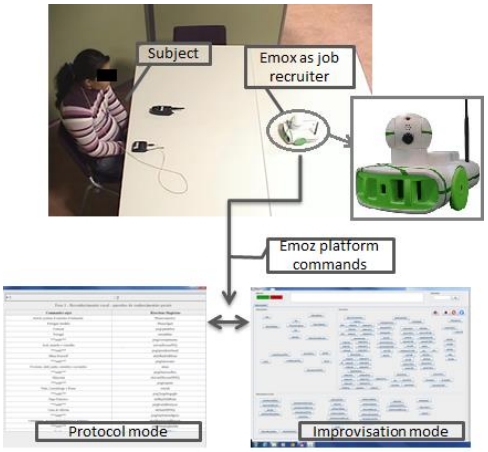

Figure 1: *Scheme to record the corpus*

When subjects arrive to do the job interview, we tell them there is a first interview phase in which the robot will make factual questions. This phase is justified by the need of voice recognition, i. e., the robot has to "learn" the subjects' voice, and the sequence of questions has this aim. In this context we placed a headset microphone on the subject, saying that this microphone would help with the voice recognition. The participants did not know they were being recorded. We also said this first phase was a pre-test used in some job interviews, in which the recruiter asks general knowledge questions. The factual questions were selected from a Brazilian factual questions collection, available in [32]. To ensure the production of answers with certainty and uncertainty we diversified easy and difficult questions. A group of 30 questions was evaluated by 10 Brazilian university students as easy, medium and difficult questions. After this evaluation, we saved 4 questions for each difficulty level (4 easy, 4 medium and 4 difficult), the four best within the judges agreement.

Along these questions we elaborated 12 mixed questions, which asked more than a thing at a time, and vary the level of difficulty among these asked items. For example, we asked which months of the year have less than 31 days. As February has 28 days, we expected subjects would easily remember February, but other months of the year that also have less than 31 days would take more time to remember. That's why in these questions, we expected to have productions in which subjects would deal with certainty and uncertainty at the same time, in the same answer. These 12 mixed questions were also evaluated by Brazilian students, and we saved the 8 in which judges agreed best in the classification. This way we saved 20 factual questions. These 20 factual questions were recorded by a Brazilian woman, with university education, who produced the questions with a standard Brazilian pronunciation. To start the experiment, the robot said it was ready to start. After each answer, there was a feedback from the robot saying it had heard the answer.

The job interview questions were taken from sites that list the main job interview questions in BP [e. g. 33 and 34]. We chose 12 of the most frequent questions in these sites. These questions were recorded by the same Brazilian woman who recorded the factual questions. To guarantee a real interaction with the subject in this phase of the experiment, the organization of the questions was made to make room to other questions, formulated at the moment of the interview, depending on the answers given by the subject. For example, one question asked was 'what are your strengths and your

weaknesses?'. If the subject answered that one of his(her) strengths was determination, we formulated a question like 'do you think your determination may help you in your work?'. These questions were included to make the robot look more intelligent, able to analyze a job interview, as we said, making our scenario more believable.

During the first (factual questions) and second (job interview) phases of our scenario we recorded the subjects, although they did not know, with two cameras: the first one directed to subjects' face and the second one taking the entire context. In Figure 1 we can see an image taken from the second camera, with the organization made for recording data.

In a debriefing phase, after the job interview, we asked the participants to evaluate the robot's system. After this, we told them that some participants evaluate as a strange situation to do a job interview with a little robot as a recruiter, so we told we would like to compare the manner to answer a robot to the manner to answer a person. With this pretext, we asked the subjects to answer again all the questions, this time asked by a human, thus we have one natural and one artificial production of the same linguistic material. Subsequently we told the subjects that we recorded all the experiment and we asked them if they could come back to watch their videos and to annotate how they felt during the experiment.

Three or four days after, subjects came back to watch their videos and freely annotate their feelings during the experiment. In this auto-annotation, the subjects could already remark they felt something related to (un)certainty. Nevertheless, to ensure this type of evaluation, we asked the participants to choose in a forced test if they felt certainty or uncertainty for each answer to factual questions.

At the end we revealed the real aim of the study: to find how we express (un)certainty in BP. According to this aim, we gave subjects their answers transcribed and we asked them to answer the questions twice again, firstly acting certainty and then acting uncertainty in each of their answers.

2.2. Audiovisual prosodic analysis

In this work, we will present only the analysis made on the answers of factual questions. With 20 answers from each of our 9 subjects, 180 answers were analyzed, and this number can vary due to the answers composed by more items.

The recorded videos were analyzed to verify the presence of eyebrows, eyes movements and funny face (considered as mouth movements), to watch gaze direction (if it was diverted or directed) and head movements (yes/no), while observing the attitude to which these factors were linked. Then we calculated the percentages of presence/absence of these factors.

Concerning audio, data were analyzed in Praat software [35], and fundamental frequency and duration measurements were made. Regarding fundamental frequency, initial, final, maximum and minimum F_0 values were taken for each sentence. After that, the final F_0 movement was measured, and its shape was observed. These values were taken in semitones, because different speakers produced the sentences and the relative semitones measurements can minimize interpersonal differences. However, results are presented separately for male and female subjects. Regarding duration, we measured the entire duration for the sentence and the number of pronounced syllables, and the ratio of these values generated the rate of articulation in syllables per second. We also took the duration of all pauses and noted if each pause was filled or not. The delay time before starting to answer was measured too.

3. Preliminary Results and Discussion

3.1. Video analysis

In table 1 we present the summary of the movements perceived in video analysis regarding answers with certainty and uncertainty. We added a third attitude, as described by subjects in their auto-annotations, when they were sure to not know the answer. In some questions (in which we asked more than a thing at the same time) they also annotated they were sure about some item(s), while they were not sure about other(s). Thus we analyzed 242 noted attitudes instead of 180.

Table 1. *Movements observed in the videos*

attitude	eyebrows movements	diverted gaze	Mouth movements	head movements
certainty (127)	7 (5.5%)	26 (20.5%)	2 (1.6%)	4 (3.1%)
cert. of not (56)	16 (28.6%)	29 (51.8%)	20 (35.7%)	17 (30.4%)
uncertainty (59)	21 (35.6%)	52 (88.1%)	25 (42.4%)	25 (42.4%)

As we can see in the first table, the percentages of movements are higher in attitudes that involve uncertainty or certainty of not knowing. In some certain answers we find movements (precisely in 25.2% of the answers classified by subjects as certain), that is mainly of the eyes. We believe these movements are not exactly the same they used to express uncertainty, but it can be related, in the case of the eyes, to a moment that the participant takes to remember a well-known answer. Regarding head movements, the times they appeared in certainty it was as a nodding movement, unlike the head movement in uncertainty, the head shake. The other movements found in certainty appearing at the end of the answer were related to the next answer item, which was not known by the subjects. Another interesting thing is that each subject has his own manner to express uncertainty by using gestures: while some of them use diverted gaze others prefer using eyebrows movements. In 97.8% of uncertain answers at least one of these gestures is used (often two or three gestures are used in the same answer). In the answers where the subjects are sure to not know the answer, 90.9% have at least one of these gestures.

In figure 2 we can see some examples of the movements found to express uncertainty, such as mouth, head and eyebrows movements or diverted gaze (on the right in each pair) in contrast with certainty (on the left in each pair) (it is important to observe that "neutral position" is to look down, with the face turned to the robot).

Figure 2: *Facial expressions in certainty (on the left in each pair) and in uncertainty (on the right in each pair).*

3.2. Audio analysis

The audio of the answers was analyzed regarding general characteristics such as the delay time, the filled pauses, the final F_0 movement (see table 2). We also analyzed the order

inversion or the presence of lexical items to say which attitudes were used (e.g. 'it can be...' or 'I think...').

Table 2- *General characteristics of the answers*

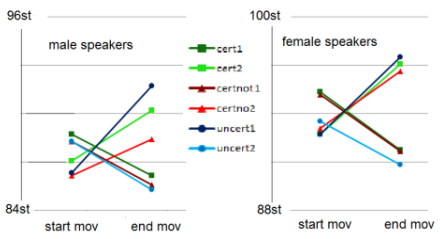
S	Delay (L-long or S-short)			Filled pauses (presence)			Final F_0 movement (A-ascending or D-descending)		
	C	CN	U	C	CN	U	C	CN	U
F	29L 84S	24L 14S	34L 13S	2	24	21	54A 59D	10A 28D	32A 15D
M	4L 10S	11L 7S	5L 7S	0	10	7	5A 9D	5A 13D	8A 4D
Tot (N)	**33L 94S (127)**	**35L 21S (56)**	**39L 20S (59)**	**2 (127)**	**34 (56)**	**28 (59)**	**59A 68D (127)**	**15A 41D (56)**	**40A 19D (59)**

Legend: F- Female subjects; M- Male subjects; C- certainty; CN- certainty of not knowing; U- uncertainty; N- number of occurrences

As can be seen in table 2, regarding the delay time, it was divided in short and long values, depending if they were longer or shorter than median value. The certainty attitude presents a tendency to have the smallest values of the delay time, while uncertainty and certainty of not knowing attitudes present the higher values. Regarding the presence of filled pauses, they were almost not found in certainty, but they could be commonly found in uncertainty and certainty of not knowing. Finally, regarding the final F_0 movement, despite some variation, we can state that mainly a descendent movement was used in certainty and certainty of not knowing attitudes, while an ascending one was used in uncertainty attitude. As we have different directions of the F_0 movements, if we compare the rising movement found in uncertainty with the falling one found in certainty and certainty of not knowing, the values found are significantly different ($p<0,05$, CI 95%).

The variations found in the F_0 movements were related to other characteristics of the attitudes' expression in our corpus: an ascending movement is expected in an uncertain answer, but if the speaker uses expressions like 'I think it is...' the uncertainty is already represented lexically, so the F_0 movement chosen was a descending one. We found ten uncertain answers with a descending movement that have these lexical expressions to express uncertainty in our data. In some answers we also found order inversion: the subject answered the most difficult item at the end of the sentence and, to indicate finality, the end of the sentence was descending. These reasons could explain why we found some uncertain answers with a falling F_0 movement. Concerning ascending movements, they were found in certainty and certainty of not knowing attitudes mainly in enumerations, in which the first items would be ascending to indicate continuousness; we have 8 questions which ask more than a thing at the same time, so we have 8 answers we expected to have an enumeration of some items.

Graphic 1 – *Final F_0 movement of the answers*



The two types of F_0 movement found in each attitude can be seen in detail in graphic 1. The darker colors represent the most recurrent movement for each attitude, while the lighter colors represent the other movement found. Comparing darker colors, we can see typical final F_0 movements: rising for uncertainty (dark blue) and falling for certainty and certainty of not knowing (dark red and dark green). In figure 3 we present a typical example of certainty and uncertainty answers.

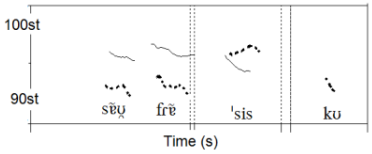


Figure 3: *F_0 contours of the answer "São Francisco" (*Saint Francisco*) with certainty (continuous line) and uncertainty (dotted ticked line), said by two women. Marked syllable is the tonic one, with a falling and a rising F_0 movement.*

Regarding duration measures, we compared results of the articulation rate (speech rate, in syllables per second) and duration of the last tonic syllable and its previous one (see table 3). The male speakers' speech rate varies, being used in a different way to express the attitudes: uncertainty is significantly different from the other attitudes, with a significantly higher value of speech rate. For female speakers no difference is statistically significant and the tendencies of higher values are different from men's tendencies. The duration of the final syllables, studied as an important cue to express uncertainty in BP previous works do not point out a clear tendency in our study; these values do not seem to play a role to express spontaneous (un)certainty attitudes in BP.

Table 3- *Speech rate and duration of the final syllables*

attitude	Male speakers			Female speakers		
	syl/s	tonic	pre-tonic	syl/s	tonic	pre-tonic
certainty	4.48	296.5	179.9	4.58	310.2	192.8
cert. of not	5.01	293.7	158.1	4.65	274.3	183.8
uncertainty	5.99	252.5	158.3	4.64	284.9	163.2

4. Conclusions

Collecting spontaneous speech data using a Wizard of Oz method within a scenario revealed to be an efficient way to induct spontaneous but comparable attitudinal speech utterances. Audiovisual prosodic results, such as F_0 and duration, eyebrows, eyes, mouth and head movements, showed personal behaviors but general tendencies used to express (un)certainty in BP. In further studies, we will compare spontaneous and acted utterances produced by the same subjects and we will also analyze other collected data with this method to study other (un)certainty characteristics in BP.

Between Recognition and Resignation – The Prosodic Forms and Communicative Functions of the Czech Confirmation Tag "jasně"

Jan Volín,[1] *Lenka Weingartová*,[1] *Oliver Niebuhr*[2]

[1]Institute of Phonetics, Charles University in Prague, Czech Republic
[2]Department of General Linguistics, ISFAS, Christian-Albrecht-University of Kiel, Germany

Abstract

Like question tags, confirmation tags such as the Czech affirmative particle *jasně* can be used with various prosodic characteristics that augment, reverse or otherwise modify their relatively unspecific lexical meaning. We extracted 172 instances of *jasně* from several dialogues and assessed their discourse function. 36 prosodic correlates in temporal, amplitude and fundamental frequency domains were measured and used in three computational classifiers: linear discriminant analysis, classification trees and artificial neural networks. All three methods significantly reflected the functional assessments and additionally indicated the relative importance of individual predictors in a mutually consistent manner.

Index Terms: affirmative particle, confirmation tag, Czech, discourse, intonation, pragmatics.

1. Introduction

It is obvious and has been repeatedly shown for many languages that 'question tags' like *isn't it* in English, *nicht wahr* in German, or *verdad* in Spanish are very rich both phonetically and functionally, cf. [1,2,3,4,5,6,7]. They are used by speakers to keep the interaction going and/or promote the flow of information. At the same time, the lexical semantics of question tags is fairly unspecific. Taken together, this allows question tags to occur in very different communicative contexts and in combination with all kinds of prosodically expressed speaker attitudes and emphatic intensifications.

The same also applies to 'confirmation tags' like *of course* in English, *alles klar* in German, or *todo bien* in Spanish. Confirmation tags, which, if they are single words, can also be called affirmative particles, are moreover everything but rare in conversation. Their high frequency in combination with their flexible application and constant segmental basis make confirmation tags – just like the better investigated but probably rarer question tags – an ideal research subject for studying the prosodic forms of a language and their respective communicative functions. In this context, the present study deals with the disyllabic Czech confirmation tag *jasně* ['jas.ɲe] whose closest English equivalents would be *sure*, *agreed*, *of course*, or *fair enough*. Speakers ordinarily insert *jasně* at the beginning of their utterances, typically as a separate prosodic phrase, in order to react to a preceding turn of the interlocutor.

Our major aim is to determine, describe, and systematize the prosodic and functional variation that can occur on *jasně*, in this way also advancing our understanding the prosodic system of Czech in general. While particularly the phonological factors and prosodic correlates of lexical stress as well as the related phenomena of phrasing and rhythm have been intensively analyzed for Czech in the last decades (cf. [8,9,10,11,12,13]), only relatively little is known about the use of intonation and emphasis patterns in Czech. Unlike research on the prosody of emphatic expressions in Czech, which does virtually not exist, there are some studies on Czech intonation. However, the corresponding research has so far often been descriptively oriented in the sense that intonational forms and functions have been characterised and contrasted on the basis of exemplars, impressions and experience, or with the primary aim to develop annotation inventories and enhance speech technology applications, cf. [14,15,16]. Analyses that aimed at a detailed, empirically based understanding of intonational forms, functions, and their linkages have only just come up in the last few years, cf. [17]. Our paper follows this more recent, empirical line of research.

This paper will summarize the production part of our study. The production data come from a large corpus of enacted (i.e., text-based) dialogues conducted by 30 native speakers of Czech. The data were acoustically analyzed in terms of a number of different duration, F0, and intensity measures. The production part will soon be complemented by a perception part, serving to cross-validate the form-function links that emerge on Czech *jasně*. Both the communicative functions and the acoustic-prosodic parameters on which our analysis of *jasně* is based were inspired by German whose intonational and emphatic categories and structures have been thoroughly explored in the last decade, cf. [18,19,20,21,22]; and it is probably not exaggerated to state that intonation and emphasis structures in German are already fairly well understood.

Against this background, the specific questions that we address here are the following:

(1) Do we find systematic prosodic variation on Czech *jasně*?

(2) If the answer to (1) is positive, is this variation functionally motivated, i.e. meaningful? Or is the variation just contextually motivated and due to speaking rate, phrase structure, or speaker-specific effects?

(3) If the answer to (1) is positive, is this variation multiparametric or rather dominated by a single prosodic parameter?

The answers to these questions will later allow to put the issue into a cross-linguistic perspective. For example, the absolutely strict lexical stress position in Czech reduces the corresponding functional load of duration and/or intensity so that these parameters could even play a more important role in signalling emphasis categories than in German. If this is the case, will the respective prosodic patterns be still associated with the same communicative functions as in German?

Three classifiers will be used to gain a cross-evidenced view of the variables, of which some map very similar properties as the others differing only in conceptual detail (see below). This will provide a methodological advantage for further research.

2. Method

A total number of 180 *jasně* tokens from the Prague Phonetic Corpus [23] were used. The target word occurred in six different contexts in the corpus and each was uttered by 30 native Czech non-professional speakers, 24 female, 6 male, aged 20-25 years. Scripted texts were used to elicit short dialogues from pairs of speakers. The speakers were explicitly encouraged to familiarize themselves with the dialogues and then act them out as convincingly as possible. The participants got along with the task very well, taking various affective approaches. Nonetheless, two trained phoneticians, who controlled the recording process, asked for new trials when dysfluencies or unnatural renderings occurred.

The recordings were made digitally at a sampling rate of 32 kHz and with a 16-bit quantization in the sound-treated studio of the Institute of Phonetics in Prague, using an IMG ECM2000 microphone and a SB Audigy 2ZS soundcard.

2.1. Perceptual categories

First, all 180 target word tokens were surveyed on an auditory basis by three Czech trained phoneticians (two of whom were authors of this paper). This auditory survey in combination with the phoneticians' native-speaker intuitions led to setting up eight functional categories:

Type 1: neutral acceptance

Type 2: eager agreement

Type 3: impatience

Type 4: indifference, patronizing

Type 5: wonder, surprise

Type 6: recognition, realizing

Type 7: resignation

Type 8: reassurance, sympathy

Having set up these categories, each target word was listened to and assigned to one of the categories. The assignment procedure was conducted independently by the three phoneticians. In the case of disagreement the respective token was discussed and the majority vote was taken. In the end, eight tokens had to be discarded due to disagreement of all three listeners, so that 172 words were left for further analysis.

2.2. Acoustic measurements

Acoustic analyses of the target words were carried out in *Praat* [24], individual segment boundaries were manually labelled. The following parameters were measured:

Temporal:

- word duration (in ms)
- relative segment duration (in % of word duration, and in % of syllable duration)
- relative syllable duration (in % of word duration)
- difference between the duration of syllable nuclei (in ms, [a]-[e])
- difference between the duration of syllable onsets (in ms, [j]-[ɲ])
- durational profiles: the outcome of a cluster analysis (4 clusters, k-means) where the individual cases (renderings of the word) were clustered according to their segment durations (in % of word duration)

F0:

- first and second extreme of the F0 contour (i.e., maximum and minimum or vice versa) normalized to speaker range (in %) and speaker average (in ST)
- the difference of the first and second extreme in the F0 contour (in ST re 100 Hz)
- the difference between vowels, i.e., between the F0 mean values taken in the middle third of each vowel (in ST)

Speaker range and average values for normalization were taken from all six utterances in which the target word occurred, rather than just from the target word itself. Errors in F0 extraction were manually corrected, and portions of the signal with creaky voice were excluded, so that we obtained an estimate of the speaker's modal range. Values of the minima and maxima in the target word were measured manually, F0 micro-perturbation was disregarded. Creaky voice in the target words was subsequently set to be at 0 % of the speaker's range rather than at negative values, since this has improved the discriminatory power of the variable in preliminary analyses and most probably reflects the speaker's intention of hitting 'ultimate low' rather than a specific frequency target.

Energy:

- maximum SPL value in the target word, normalized by average utterance SPL (in dB; pauses and silences were excluded)
- location of the SPL maximum (in % of word duration, and in the corresponding segment)
- SPL in the middle of each segment, normalized by average utterance SPL (in dB)

Apart from these acoustic measurements, the intonation contour was also annotated by the third author with labels adapted from the Kiel Intonation Model [20,25]:

- prominence strength of each syllable in three levels (0 = no prominence, 1 = weak prominence, 2 = strong prominence)
- synchronization of the pitch-accent peak (early, medial, late) in weakly or strongly prominent syllables
- final boundary tone (0 = flat, 1 = moderately descending, 2 = falling to the lower end of the speaker's range)

Afterwards, the position of the (more) prominent syllable in the disyllabic target word and its and pitch-accent synchronization were merged into a single contour-descriptor label (e.g., 'FA' = early peak on the first syllable; 'MB' = middle peak on the second syllable).

All 36 parameters listed above were then used as variables in subsequent statistical analyses.

The discriminative strength of each variable was explored through one-way ANOVAs. For classifying the data into the eight perceptual categories, linear discriminant analysis (LDA), classification and regression trees (CART) and artificial neural nets (ANN) were used. The advantage of using CARTs and ANNs is the possibility to employ both continuous (e.g., temporal or F0 parameters) and categorical (e.g., duration profiles, intonation labels) variables as predictors. Moreover, CART can use one and the same variable repeatedly at different split decisions. All the classifiers used were from the STATISTICA software package [26].

3. Results

3.1. Counts of Tokens in Functional Categories

Out of the 172 investigated tokens, 43 cases were assigned to Type 2 (eager agreement) and 42 cases to Type 1 (neutral acceptance). Type 6 (recognition, realizing) was represented by 29 cases, Types 4 (patronizing) and 5 (wonder) both by 18 cases, while for Types 7 (resignation), 8 (reassurance), and 3 (impatience) only 9, 8 and 5 cases, respectively, were found.

3.2. Discriminant Analysis

Linear discriminant analysis was performed after searching for continuous variables that do not correlate too highly with each other and differentiate well among the individual functional categories. Unrestrained analysis (i.e., mapping the structure of the dataset with rather loose tolerance levels) resulted in a success rate of 57.6 % and identified the following variables as best reflecting the assumed functional categories: duration of the vowel /e/ in the second syllable of *jasně* relative to the word duration, vowel /e/ duration relative to syllable duration, consonant /s/ duration relative to syllable duration, duration of first syllable relative to word duration, durational difference between vowels, durational difference between syllable onsets, and F0 difference between the first and second extreme.

Several further analyses were performed with more stringent tolerance levels. Although the success rate for the best outcome dropped to 52.3 %, the results can be considered more generalizable. Only five variables were ultimately used: word duration, durational difference between vowels, durational difference between syllable onsets, F0 difference between vowels and normalized value of the first F0 extreme. Table 1 displays the ensuing confusion matrix. It is apparent that under-represented functional categories (Type 3, 7 and 8, i.e., impatience, resignation and reassurance respectively) were not recognized in this more rigorous setting of the LDA.

LDA		Observed Types							
		1	*2*	*3*	*4*	*5*	*6*	*7*	*8*
Predicted Types	*1*	22	11	0	4	1	2	1	1
	2	15	28	2	2	0	7	2	1
	3	0	0	0	0	0	0	0	0
	4	2	1	1	9	5	0	0	4
	5	2	0	0	1	10	0	0	1
	6	0	3	2	2	0	20	6	0
	7	0	0	0	0	1	0	0	0
	8	1	0	0	0	1	0	0	1
Corr. %		**52**	**65**	**0**	**50**	**56**	**69**	**0**	**12**

Table 1. *Confusion matrix resulting from the most successful discriminant analysis. Figures represent individual cases, except in the last line with percentages of correctly recognized cases within a category.*

The success rate for other categories was 50 % and more. The highest numbers off the diagonal can be found for Types 1 and 2 (neutral acceptance and eager agreement). They seem to be highly confusable, although the correctly identified cases in these two abundant types still prevail. The most distinct functional category seems to be Type 6 (recognizing) with nearly 70 % of the cases correctly separated from other categories and with errors towards Types 1 and 2 again. As stated above, the lowest success was achieved for the smallest groups, of which Type 3 was represented by 5 instances only.

3.3. Classification and Regression Trees

The algorithm used in STATISTICA calculates automatically the usefulness of all the input variables and ranks them according to their effectiveness in the classification process. The most successful tree achieved the success rate of 65.7 %, which is by about 10 % more than in our earlier discriminant analyses. The best tree had 9 splits and was based on word duration (ranked as the most important predictor), F0 difference between vowels, durational difference between syllable onsets, relative duration of a syllable within the word, normalized F0 value of the first extreme and normalized intensity of the first vowel. Other intensity measures and categorical labels of intonation and temporal profile were found unimportant, while the word duration and F0 difference between vowels were used twice, i.e. for two different splitting decisions. The ensuing confusion matrix is shown in Table 2. Further splitting could still be ordered, but only at the expense of generalizability, hence we did not proceed with it. The number of confusions between Types 1 and 2 is lower than in previous analyses, but a considerable number of Type 2 cases were misclassified as Type 6 (see below, Table 2, the second numbered column).

CART		Observed Types							
		1	*2*	*3*	*4*	*5*	*6*	*7*	*8*
Predicted Types	*1*	21	4	0	0	0	0	0	0
	2	12	28	2	0	0	0	1	0
	3	0	0	0	0	0	0	0	0

	5	3	0	1	0	18	0	0	0
	6	2	11	2	4	0	29	8	1
	7	0	0	0	0	0	0	0	0
	8	3	0	0	3	0	0	0	6
Corr. %		**50**	**65**	**0**	**61**	**100**	**100**	**0**	**75**

Table 2. *Confusion matrix resulting from the most successful CART analysis. Figures represent individual cases, except in the last line with percentages of correctly recognized cases within a category.*

The best classification of categories was achieved for Types 5 and 6 (wonder and recognizing) whose all instances were correctly found. However, some other types were also mistakenly added to these categories. From this point of view, Type 5 seems to be better as only four improper cases were added to it. The rare Types 3 and 7 (impatience and resignation) were not recognized at all, but Type 8 (reassurance), which was represented by 8 cases in our dataset was classified relatively successfully.

3.4. Artificial Neural Nets

Thirty different architectures and settings were tried always with eight output neurons (corresponding to eight functional categories). The initial analyses used all the variables available as the input with the aim to evaluate of their individual usefulness. Sub-sequent analyses only utilized the most effective predictors. It turned out that Multilayer Perceptron Neural Networks outperformed other available types (RBF, LNN).

ANN		Observed Types							
		1	*2*	*3*	*4*	*5*	*6*	*7*	*8*
Predicted Types	*1*	30	11	1	2	1	3	1	1
	2	6	27	1	1	2	3	0	1
	3	1	0	2	1	1	1	0	0
	4	2	1	0	9	0	1	0	2
	5	2	1	0	3	14	0	2	2
	6	0	3	1	2	0	20	2	0
	7	0	0	0	0	0	0	4	1
	8	1	0	0	0	0	1	0	1
Corr. %		**71**	**63**	**40**	**50**	**78**	**69**	**44**	**12**

Table 3. *Confusion matrix resulting from the most successful ANN classification. Figures represent individual cases, except in the last line with percentages of correctly recognized cases within a category.*

As in the previous analyses, the most efficient variable was the duration of the word. Rather surprisingly, the second best was the durational profile of the word (a categorical variable), followed by the prominence strength on the first syllable (categorical), durational difference between syllable onsets, F0 difference between vowels, synchronization of the F0 peak (categorical), and normalized intensity of the first vowel. The automated neural networks that we used weigh some of the input variables by zero and make them ineffective. As a result, they do not suffer from dimensionality problems. The unrestrained model achieved a success rate of 66.3 %. When only the nine best variables were used in a three-layer perceptron architecture, the success rate dropped to 62.2 %, but probably with the advantage of better generalizability. Confusion matrix of the final analysis is displayed in Table 3.

Unlike in CART analyses, there are no 0 % or 100 % success rates in mirroring the functional categories. Type 5 (wondering) and Type 1 (neutral acceptance) were the best recognized with the success rates over 70 %. Some correct classification occurred even in the small groups of Type 3, 7 and 8 which were previously found difficult to capture (apart from Type 8 in CART analysis).

4. Discussion

Three classifiers performed their analyses with comparable levels of success. However, the lowest success rate in the case of the conventional discriminant analysis suggests that continuous linear relationships do not model prosodic dependencies best. As noticed in the past, acoustic correlates of prosodic features are used in various combinations, and the same features can be used for different communicative functions, in this way creating discrete 'islands' in a multidimensional space. If this is true, more advanced classifiers should be advantageous. More specifically, the best recognized categories, Types 5 and 6 (wondering and recognizing), were each found by CART at two different endpoints of the classification tree. This supports the idea that the same pragmatic or discourse effect can be achieved through different prosodic means. One way or another, our results allow for positive answers to the first two questions from the introduction: the prosodic variation in our data set appears to be systematic and functionally motivated.

The third question concerned the variables responsible for prosodic profiling of the individual functional categories. The word duration as an expression of the articulation rate was identified as a useful discriminatory element in all analyses performed. It seems that the rapidity (or slowness) with which the word *jasně* is pronounced is a reliable marker of the appended functions. Various other durational characteristics kept reoccurring as well, of which the most important one was the difference in duration of the consonantal onsets of the syllables. Interestingly, auditory inspections turned our attention to the duration of the word-initial consonant, which was markedly longer for some functional categories than for others, but the duration of this consonant relative to the duration of the word was computationally less useful than the same duration relative to the duration of the second syllable onset. Local durations of consonants thus might function in speech by being contrasted against each other rather than by being compared with the carrier unit as a whole.

As to the melodic correlates, the one repeatedly occurring as effective was the difference between F0 means measured in the middle thirds of the vowels (in ST). This variable could be sometimes replaced with the difference in F0 extremes within the word with a few percent shifts in the success rates. The relative pitch of the first syllable – expressed as either the F0 value within the speaker's range or as the annotated labels adapted from the Kiel Intonation Model – were also found relevant by the computational classifiers, although they were not eventually utilized in the most successful models.

The profiles of functional categories to be further examined in perceptual tests appeared to be as follows. Types 1 and 2 were spoken significantly faster than all the other types. It seems plausible to find neutral and eager stances brisk, whereas patronizing, wonder, realizing, resignation, and reassurance spoken more slowly. The major discriminator between Types 1 and 2 was then the difference in duration of the syllable onsets. Type 2 (eagerness) has significantly longer the word-initial consonant. A similar relationship is found between patronizing (short word-initial consonant) on the one hand, and wondering and realizing on the other hand (longer word-initial consonant). Melodically, Type 5 (wonder) was the only one with clearly rising F0 contour. Patronizing (Type 4) and reassurance (Type 8) were spoken with flat contour, while the rest of the types had falling melodies. As to energy, Types 1, 2 and 6 exhibited high SPL in first (i.e, stressed) vowel, whereas Types 4, 5 and 8 low SPL.

Similarly to English [27] or German [21], Czech functional categories seem to rely to a great extent on temporal and melodic cues, although intensity plays its role, too. An experiment is currently in progress, testing the perceptual response of German and Czech listeners to the exemplars from our current study.

The under-represented categories 3, 7 and 8 were difficult to classify. Although this can be due to the computational safeguards (not generalizing for small samples), our intuitive evaluation suggests that these categories are not just relatively rare, but also internally disparate. The pragmatic messages they signal (impatience, resignation, or reassurance, respectively) may be expressed by various means and, therefore, be less well-defined than their more frequent counterparts. Further research in this respect is needed, but prior verification of these categories by larger listener groups is crucial.

Abstract

Based on the Momel algorithm, a set of acoustic parameters was analyzed automatically on Chinese emotional speech. Global prosodic features were calculated on the sentence level, which showed a concordance with the usual pattern reported in the literature. Local constraints were also considered on the syllable layer. An ANOVA showed that there were interactive effects among emotions, syllable positions and syllable tones on certain parameters. Further more, by examining the pitch movements, no significant difference was found between neutral speech and active emotional speech, which was different from the performance in non-tonal languages. However when reducing the tonal influence by using utterances composed of only tone 1 syllables, this inverse effect disappeared. Hence we posited an interpretation that due to the existence of lexical tone in Mandarin Chinese, the paralinguistic use of pitch movements has been reduced.

Index Terms: emotional prosody; the Momel algorithm; Mandarin Chinese; lexical tones

1. Introduction

Human speech communication conveys not only linguistic information, but also shows the speaker's age, gender, emotions and other paralinguistic cues, among which the importance of emotions in vocal speech has been recognized throughout history. Emotion-specific patterns of acoustic cues have been widely investigated in non-tonal languages, such as in [1], [2] and [3], and showed some common properties across languages. However, the acoustic realization of emotion in lexical tone languages like Mandarin Chinese does not seem to always work the same way. [4] posited that the presence of lexical tones significantly constrains the manipulation of f_0 in emotional speech. Therefore, language-specific attributes, especially in tone language, still need more attention.

In Chinese, the lexical tones and intonation are intertwined as one phonetic representation of the raw f_0 curve conveying both linguistic and paralinguistic functions. How lexical tones and intonation interact with each other is still an unsolved problem. Chao [5] was one of the pioneers who studied Chinese emotional prosody. He pointed out that the emotional intonation depends on the voice quality, stress, phrase pitch and tempo of speech. Yuan et al. [6] proposed that anger and fear are mainly realized by phonation; joy is mainly realized by f_0; whereas sadness is realized by both phonation and f_0. Zhang et al. [7] investigated f_0, duration and short-time amplitude on both sentential level and syllable level. Li et al. [8] investigated emotional intonations by analyzing mono-syllabic utterances. Results showed that the tonal space, the edge tone and the duration differ greatly across 7 emotions. Wang et al. [9] studied the cross-linguistic perceptual patterns of four basic emotions. However, many questions are still waiting to be answered. For instance, the interaction between global intonation and local constraints like tone and position is still not quite clear. Furthermore, we should also find a proper way of modelling the emotional melody to account for microprosody and noise in f_0 extraction.

In this paper, the Momel algorithm was adopted to represent the surface f_0 contour in Chinese emotional speech. Model based acoustic analysis has been conducted on both global layer and syllable base. Finally, the restriction of lexical tone and vocal emotion realization was examined.

2. Method

The emotions used for investigation were four basic emotions including happiness, fear, anger and sadness, supplemented by a neutral state for comparison. Corresponding to the discrete emotion theory [10], these four emotions are among the most commonly postulated basic emotions and are most frequently studied [11]–[13].

2.1. Corpus

Recording materials are 36 sentences. Each sentence contains eight syllables. Target words differing in tones are put at the beginning, middle and end of each sentence respectively. All sentences are proper to elite different emotions under certain scenario. Examples of one group of 12 sentences are given below. The other two groups of 12 sentences have the same syntactic forms but with different contents.

ma1 ma1 jiao4 xiao3 ming2 qu4 mai3 ***{mao1/yang2/niao3/lu4}****.*
"Mom asked Xiao Ming to buy a cat/ sheep/ bird/ deer."

The recordings were made in the sound booth at 48 kHz sampling rate with a 16-bit resolution. Two professional actors (one male one female) were recruited from Cinema College of Tongji University. The speakers were asked to act each utterance with each of the four emotional states and in a neutral way as a contrast. Each emotional state was accompanied by a short scenario with a picture. The elicitation scenarios help to minimize the interpretation variations that

may differ from speaker to speaker [14]. In total, we obtained 360 utterances (36 sentences × 2 speakers × 5 emotional states).

2.2. Listening test

Listening tests were conducted to confirm that the intended emotions were accurately decoded. Ten Chinese listeners were asked to choose for each the most suitable emotion among angry, happy, fear, sad and neutral options in a forced-choice task. Finally 303 utterances (72 for anger, 50 for fear, 56 for happiness, 53 for sadness and 72 for neutral) were chosen for further analysis.

2.3. Automatic alignment

For acoustic-related researches, one fundamental but time-consuming step before *real* analysis is the correct segmentation and alignment of the speech with the orthographic transcription. Several tools have been developed to make this laboursome task automatic, such as HTK [15], Julius [16] and the P2FA [17].

Here we chose a recently developed tool, SPPAS [18], to implement automatic phonetisation and alignment of Chinese emotional speech. SPPAS generated four tiers in the TextGrid including *inter-pausal units, words, syllables and phonemes*. For our Chinese speech, only three tiers were used in later analysis. An example is shown below:

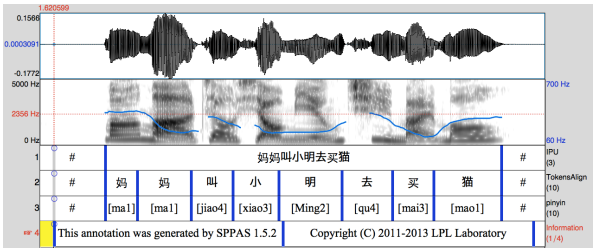

Figure 1: *SPPAS output example.*

2.4. The Momel algorithm

The Momel algorithm [19], [20], short for Modelling Melody, assumes that the raw f_0 curve is the interaction between two components: a global *macroprosodic* component determined by the underlying intonation pattern of the utterance, and a local *microprosodic* component caused by the articulatory constrains of segmental phonemes. Hence the underlying intonation pattern can be modeled as a continuous and smooth f_0 curve. In the Momel algorithm, this continuous curve is realized by a sequence of *target points* interpolated with a quadratic spline function.

The Momel algorithm has been applied to many languages including Standard Chinese, English, French, Korean, Italian, Catalan, Brazilian Portuguese, Venezuelan Spanish, Russian, Arabic and isiZulu [19]. In [21], this algorithm was first used on the lexical tone language, Standard Chinese, which showed its robust capability to model pitch contours.

The Momel algorithm is considered to be theory-neutral, or, better, *theory-friendly* [20], since it works as a phonetic representation of the intonation pattern with respect to speech production and speech perception. It can be compatible with some different theoretical approaches to describe speech prosody, and actually has been used as the first step in deriving the f_0 representations such as in the Fujisaki model [22], ToBI [23] and INTSINT [24].

Since this algorithm optimizes the modelling of speech prosody by taking the raw f_0 curves as input, and outputting the continuous and smooth macroprosodic components, it should be a powerful model to account for the rich local pitch changes in emotional speech.

2.5. Applying Momel algorithm to the corpus

The utterances in the emotional speech corpus were coded using the automatic Momel algorithm. Main steps were described in detail below.

2.5.1. Detect f_0

The quality of f_0 detection is a crucial fundamental step for all the pitch contour models. Unfortunately, most software like Praat will produce errors when extracting f_0 values if only the default parameters are used. Especially when there are a lot of pitch movements and for non-modal speech styles, f_0 extraction using the default parameters is not reliable. The most common errors are due to the inappropriate setting of minimum value and maximum value allowed for the f_0 analysis, that is, Pitch Floor and Pitch Ceiling in Praat.

The Momel plugin [19] on Praat provides an automatic f_0 detection algorithm to generate appropriate Pitch Floor and Pitch Ceiling parameters. This is a two-pass method. In the first pass, default parameters (50Hz for Pitch Floor, 700Hz for Pitch Ceiling) are used to calculate the f_0. Then, the first and third quartiles, named q1and q3, of the f_0 distribution are taken. In the second pass, Pitch Floor and Pitch Ceiling are recalculated respectively by the formula 0.75*q1 and 2.5*q3.

In this paper, we adopted this method by treating our emotional speech corpus with the automatic f_0 detection algorithm in Momel. The outputs were the corresponding *.Pitch* files. Instead of manual correction, this automatic way of detecting f_0 is preferable for the analysis of large speech corpus and is reproducible for further research.

2.5.2. Calculate Momel targets

Once we obtained the *.Pitch* files after the above step, a sequence of pitch target points was calculated by the Momel algorithm, which resulted in the *.PitchTier* files. Figure 2 shows an example of these pitch targets (black circles) detected in a happy utterance from our emotional speech corpus. The red curve is the modeled f_0 contour interpolated quadratically from the targets points with a quadratic spline function.

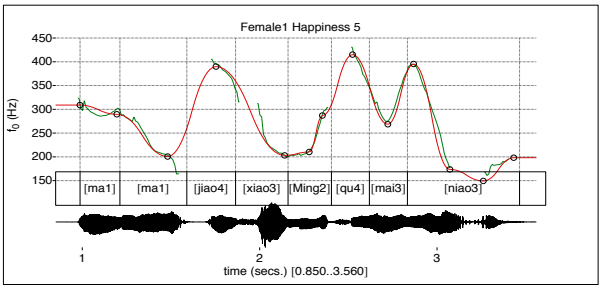

Figure 2: *Automatic Momel algorithm for the utterance "Mom asks Xiao Ming to buy a bird." Raw f_0 (green curves), pitch targets (black circles) and modeled f_0 (red curve).*

For best results, the output *.PitchTier* files containing pitch target points were manually checked using the *Correct Momel* interface. Any erroneous or missing target points were either deleted or added by hand.

3. Model-based acoustic analysis

Melody metrics [19], [20] were extracted by a Praat script based on the Momel outputs on the unit of sentence or syllable, including parameters of duration, intensity, f0 and their variance measures which are regarded as the basic parameters of speech prosody.

3.1. Global prosodic pattern

We first used sentence level as the analysis unit to capture the global prosodic pattern under each emotional state. The averaged results are listed in table 1.

Table 1: *Summary of the acoustic measurements*

	Anger	Fear	Happiness	Sadness	Neutral
Intensity (dB)	68.64	65.54	67.86	63.81	65.00
Speech rate (syl/s)	4.904	4.270	4.105	3.046	3.469
f_0 (octave in z-score)	-.043	.974	.784	-.238	-1.067
f_0 range (octave in z-score)	.261	-.481	.752	-.594	-.075
Mean abs slope (octave/s)	2.447	1.607	2.30	1.500	2.470

A one-way ANOVA with emotions (5 levels) as factor was conducted on the parameters described above.

For intensity, there was a significant main effect of emotions, F (4, 298) = 33.897, p = 0.000<0.05. The mean intensity of anger and happiness were significantly higher than others, while sadness is significantly lower, as indicated by post hoc multiple comparisons. For speech rate, there also appeared main effect of emotions, F (4,298) = 68.730, p = 0.000 < 0.05. The utterances spoken in an angry way were significantly faster, followed by fear and happiness. The speech rate under the sadness state was the lowest, and we only found inner-sentence pauses in sad speech. f_0 and f_0 range values were calculated on interpolated *.PitchTier* files from Momel. All values were first converted from Hz to octave, and then z-transformed with each speaker to reduce the inter-subject variability. A main effect of emotions was found for both parameters, F (4, 298) = 92.831, p = 0.000 < 0.05 and F (4, 298) = 21.436, p = 0.000 < 0.05 respectively. Post hoc tests showed that happiness and fear had significantly higher mean f_0, followed by anger, sadness and neutral. Anger had largest f_0 range, then happiness larger than neutral significantly. Fear and sadness had no significant difference.

Mean absolute slope was measured as absolute difference from the previous pitch point divided the by distance in seconds, which indicated whether there were a lot of pitch movements or not. A significant main effect was shown across different emotions, F (4, 298) = 21.381, p = 0.000 <0.05. In post hoc tests, we found that neutral, anger and happiness had significantly more pitch movements than fear and sadness as illustrated in Figure 3. What drove us to pay attention was that the mean absolute slope of neutral versus anger and happiness in Chinese showed a different pattern to that found in other non-tonal languages in [25], [26]. As reported in the literature, active emotional speech, such as anger and happiness, have much more pitch movements than neutral speech. However, we didn't find such an effect in our Chinese corpus. Either because speakers in our study used a different strategy to express these emotions, or because there's some underlying difference of pitch movements across emotions between Chinese and other non-tonal languages. Detailed discussion will be given later.

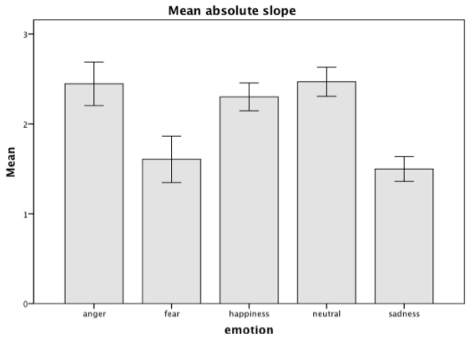

Figure 3: *mean absolute slope on sentence level.*

In summary, as for the sentence level, different emotional speech showed significantly different acoustic patterns, which are largely in concordance with the usual patterns reported in the literature, such as in [2] and [27]. However, the amplitude of pitch movements indicated by mean absolute slope showed different results, which required further analysis.

3.2. Emotions, positions and tones interaction

Although many of the acoustic studies focus on the global realization of prosody, studies on synthesis of emotional speech didn't work like this. A bottom-up method has been adopted. For synthesis purpose, different parameters were usually manipulated on the levels of syllables or even phonemes. Here we should draw attention to the local constraints. In this study, different tones and sentence positions were considered together with emotions on the acoustic analysis of target words/syllables in the utterances.

Table 2 shows the significant level for each of the acoustic parameters analyzed by ANOVA, with emotions (5 levels), positions (3 levels: beginning, middle and end of the sentence) and tones (4 levels: tone 1, tone 2, tone 3 and tone 4 in Mandarin Chinese) as factors. There were significant main effects of emotion, position and tone on most of the parameters except for mean slope. Significant effects of interaction between factors were also found on some parameters. Due to the limitations of space, detailed analysis of these results will be postponed for future publication, instead we focus on f_0 and mean absolute slope.

For mean f_0, the interaction between emotions and positions, emotions and tones were significant, F (8, 243) = 7.985, p = 0.000 < 0.05 and F (12, 243) = 2.519, p = 0.004 < 0.05 respectively. Figure 4 shows the mean f_0 performance in z-scored octave at different tones and emotions.

Across all emotions, tone 1 and tone 4 had higher f_0, which is in line with the fact that in Mandarin Chinese tone 1 and tone 4 begin as high tones. Interestingly, if look at the amplitude difference between tone 1, tone 4 and tone 2, tone 3, we found that compared with neutral speech, this difference is reduced in emotional speech. This phenomenon suggested the possibility that emotions, to some extent, restricted the distinction between the four tones in Chinese. This result seemed to provide an explanation for the unusual performance

of pitch movements described in 3.1. When speaking with emotions, pitch movements were reduced compared to neutral speech in Mandarin Chinese. To further investigate this phenomenon, we did an additional experiment.

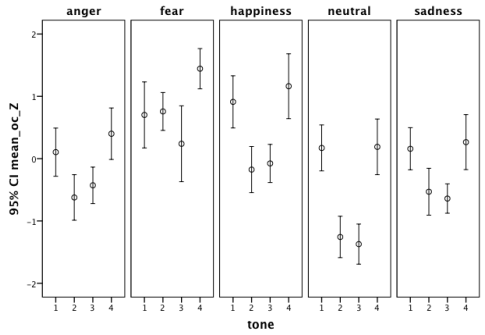

Figure 4: *mean f_0 value (z-scored octave) at different tones and emotions.*

3.3. Lexical tone and vocal emotion restriction

To test the hypothesis above, we recorded four groups, each for one tone, of monotone utterances in Mandarin Chinese using the same female speaker. The utterances are digital strings, which also contain eight syllables for each. The recording procedure was the same as the previous experiment, which yielded 189 utterances. One example is as follow:

yi1 ba1 ba1 san1 qi1 yi1 ba1 qi1.

"One eight eight three seven one eight seven."

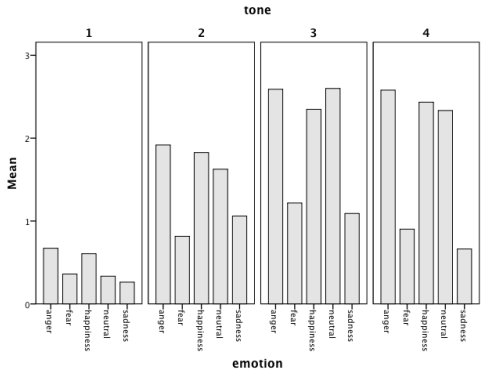

Figure 5: *mean absolute slope in monotone utterances.*

Mean absolute slope was calculated on Momel output as illustrate in Figure 5. In utterances with only tone 2 or tone 3 or tone 4, we found the same pattern as in Figure 4 that, neutral, anger and happiness had significantly more pitch movements than fear and sadness. However, in utterances with tone 1, anger and happiness had significantly more pitch movements than neutral, which was consistent with the pattern in non-lexical tone languages [25], [26]. Since tone 1 in Mandarin Chinese is a level tone (usually represented as 55), the utterances with only tone 1 syllables, to some extent, reduce the tonal influence on intonation compared to other tone combinations, and can be regarded as similar to a non-tonal utterance. From the evidence above, we came to the conclusion that the lexical tone in Mandarin Chinese has an influence on the realization of emotional prosody. It seems that the lexical tone restricts the paralinguistic use of pitch. This point has also been reported from other evidences in [28]. A similar result was also shown for Cantonese [29] which has a richer tone system than Standard Chinese.

4. Discussion and conclusion

Based on the Momel algorithm, a set of acoustic parameters has been analyzed automatically on Chinese emotional speech. Global prosodic features were calculated on the sentence level, which showed a consistency with the usual pattern reported in the literature. Given the local constraints, we further examined the acoustic performance on the syllable level. An ANOVA showed that there were interactive effects among emotions, syllable positions and syllables tone on certain parameters.

Although previous findings such as [30] showed evidence for the existence of universal patterns from vocal characteristics to specific emotions across cultures, the existence of language-specific paralinguistic features were still found in vocal emotion expression. By examining the pitch movements indicated by mean absolute slope, no significant difference was found between neutral speech and active emotional speech, which was quite different from the performance in non-tonal languages. However when reducing the tonal influence by using utterances composed of only tone 1 syllables, this inverse effect disappeared. Hence we posited an interpretation that due to the existence of lexical tone in Mandarin Chinese, the paralinguistic use of pitch movements has been reduced. This result served as a further proof of the finding in [28] and [29].

The automatic phonetic representation of the intonation pattern, with respect to both speech production and speech perception, by the Momel algorithm makes it possible to account for more tonal and non-tonal language comparison in the future. More over, we should take into consideration more local constrains such as narrow focus and tone sandhi.

Abstract

This work examines the production side of social affects in Mandarin Chinese, with the aim of extracting the more prominent patterns of acoustical variations. Results are then compared to previous perception data obtained on the same expressions. The F_0, intensity and duration characteristics of 76 utterances conveying 19 prosodic attitudes are statistically examined in this study. All attitudes are regrouped into 5 clusters according to their prosodic features. The result of the statistical analysis shows that the prominent differentiation between clusters is mostly related to F_0 and duration parameters; some similarities are noted between the clustering of attitudes from acoustic features and from perceptual confusions obtained in previous experiments; inside each cluster, some attitudes show typical characteristics in F_0 and duration.

Index Terms: prosodic attitudes, social affects, acoustic parameters, Mandarin Chinese

1. Introduction

Since the voice is considered as a carrier of affective signals in human speech, vocal cues, and especially prosodic cues, shall have an important role in the expression of affective nuances, which ensures some interaction functions like situation cues, mental states and processing, intentions, attitudes and emotions. [1] distinguished the socio-affective expressions (or expressions of attitude), which can be voluntarily controlled, from the expressions of emotion, which cannot be. Meanwhile, both emotional expressions and socio-affective expressions are often conveyed by the prosodic variations, which influence significantly the interpersonal interaction and social communication [2].

Many empirical studies demonstrated that people decode the acoustic signal conveying emotional expressions and attitudes with only voice samples (e.g. [3, 4, 5, 6]). On the other hand, many scholars have been engaged in finding out how affective signals are encoded in voice, with special focus on the acoustic measures of emotion encoding (e.g. [7, 8, 9, 10, 11]). The acoustic variables which have been widely measured in the literature are mostly fundamental frequency, energy (or intensity), duration (or speech rate), harmonics, stress, intonation, timbre, etc. Fundamental frequency, intensity and duration are the most classical acoustic parameters used as correlates of prosody [10], and it was commonly accepted that the fundamental frequency play an important role to signal affect, intention, or emotion [12].

Although [13] has claimed that the affective prosody universally exists in every language, there is also no denying that the expression of affective prosody varies from one language to another, and many studies have been conducted for the specific purpose of investigating the prosodic characteristics of affective speech specifically in Chinese (e.g. [14, 9, 11, 15, 16]).

Following the example of these previous studies, we will intend in the present work to identify the main prosodic profile of 19 social affects expressed in Mandarin Chinese by statistically separating them into different clusters. The characteristics of these expressions on F0, intensity and duration parameters, both at the sentence and the syllable levels will be took into consideration. Meanwhile, this work also aims at finding explanations for the perceptual confusions observed between these social affects during previous perception experiment [6], because acoustic proximity is thought to be possibly explicative of certain confusions because they remain important cues for encoding and decoding studies [17].

2. Method

2.1. Corpus of Chinese social affects

Based on research on attitudes in Chinese and other languages [18, 19, 20, 3, 4], 19 Chinese daily encountered attitudes have been selected for our study. The speech corpus of this work contains four sentences performed with these 19 attitudes by one native Chinese female speaker speaking an unmarked standard Mandarin Chinese. The corpus has been perceptually validated in [6], where almost all attitudes have been recognized over the chance level (except “confidence”). The sentences analyzed in this paper received the best average recognition score across all attitudes in each length (monosyllable, disyllable, 4-syllable and 9-syllable). These sentences can be considered as the most representative of a prototypical expression of the targeted attitude. Table 1 lists the sentences composing the corpus and Table 2 presents the 19 Chinese attitudes which will be analyzed in the present work.

Table 1. *Sentences composing the corpus.*

Chinese	Pinyin	English

negative surprise(NEG-S)	obviousness(OBVI)
politeness(POLI)	positive surprise(POS-S)
question(QUES)	resignation(RESI)
seduction(SEDU)	

2.2. Measurements of prosodic features

According to some studies on emotional expressiveness in Chinese and other tonal language, the global intonation form of sentence is often linked to its expressive function [16; 21] and the variation of the initial and final movements of F_0 contour is more significant in characterizing the F_0 contour of different attitude than the movement in middle [22]. Therefore, we will observe in this work both global prosodic characteristics of social affects in sentence level and the specific cues at the beginning and end of sentence.

The majority of the values of prosodic parameters were automatically extracted from the 76 stimuli using the PRAAT software. Each sentence was previously hand-labeled at the phonemic level. The prosodic parameters measured are the fundamental frequency, the syllabic duration, and the intensity. For each sentence, six measures in F_0 were considered: mean F_0, standard deviation of F_0, maximum and minimum values of F_0 of the sentence, mean values of the first and the last syllable for F_0. Similarly, the durations of the first and the last syllable and of sentence were also measured, as well as the mean intensity of sentence. F_0 values were extracted by cross-correlation method and are expressed in semi-tone (with reference to 1Hz). The intensity values are expressed in decibel (dB). The decimal logarithm of duration (in millisecond) is used here [14]. Two other parameters were calculated manually in Excel:

- F_0 range (in semitones): the difference between the maximum and the minimum value of F_0 [16].
- F_0 slope (semitones/s): is here defined as the direction and rate of F_0 change. It is the difference of the mean F_0 of the last syllable to the mean F_0 of the first syllable divided by sentence duration [14].

The means for selected acoustic parameters of vocal utterances conveying 19 attitudes were calculated before being statistically analyzed. Table 3 shows the 10 prosodic variables extracted from the audio samples.

Table 5. *Matrix of rotated components.*

	Component 1	Component 2
F_0_range	0.95	0.17

F_0 register of the last syllable	semitones	L_ F_0_mean	F_0
F_0 slope	semitones/s	F_0_slope	F_0
Intensity register of sentence	dB	Intensity_mean	Intensity
Duration of the first syllable	$\log_{10}$(ms)	F_dur	Duration
Duration of the last syllable	$\log_{10}$(ms)	L_dur	Duration
Duration of sentence	$\log_{10}$(ms)	Sentence_dur	Duration

3. Results

3.1. Hierarchical clustering of attitudes based on principal component analysis

Combining a principal component analysis and an agglomerative hierarchical cluster analysis, this method has the advantage of clustering the individuals with less noise [23]. Therefore, a principle component analysis (hereafter referred to as PCA) was performed as a preprocessing step before the cluster analysis. After having measured the sampling adequacy with KMO & Bartlett's test (KMO = 0.614; Bartlett's Sig. < 0.001), the PCA was carried out on the dataset with 19 individuals (attitudes) and 10 prosodic variables. The measures were standardized during the procedure. The SPSS software was used to carry out the analysis.

The result of the PCA is presented in Table 4: two principal components were extracted, which explained cumulatively almost 82% of the variance. Table 5 shows the matrix of components after rotation (the "varimax rotation" method was used here). The main results indicate that the first principle component is more linked to F_0 parameters, intensity register and the duration of the last syllable, while the second one is linked to the duration parameters and the slope of F_0.

Table 4. *Proportion of variance explained by the first four components of PCA over all prosodic parameters.*

		1	2	3	4
Initial Eigenvalues	% of variance	59.00	22.95	9.03	5.23
	Cumulative %	59.00	81.96	90.98	96.21

The factor scores of the 19 attitudes on the two first components were then used as a new variable on which was performed a hierarchical cluster analysis based on an agglomerative procedure. The Ward's minimum variance criterion was used to calculate the distance between clusters, while the squared Euclidean distance of observations was

defined as their distance. To determine the optimal number of clusters from the hierarchical tree, we referred to the "elbow criterion" based on the variance explained by each clusters [24]. Figure 1 shows the dendrogram of the hierarchical clustering and the graph of the between-inertia in function of the number of clusters on the top right of corner. Observing the inertia graph, we thought it would be reasonable to consider 5 clusters.

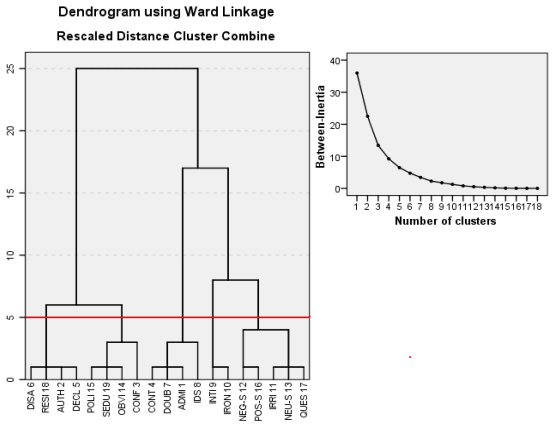

Figure 1. *Dendrogram resulting from a hierarchical clustering of 19 social affects. The red line marks the clusters resulting in the observation of inertia reduction presented in the graph on the top right corner.*

The last step of this analysis consists in visualizing the 5 clusters' position on the two principal components, with the aim of highlighting how these attitudes disperse on these two dimensions, and of looking at how the acoustic dimensions allow separating or grouping them together.

As showed in Figure 2, the majority of attitudes are projected along the axis in the plot, while certain ones are in the extremity of the axis: "positive surprise", "negative surprise" and "neutral surprise" are marked by their highest values on dimension 1, while "disappointment", "resignation" and "confidence" the lowest values; "infant-directed-speech" shows the highest values in dimension 2, at the opposite of "intimacy". The coordinates of some attitudes almost overlap on the graph, and it is the case of "positive surprise" and "negative surprise", "disappointment" and "resignation", "seduction" and "politeness", "authority" and "declaration". This proximity of distance between two attitudes implies the similarity of their prosodic features. That may be an important cue to explain some confusion patterns observed during the perceptual experiment.

As regards the 5 clusters obtained in hierarchical cluster, they are well separated on the two principal dimensions (cf. Figure 2):

- Cluster 1 groups "admiration", "infant-directed speech", "contempt" and "doubt". These attitudes show some high values in both F_0 and duration parameters.
- Cluster 2 groups "authority", "declaration", "resignation" and "disappointment". On the contrary to the first group, they have low values in both F_0 and duration parameters.
- Cluster 3 groups "obviousness", "seduction", "politeness" and "confidence". These attitudes show some similarities with the members of cluster 2 in F_0 phenomenon, but differ from them with their higher values in the dimension of duration.
- Cluster 4 groups "irony" and "intimacy", which are quite separated from other attitudes and characterized by their extremely low values in duration parameters.
- Cluster 5 groups "positive surprise", "negative surprise", "neutral surprise", "question" and "irritation". They look more similar to the first group in F_0 parameters, but quite different in duration dimension.

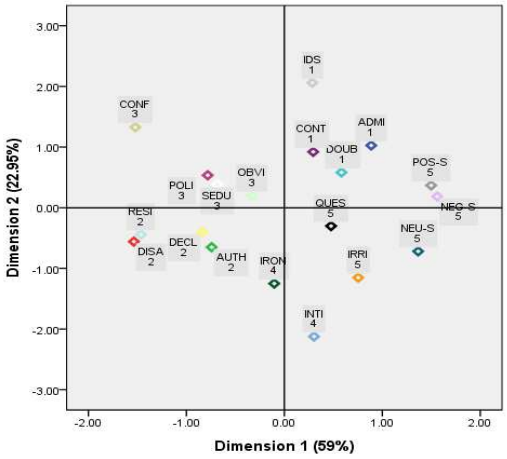

Figure 2. *Representation of the 19 attitudes clustered in 5 groups on the first two principal components of the PCA. Numbers under labels refer to the cluster they belong to.*

3.2. Differentiation of attitudes clusters

The analysis of the hierarchical clustering gives a global impression of the dispersion of attitudes and of their clustering according to their prosodic features. But it is also necessary to observe the prosodic characteristics of each cluster — in other words, how do the clusters differentiate prosodically one from another. Consequently, another analysis was done by comparing the means of each cluster across all variables. The results are detailed in Figure 3:

(1). For the F_0 measures (F_0 range, F_0 register of sentence, mean F_0 of the first and the last syllable, F_0 variation and F_0 slope), cluster 1 and 5 have higher values, while cluster 2 and 3 have the lower ones. Cluster 5 displays the highest values on F_0 range, F_0 register of sentence, mean F_0 of the first and the last syllable; cluster 1 has the highest value in F_0 variation; cluster 2 has the lowest values on almost all F_0 variables except F_0 slope. Cluster 4 has the highest negative value of F_0 slope. All clusters show slight differences in F_0 register of sentence. On the other hand, it can be found that the difference between cluster 1 and 5 is linked to the duration of the first syllable and of the sentence, with higher values for cluster 1 than for cluster 5. Cluster 3 and 2 also present some differences in duration measures, with higher values for cluster 3 than for cluster 2, and they are especially different in duration of the last syllable.

(2). For duration measures (duration of the first syllable and the last syllable, sentence duration), cluster 1 shows the highest values, while cluster 2 and 4 shows the lowest ones. Cluster 3 and 5 are in between and the latter has a very high value of duration of the last syllable just next below cluster 1. It is worth noting that cluster 4 and 2 does not show remarkable difference in duration measures neither in F_0 measures. Regarding the differences between cluster 3 and 5, we found that their differences mostly concern F_0 measures: the values of cluster 5 are apparently higher than that of cluster 3.

(3). Concerning intensity measure (intensity register of sentence), no clear patterns of differences between clusters were found.

4. Discussion and Conclusions

In the present work, we investigated how the attitudes could be clustered according to their prosodic features by observing the acoustic parameters of F_0, intensity and duration. The corpus of attitudinal speech contained 4 sentences of different length conveying everyone 19 Chinese attitudes and it had been perceptually validated during a previous experiment. Although the present study is still preliminary and the data involved is not large, some interesting and valuable results have been obtained.

First of all, the result of the hierarchical clustering ran on principal components gives a separation of attitudes into two main groups (cf. Figure 1) and this separation is basically based on the characteristics of fundamental frequency of attitudes (cf. Figure 2). One group is composed of attitudes which have high pitch level (e.g. “positive surprise” and “admiration”) and large pitch span (e.g. “question” and “doubt”); the other is composed of attitudes whose pitch level and pitch span are lower and narrower, (e.g. “declaration” and “politeness”). Such a higher and wider pitch span for surprise and admiration may be related to hypothesis of the “effort code” postulated by Gussenhoven [25]. A similar separation between the studied attitudes has been found in the perception experiment where the main distinction was observed between “assertive” attitudes and “interrogative” attitudes [6]. This observation implies an important role of F_0 in affective expression decoding. The attitudes regrouped in clusters 2 and 3 appear more homogeneous in terms of F_0 features, and that could help us to understand the perceptual confusions observed between “declaration” and some other “assertive” attitudes like “politeness” and “obviousness”, as well as the confusion between “disappointment” and “resignation”. Of course, some perceptual similarities remain unexplained with only these acoustic cues: for example, the confusions between “infant-directed speech” and “seduction”, “authority” and “irritation”. In these cases, one analysis of voice quality seems necessary, because voice quality, as the fourth dimension of prosody [26], is an important aspect of the affective expression.

The F_0 slope did not exhibit important difference across clusters, except for cluster 4 (“irony” and “intimacy”) which is distinguished by its highest value. All of the clusters are homogeneous in intensity register. Hence, we can summarise the salient prosodic features of each attitude cluster essentially in function of their F_0 and duration profile: the cluster 1 (“admiration”, “infant-directed speech”, “contempt” and “doubt”) shows a very long duration; on the contrary, the cluster 4 (“irony” and “intimacy”) shows the lowest duration values and the highest for F_0 slope. The cluster 5 (“positive surprise”, “negative surprise”, “neutral surprise”, “question” and “irritation”) is typically marked by large F_0 range and high F_0 level, while the cluster 2 (“authority”, “declaration”, “resignation” and “disappointment”) by lower F_0 values. Cluster 3 (“obviousness”, “seduction”, “politeness” and “confidence”) is characterized by low F_0 values and in particular the lowest F_0 slope.

Some differences inside clusters also deserve our attention: “infant-directed speech” shows the longest duration and “intimacy” the shortest duration; positive, negative and neutral surprises are marked by their high F_0 values while “resignation” and “disappointment” show the lowest F_0 values of all attitudes; “confidence” differs from the other attitudes of cluster 3 by lower F_0 values and a longer duration.

Another acoustic analysis about voice quality of the same audio samples is under way in order to investigate the potential influence of voice quality to the perception of the attitudes in question.

Abstract

In this paper we study the relationship between acted perceptually unambiguous emotion and prosody. Unlike most contemporary approaches which base the analysis of emotion in voice solely on continuous features extracted automatically from the acoustic signal, we analyze the predictive power of discrete characterizations of intonations in the ToBI framework. The goal of our work is to test if particular discrete prosodic events provide significant discriminative power for emotion recognition. Our experiments provide strong evidence that patterns in breaks, boundary tones and type of pitch accent are highly informative of the emotional content of speech. We also present results from automatic prediction of emotion based on ToBI-derived features and compare their prediction power with state-of-the-art bag-of-frame acoustic features. Our results indicate their similar performance in the sentence-dependent emotion prediction tasks, while acoustic features are more robust for the sentence-independent tasks. Finally, we combine ToBI features and acoustic features together and further achieve modest improvements in sentence-independent emotion prediction, particularly in differentiating fear and neutral from other emotion.
Index Terms: ToBI, emotion, automatic prediction

1. Introduction

Despite clearly perceived connection between emotional meanings and prosody, a satisfactory model linking the two has been elusive. Both prosody and emotion are complex phenomena and the adopted framework for their representation vastly influences the interpretability of discovered relationships between the two. The main question for prosody analysis in emotional speech research is how to represent the melody contour. Most research relies on continuous features extractable automatically from the acoustic signal for studying the relationship between emotions and prosody [10]. Discrete representations of prosody in the ToBI [20] or Tilt representations [21] on the other hand mark perceptually salient properties of the utterance tune.

Given that the nature of the precise mapping between the underlying phonological representation of intonation and its phonetic implementation is not known, such labeling might tap into a different type of information regarding the relationship between emotion and prosody. Mozziconacci [14] reviewed several studies including Scherer et al. [19] and Mozziconacci [13] arguing that both the representations of F0 contour using models traditionally considered phonological as well as those representing phonetic implementation of pitch in terms of levels and ranges, offer independent, and possibly additive information for the perception of emotions. Furthermore, Liscombe [12] explored the usefulness of categorical intonation labels in emotion classification in a subset of the EPSAT corpus [11], in which actors read 4-syllable semantically neutral phrases (numbers) in 15 emotions. Ten of the emotions balanced for valence (angry, anxious, bored, confident, encouraging, friendly, frustrated, happy, interested, and sad) plus a neutral utterance from 4 speakers (N=44 utterances) were then subsequently selected for rating of perceived level of emotion by 40 subjects. The relationship between ToBI labels and perceived emotion was then analyzed. Liscombe found a significant effect of pitch accent type on emotion rating for confident, happy, interested, friendly, and bored with L+H* accent showing the greatest disambiguation potential favoring the first five emotions and in general positive valence and high activation while disfavoring boredom. A plateau contour (H*H-L%) was associated with boredom and, in general, H-L% boundaries tended to be associated with negative affect while low boundaries (L-L%) were not.

In addition to the potentially relevant role of phonological description of contour, some studies on very short phrases have shown that knowledge gained from phonological coding of F0 is comparable to information obtained from phonetic features simulating this coding. For example, Benus et al.[4] reported correlation between the backchannel function of cue words and rising F0, which was reflected both in linguistic ToBI labels (H-H% boundaries) and in (stylized) pitch slope extracted over the entire token, its second half, or the last 200ms. These findings suggest that ToBI-like labels offer a feasible description of F0 contours for general analyses, as well as for data with low-quality audio signal.

Our interest in categorical representations of emotion in voice is also motivated by the huge success of such an approach in facial analysis of emotion. For emotion recognition in face, Darwin proposed that a cluster of discrete facial configurations (action units) (such as nostrils raised, mouth compressed, furrowed brow, eyes wide open) need to occur to facially express and interpret emotions [23]. His ideas were later further developed and widely promoted in Ekman's influential work [24], leading to the development of accurate systems for automatic detection of action units on the face [25]. Our interest is in asking if discrete "action units" in voice may similarly be related to emotion expression. A long-term goal would be to develop systems to detect such action units in voice and use them as the basis for emotion prediction, possibly in combination with standard low-level acoustic descriptors.

In this paper we present experiments on a dataset of 433 utterances conveying five basic emotions and manually annotated prosody in the ToBI framework. We analyze the distribution

of discrete prosodic labels in the emotion classes and find several prosodic markers of emotion. Then we present a series of machine learning experiments based on discrete representations of prosody, which have not been done in prior work where the dataset was usually too small to allow for learning. Finally we compare the predictive power of categorical ToBI features and conventional acoustic features, and further combine these two types of features together.

2. Emotional Data

Our data contains recording of emotional utterances produced by 91 professional American actors acting pre-selected sentences under the supervision of a director. The actors were asked to act out a given sentence in a specific target emotion until the director's approval. The dataset contains examples of six basic emotions (*anger, disgust, fear, happy, neutral, sad*) [8] on the following three sentences: [TAI] *The airplane is almost full.*; [TIE] *That is exactly what happen.*; [ITH] *I think I have a doctor's appointment.*

Each of the recorded utterances was classified by ten subjects as expressing one of the possible emotions. The dataset we analyze in this paper contains only utterances which were clearly recognized as the intended emotion by more than five of the of ten raters. We aimed to select 25 examples for each of the six emotions, for each sentence. If more than 25 candidates remained after the perception test, we selected the 25 examples with the highest human recognition rate. Otherwise all validated clear utterances were selected.[1]

3. Annotation of ToBI Labels

All stimuli for a given carrier sentence were randomized across emotions and no information about the emotion label was preserved. They were labeled by an experienced qualified annotator with linguistic and phonetic background, using the ToBI framework [3, 2] within Praat [5].

ToBI labels encode the underlying phonological representation of an utterance primarily in terms of perceived pitch targets (H)igh and (L)ow and disjunctures between words (breaks 0-4 from minimal to strong). Perceptually prominent syllables, primarily due to pitch excursions but also lengthening and intensity, are associated with pitch accents that could consist of single tonal targets (H, !H*, L*), or bi-tonal combinations, most commonly L+H*, L*+H, H+!H*; !H represent a target downstepped from a preceding H target, and "*" corresponds to the tone aligned with the stressed syllable. To provide a rough estimate of pitch range, ToBI includes HiF0 label that indicates the point of the highest F0 in a given intermediate or intonational phrase. For prosodic chunking, breaks 0 and 1 correspond to regular fluent word transitions, 2 to a perceived disjuncture with no salient tonal marking, 3 marks an intermediate phrase associated with H-, L-, or !H- targets, and 4 signals the strongest disjuncture corresponding to the intonational phrase boundary representing a combination of the three phrase accents, marked with dashes and listed above, and a L% or H% tone: H-H%, L-H%, etc. Only minimal adjustments to the ToBI guidelines were employed. Regarding the break indices, diacritics describing uncertainty and disfluency were not used since the nature of the data elicitation minimized these phenomena and we wanted to mitigate data sparsity. Additionally, break 0 was not used. The full set of tonal events was employed.

[1] Specifically there were 23 sad samples of TAI, 19 happy for TIE, 24 disgust and 17 sad for ITH. All other emotions and sentences are represented by 25 different stimuli each.

4. Pitch events across emotions

We now turn to our utterance-level analysis of categorical prosody cues for emotional speech. We consider five sets of ToBI features: types of breaks, intermediate phrase accents, boundary tones in the end of the utterances, pitch accents, and the position of HiF0 in the utterances. For each set of features, we compute the distribution of possible pitch events across different emotion. The results are shown in Table 1. For ease of comparison and interpretation, the first column lists the distributions on *neutral* speech, while the last column gives the average across six emotions. These can be interpreted as benchmarks, providing an insight on how speech associated with a particular emotion differs from neutral speech and the overall average.

The table shows that different emotion classes have different distribution of ToBI features. *Anger* and *disgust* utterances are more likely to contain salient disjunctures between words as shown by higher frequency of 2 and 3 breaks. In particular, *anger* and *disgust* utterances have higher occurrence of !H-L% and L- in the middle of utterance, respectively. Similarly, *fear* and *sad* are characterized by increase in the use of H-L%. *Neutral* utterances on the other had contain only H- intermediate phrasal tones. Hence, emotions with negative valence and high activation tend to be associated with utterances 'chunked' into more prosodic units despite their relatively short duration. This finding is in line with findings that perceived negativity of the word 'whatever' correlated with a prosodic boundary between the first two syllables [4]. Similarly, plateau boundary tones correlate with negative valence, which corroborates the findings discussed in section 1 [12].

Most of the examples in our data are uttered with declarative ending of L-L% final boundary tones. The exceptions are *fear* and *happy* and to a lesser extent also *sad*. They have fewer declarative endings of L-L% and are characterized by a somewhat higher rate of !H-L% and H-L% boundary tones. The association of !H-L% boundary with a positive valence *happy* has not been previously reported and is connected to emotional meaning of H*!H-L% contour that we discuss later.

Compared with *neutral*, emotional speech has more accented words, particularly for *anger*. We can also see the differentiation of emotions on pitch accent distributions. Apart from *neutral*, all other emotions have less occurrence of downstepped (!H*) pitch accents. *Fear* and *sad* have extremely high frequency of H* accents, while *happy, disgusted* and *fear* are associated with the use of L+H* accents. The L+H* association with *happy* and *fear* is a novel surprising finding given the observation of Liscombe's dataset [12] in which mostly positive valence emotion were associated with this accent.

Finally, emotions are very different in terms of the placement of the highest F0 in the prosodic phrase. For example, most of *neutral* and *disgust* utterances start with high pitch, while *fear* and *happy* utterances tend to have highest F0 in the end of the utterances. This HiF0 placement in these two emotion is another indication for the special status of extra-high last pitch accent associated with (L+)H*!H-L% contour for these two emotions, which we discuss later.

In addition to the analysis of individual ToBI labels, we also explore bi-grams of pitch accents. These capture the intonation contour of two concatenated accented words. Final boundary tones were also involved in the bi-gram analysis. Table 1 also lists the most frequent bi-grams in terms of pitch accents and

H*, !H-L%	0.0	1.3	4.1	14.7	18.8	6.2	7.40
H+!H*,L-L%	12.0	2.7	2.7	2.7	0.0	9.2	4.80

the combination of a pitch accent and a boundary tone.

Compared with the analysis of individual ToBI features, the bi-gram features give us insights of more global and contextual intonation patterns associated with emotions. For example, *fear* can be characterized by increased occurrence of two adjacent H* accents, *happy* and *fear* are associated with pitch accent of H*, followed by down-stepped !H-L% boundary in the end, while *anger* utterances are more associated with H* followed by low (L-L%) boundary. In general, bigrams support the observation about the tendency for avoiding down-stepped pitch accents in emotion speech compared to emotionally neutral speech. One note regarding H*!H-L% contour is that the target for H* pitch accent was commonly extremely high, which gave a particular contour especially for *happy* utterances. Since standard ToBI does not have a dedicated label for this situation, we could not determine if disambiguation between *happy* and *fear* might be facilitated with this additional information. In future work we can consider adaptations of ToBI for emotional speech which would account for this difference.

5. Classification with ToBI features

Our analysis clearly indicates that different emotions exhibit differences on discrete intonation patterns.Now we turn to investigate the effectiveness of these ToBI features for automatic emotion classification. No prior work has tested the applicability of ToBI labels for automatic prediction.

Each utterance is represented by 41 discrete prosodic features which are a combination of all sets of individual ToBI features and bi-gram features in Tables 1. We use SVM classifiers with radial basis kernel constructed using the LIBSVM library [7]. We performed one-versus-all emotion classification tasks: recognition of each of the six emotions versus the other five emotions. For example, one of the tasks was to recognize if an utterance conveys *anger* versus some other emotion among *disgust, fear, happy, sad,* and *neutral*. Since the number of utterances for class *all* is much higher than the one for the target emotion, we performed down-sampling to equal size classes.

To investigate the effect of the sentence structure and context information, we performed experiments on both within-sentence and cross-sentence classification. For the within-sentence classification task, one-versus-all emotion recognition was performed on each of the three selected sentences separately. We perform 10-fold cross-validation on all renditions of the same sentence in different emotions. There are about 145 renditions of each sentence. The accuracy of prediction for each sentence is shown in the top section of Table 2.

Table 2: *One-versus-all accuracy for ToBI features*

	NEU	ANG	DIS	FEA	HAP	SAD	Ave.
within-sentence classification rate (%)							
TAI	82.4	81.0	81.4	77.6	80.4	73.9	79.5
TIE	78.8	79.6	76.4	76.8	81.6	75.1	78.1
ITH	82.0	76.2	74.3	76.8	74.8	77.9	77.0
Ave.	81.1	78.9	77.4	77.1	78.9	75.6	78.2
cross-sentence classification rate (%)							
TAI	77.0	69.0	69.8	77.0	75.4	57.9	71.0
TIE	69.3	68.0	68.4	64.8	75.9	55.7	67.0
ITH	75.1	67.2	64.1	66.0	51.5	70.8	65.8
Ave.	73.8	68.1	67.4	69.3	67.6	61.5	67.9

The results show that the sentence-specific ToBI features represent a promising line of research for predicting the target emotion. The performance is reasonable on all emotions for all three sentences, with average classification rate of 78.2%. Interestingly at the same time there is a noticeable performance difference for different sentences. For instance, we obtain much higher classification rate of 80.4% and 81.6% on TAI and TIE respectively for *happy*, while the lowest one on ITH of 74.8%.

In our second set of experiments, we turn to the analysis of the cross-sentence performance of emotion recognition. Here we train the model on all data from two sentences and test on the data from the remaining sentence. The results are shown in the bottom part of Table 2, each row representing results when

the given sentence was used as a test set. Compared to the results of within-sentence prediction, cross-sentence accuracy degrades considerably, as can be expected. In contrast to the within-sentence validation, the average classification rate drops from 78.2% to 67.9% and we observe consistent degradation of around 10% on all emotions. This indicates that the ToBI features are highly related to the carrier sentence.

Neutral was the emotion for which classification rate was highest in both types of experiments. It was also the emotion for which there was least degradation in accuracy between the two types of experiments. This finding suggests that the intonation patterns in terms of ToBI features are more robust on *neutral* utterances than on sentences expressing emotions. The worst performance in both experiments is on *sad*, which further corroborates the complex nature of emotions with low-activation.[2]

6. Classification with Acoustic Features

To compare the prediction power of categorical prosody cues and conventional bag-of-frame acoustic features for emotion classification, we conduct similar 1-vs-all emotion classification experiments with a set of state-of-the-art acoustic features.

We use the openSMILE feature extraction library [9] to obtain a comprehensive set of standard acoustic features. The openSMILE library extracts 26 low-level descriptors including intensity, loudness, F0, F0 envelope, probability of voicing, zero-crossing rate, 12 MFCCs, and 8 LSFs. We also use the first order delta coefficients for these features, as well as 19 summary functions for a total of 988 features.

Table 3 lists the corresponding performance of acoustic features in the within-sentence and sentence-independent emotion classification tasks. In the within-sentence emotion classification tasks with conventional acoustic features achieved average accuracy of 78.5%, which is comparable to the 78.2% we obtained with ToBI features in Table 2. However, the prediction power of acoustic features and ToBI features vary among different emotions. For instance, acoustic features show the highest prediction power on *anger*, while ToBI features work better on differentiation of *neutral* and emotional utterances.

Unlike ToBI features, raw acoustic features appear to be less sensitive to the carrier sentence and lead to practically identical accuracy on within- and cross-sentence prediction.

Table 3: *Classification rate of one-versus-all emotion classification using acoustic features.*

	NEU	**ANG**	**DIS**	**FEA**	**HAP**	**SAD**	Ave.
within-sentence classification rate (%)							
TAI	77.0	90.2	72.6	70.2	68.2	79.3	76.3
TIE	84.6	90.0	72.6	74.6	80.0	84.0	81.0
ITH	76.4	90.0	76.2	76.2	71.8	79.4	78.3
Ave.	79.3	90.0	73.8	73.7	73.3	80.9	78.5
cross-sentence classification rate (%)							
TAI	75.4	89.1	71.4	77.4	79.0	77.2	78.3
TIE	87.7	90.6	73.4	67.6	77.6	77.9	79.1
ITH	81.3	88.8	75.1	69.7	78.4	77.4	78.5
Ave.	81.5	89.5	73.3	71.6	78.3	77.5	78.6

[2]In experiments that fall out of the scope of this paper, we also conducted experiments with automatically derived ToBI annotation using AutoToBI [17]. The classification results were poor, and the most predictive ToBI features were practically never recognized correctly, probably because of their rare occurrence in the non-emotional data on which the system is trained.

Finally, we turn to discuss the combination of acoustic and categorical prosodic cues for emotion classification. We apply early stage feature fusion and train SVM classifiers with one feature vector concatenating ToBI features and acoustic features. We consider the sentence-independent task and list the corresponding emotion classification performance of the fusion classifiers in Table 4. Compared with the best single classifiers with standard acoustic features, we can obtain modest improvement by including categorical prosodic ToBI information, where the final average classification accuracy increases from 78.6% to 79.3%. The combined feature representation does achieve noticeable improvement on *neutral, fear,* and *anger*, which is consistent with what we found in cross-sentence results in Table 2 that ToBI features also show higher prediction power on these three emotion classes.

Table 4: *Classification rate of one-versus-all emotion classification by fusion of acoustic and ToBI features*

	NEU	**ANG**	**DIS**	**FEA**	**HAP**	**SAD**	Ave.
sentence-independent classification rate (%)							
TAI	78.2	89.1	71.0	78.2	78.6	75.6	78.5
TIE	88.5	93.0	73.4	69.3	76.0	77.9	79.7
ITH	83.8	88.8	75.1	71.4	81.3	78.2	79.8
Ave.	**83.5**	**90.3**	73.2	**73.0**	78.6	77.2	79.3

7. Conclusions

We have presented a study of the relationship between prototypical emotion expression and discrete, perceptually based characterization on prosody. Our corpus is much larger than any of those used in prior work addressing a similar question. We show promising results both in descriptive and predictive power of ToBI features. Our findings reveal targets for continuous feature extraction that can capture the relevant prosodic phenomena.

In addition, we compare the prediction power of categorical prosodic ToBI features with state-of-the art bag-of-frames acoustic features. We find that ToBI features and acoustic features show comparable performances on within-sentence emotion predictions. Unlike ToBI features, conventional acoustic features are very robust to different carrier sentences. It is nevertheless notable that the much smaller and interpretable set of ToBI features conveys rich information about emotional state.

Finally, we achieved further improvements by integrating ToBI features and acoustic features. This suggests that categorical prosodic ToBI representations can provide complementary information to the conventional acoustic features in prediction of emotion. Our work presents evidence that discrete characterizations of intonation have the potential to inform future feature development for emotion recognition and may lead to overall improved performance.

"Young" and "Old" Voice: the prosodic auto-transplantation technique for speaker's age recognition

Massimo Pettorino, Elisa Pellegrino, Marta Maffia

Abstract

The present study is intended to figure out the extent to which prosody and intonation affect listeners' ability to estimate the speaker's age. The performance of a 40-year old anchorman and another by the same speaker at the age of 80 were spectro-acoustically analyzed in order to identify the prosodic features of a "young" and an "old" voice. The results of the analysis have shown significant differences between the two voices on a suprasegmental level. To test the effects of these differences on a perceptual level, through the prosodic transplantation technique, the F0 values and the durations of segments and silences were transferred from the "young" to the "old" voice and viceversa. Two age recognition tests, based on original and transplanted voices, were administered to Italian listeners. The results of perceptual tests have confirmed the strict relationship between some rhythmic and prosodic features and the speaker's age and have demonstrated the effectiveness of the transplantation technique. With advancing age, articulation rate and speech rate slow down, voice register rises and tonal range widens. Moreover, the "old" voice is also characterized by a higher percentage of vocalic portion which determines a shift of the Italian rhythm towards the isomoraic pattern.

Index Terms: Prosodic correlates of speaker's age, Speaker's age recognition, Prosodic Transplantation Technique.

1. Introduction

The relationship between the speaker's age and his/her own voice has been investigated in several experimental studies. Acoustic [1], [2], [3] and perceptual researches [4], [5], [6] have underlined that the voice changes with age, at both segmental and supra-segmental levels, because of the numerous anatomical and physiological modifications of the respiratory mechanism and of the phonatory apparatus. For example, lung tissue loses its elasticity, the thorax tends to stiffen, muscles weaken and vital capacity decreases [7]. In the elderly, a process of calcification of laryngeal cartilages also occurs and the vocal folds become thinner, stiffer and less elastic [8]. Previous studies on the effects of aging on acoustic parameters of voice have demonstrated that older voices are likely to undergo progressive tonal lowering [9], lowering of speech rate [10], [1], increasing of jitter and shimmer [8], [11], [12], lowering of formant frequencies [13], lengthening of vowels and stop consonants [14], increasing of standard deviation of F0 [13], [15], [16].

Nevertheless, it is important to underline that these data result from studies that analyze different kinds of corpora (spontaneous or read speech), use different techniques of speech data collection and involve different languages [2]. The considerable methodological heterogeneity across these kinds of studies certainly does not guarantee that the changes undergone by older voices are dependent exclusively on the speaker's age. Besides the chronological age, other relevant variables, such as the idiosyncratic characteristics of a speaker's voice, the contextual situation, the kind of speech and the subject matter could influence the oral performance of the speakers and affect data comparability.

In order to control all these variables, and thus, to be able to exclusively assess the effect of aging on the acoustic parameters of voice, it would be very effective to record the same speakers uttering the same words in the same communicative situation, but at different ages.

2. The study

The objective of this study is to verify the role played by prosody and intonation in the listener's ability to evaluate the speaker's age. To achieve this, a particular corpus of Italian speech was collected. The read speech of a 40-year old anchorman, Piero Angela, was extracted from a 1968 TV news broadcast and orthographically transcribed. In 2007, the 79-year old Piero Angela, who still worked as a RAI journalist, read the same 1968 script again, acting as if he were hosting a real TV news broadcast. The recording was taken at RAI TV studios in Rome, in order to maintain the same communicative situation.

Preliminary spectro-acoustic analyses conducted on the 1968 and 2007 corpora showed differences between the two voices, both on the segmental and suprasegmental levels [17]. The "old" speech was clearly more isochronous, exhibited wider tonal range and presented longer and more frequent silent pauses than the "young" voice.

In order to investigate further the role played by the specific acoustic parameters of the "young" and "old" voices, three utterances drawn from the 1968 TV news broadcast and the corresponding utterances of the 2007 corpus were manipulated through the prosodic transplantation technique. This procedure is based on the PSOLA (Pitch-Synchronous Overlap and Add) algorithm and it is implemented in Praat [18], [19], [20]. The six utterances were segmented and annotated into four tiers:

- phones
- syllables
- intervals of consecutive consonants and vowels
- intervals between two consecutive vowel onset points (VtoV).

In order to apply the transplantation procedure, the "phones" tiers were duplicated and modified, so that each segment of the 1968 utterance had a corresponding segment in the 2007 utterance. Since the transplantation procedure requires that the TextGrids of donor's and receiver's voices contain the same number of elements [21], a micro segment was inserted to avoid mismatch between the 1968 and 2007 utterances. Thanks to the transplantation procedure, the rhythmic and prosodic features of the donor's voice were

transferred to the receivers' voice. As a result, in the present study, the utterances produced in 1968 by the 40-year old Piero Angela were made sound "older" by transferring the pitch contour on them, the durations of phones and silences of the corresponding 2007 utterances. By contrast, the latter were made to sound "younger" since they acquired the prosodic features of the 1968 utterances.

The resulting corpus was, thus, made up of three original utterances produced in 1968, three original utterances produced in 2007, three 1968 utterances with 2007 prosody and three 2007 utterances with 1968 prosody.

2.1. Perception test

In order to assess on a perceptual level the effect of the acoustic differences between the "old" and "young" voices, 70 university Italian students, ranging in age from 23 to 26, were administered a perception test. Following the experimental protocol used in a previous research [6], the test was divided into two main phases. In the first phase, participants listened to 16 pairs of utterances. Each pair was composed of two voices reading the same news. For each pair, listeners were asked to rate if the youngest speaker was the "1st voice" or the "2nd voice", or if the two speakers were of the "same age". The test was designed with the following voice combinations:

- 2007 voice - 2007 voice (Old –Old; henceforth O-O);
- 1968 voice -1968 voice (Young-Young; henceforth Y-Y);
- 2007 voice – 1968 voice (O-Y);
- 1968 voice - 2007 voice with the transplanted prosody of 1968 voice (Y-tY);
- 2007 voice - 2007 voice with the transplanted prosody of 1968 voice (O-tY);
- 1968 voice - 1968 voice with the transplanted prosody of 2007 voice (Y-tO);
- 2007 voice - 1968 voice with the transplanted prosody of 2007 voice (O-tO);
- 2007 voice with the prosody of 1968 voice – 1968 voice with the prosody of 2007 voice (tY-tO).

The test material also included a control pair (cO-cY), consisting in a 85 year-old voice and a 27 year-old voice reciting the same utterance: "le foglie diventano gialle, l'albero muore" (Engl. "when the leaves turn yellow, the tree dies"). In the second phase of the perception test, the same subjects were asked to listen to 14 single utterances and to indicate the speaker's age, choosing between seven age bands: 26-35, 36-45, 46-55, 56-65, 66-75, 76-85, 86-95.

2.2. Results of perception test

2.2.1. First test

Overall results of the perception test show listeners' ability to accurately recognize the speaker's age from speech sample alone. As a matter of fact, when exposed to the pairs based on the same voice O-O, Y-Y, these pairs are properly rated as being of "the same age", respectively in 100% and 96% of cases. When the pairs were composed of the 2007 voice and the 1968 voice (O-Y), 84% of listeners rate the second voice as the youngest.

The results obtained by the pairs composed by original and transplanted voices confirm the role of prosody and intonation in the perception of speaker's age. At the same time, the listeners' judgments highlight the effectiveness of the prosodic transplantation technique in making voices sound "older" or "younger". As for the aging effect, it was tested both with respect to the 2007 "old" voice and to the 1968 "young" voice (figs 1 and 2). As it is shown in figure 1, when the aged voice (tO) was paired with the original old voice (O), on average, the 60% of listeners judged the two items as being of the "same age".

Comparing the rates given to the O-tO pair with those assigned to the O-Y pair, the percentage of the answer "2nd voice" decreases from 84.2% to 30.8%, while the answer "same age" increases by about 50%, from 13 to 60.3%.

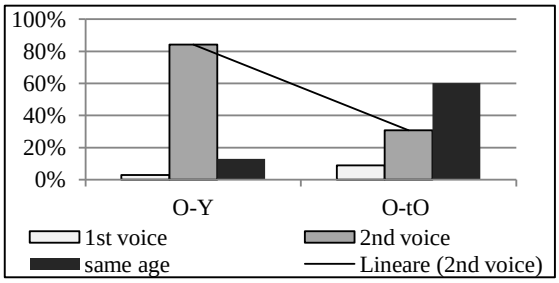

Figure 1: Aging effect with respect to the 2007 old voice. The rates given to pairs O-Y and O-tO are significantly different ($p<0.01$).

The data in figure 2 show the results obtained from the comparison between the young and the aged voice (Y-tO). 60% of listeners rate the "1st voice" as the youngest. The aging effect is particularly evident if one compares the answer "same age" obtained with the Y-Y pair and that of the Y-tO pair. In the former case, the third option is chosen by 96.8% of listeners, while in the latter, this percentage decreases to 38%.

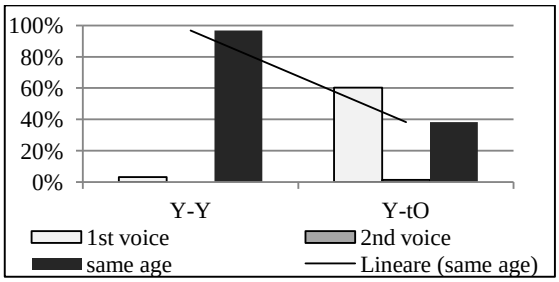

Figure 2: *Transplantation effect with respect to the 1968 young voice. The rates given to pairs Y-Y and Y-tO are significantly different ($p<0.01$).*

As regards the effect of making the voice sound "younger" (fig. 3), it is possible to claim that it produces changes in the "old" voice but its influence on listeners is not as effective as the aging effect. In the pair O-tY, the transplanted voice is recognized as the youngest by the 31.8% of listeners.

The data in figure 4 show that the rates given to the two pairs Y-O and Y-tY do not undergo a significant variation ($p>0.05$). However, in the Y-tY pair the percentage of "1st voice" decreases from 84.2 to 67. By contrast, the percentage of "same age" increases from 13 to 20.5 and in 11.5% of cases the synthesized young voice is even recognized as the youngest. In the pair composed of both transplanted voices,

tY-tO, 56% of listeners judge it as if it was composed of voices of the same age.

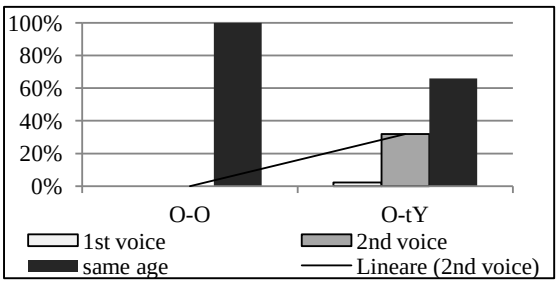

Figure 3: *Transplantation effect in respect to the 2007 old voice. The rates given to pairs O-O and O-tY are significantly different (p<0.01)*

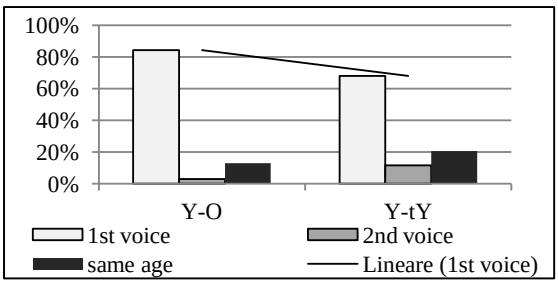

Figure 4: *Transplantation effect in respect to the 1968 young voice.*

2.2.2. Second test

In the second perception test, listeners were asked to estimate the speaker's age, choosing from 7 age bands. The data in figure 5 show that the young control voice (actual age 27) is recognized as belonging to the first age band (26-35) by 98% of listeners; while the control old voice (actual age 85) is judged by the 60% as ranging in the band 76-85. On a perceptual level, the 1968 voice varies from the 2nd to the 4th band, with the highest percentage of rates given to the 3rd band (46-55). On the contrary, the rates given to the 2007 voice are distributed on higher age-bands (4-6), with 44% of listeners choosing the 5th band.

As for the synthesized voices, they occupy an intermediate position between the original young and old voices. The age bands chosen by the highest number of listeners were the 4th and the 5th. These results indicate that the prosodic transplantation technique had a strong effect on the recognition of speaker's age in both directions: the aged voice is perceived as older than the original 1968 voice, as well as the synthesized young voice being rated as younger than the original old voice. From the data relative to the age bands, the weighted average of the perceived age was calculated, taking into account the recognition percentage scored by each band. Figure 6 plots the perceived and actual ages of the original, control and transplanted voices. The comparison between the perceived and actual ages of the speakers suggests different considerations. First of all, the variance between the two original voices decreases from the actual 40 years to perceived 20 years. The manipulated voices are perceived as produced by 66 and 65-year old speakers respectively.

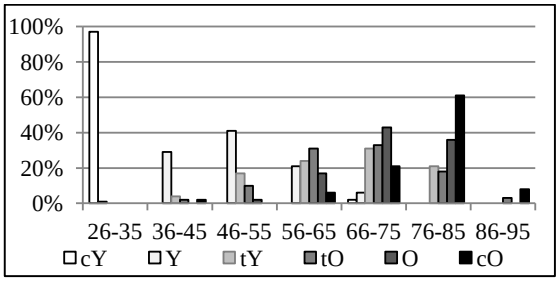

Figure 5: *Perceived age of control, original and transplanted voices.*

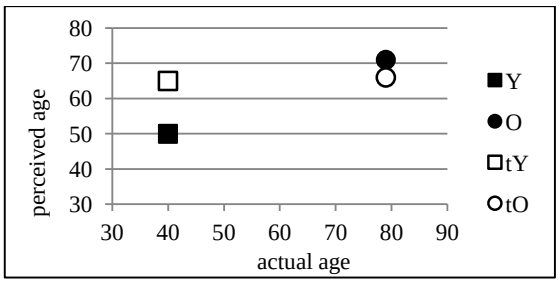

Figure 6: *Perceived and actual age of the original and transplanted voices.*

2.3. Spectro-acoustic analysis

The results of perception have shown that the 70 subjects were able to accurately judge speaker's age relying solely on single voice excerpts. This datum leads us to assume that the perception of the speaker's age is greatly influenced by the prosodic and intonational features of the utterance. To test this hypothesis, the whole corpus was spectro-acoustically analyzed. On the basis of the speech segmentation in phones, syllables, vocalic and consonantal intervals, VtoV intervals, the following measurements were taken: duration of phones, syllables, silent and filled pauses, length of vocalic and consonantal intervals, duration of VtoV intervals. Additionally, for every utterance the minimum, the maximum and the mean F0 values were measured.

On the basis of these measurements, the following rhythmic and prosodic parameters were calculated:

- articulation rate (AR) (syll/s.), i.e. the ratio between the number of syllables really uttered and phonation time;
- speech rate (SR) syll/s), i.e. the ratio between the number of syllables really uttered and total time of the utterance, including silent and non silent pauses;
- fluency (F) or frequency of silences in the utterance;
- tonal range (Hz);
- F0 register (Hz);
- speech time composition in terms of syllable, silence and disfluence percentage;
- utterance composition in terms of vocalic and consonantal percentage (%V and %C);
- mean duration of VtoV intervals (s).

In order to figure out which of the above-mentioned prosodic parameters could have influenced the listener's discrimination between the "young" and the "old" voice more

profoundly, for every prosodic parameter the average values obtained in the 1968 corpus and 2007 corpus were calculated.

Table 1 shows the data regarding AR and SR. Unsurprisingly, the 2007 voice exhibits a decrease both in terms of AR and SR, due to the slower mobility of the articulators. However in both the 1968 and 2007 voices, the SR is 0.8 syll/s slower than AR, and this is imputable to the same portion of silent pauses (13%) occurring in the two corpora. It is worth underlining that, despite the duration of the silent portion being stable between the two voices, the frequency of silences increases considerably with advancing age: in 1968 silences are more rare, on average 1 out of 14 syllables, while in 2007 they are more frequent, 1 out of 7.6 syllables.

Table 1. *AR and SR.*

	AR	SR
1968	6.3	5.5
2007	5.4	4.6

As for pitch contour, figure 7 shows that with advancing age the voice register and tonal range become higher. In the 2007 voice the average pitch reaches 146,8 Hz, while it is lower in the 1968 voice (68 Hz). The tonal range widens by about 17% from 1968 to 2007.

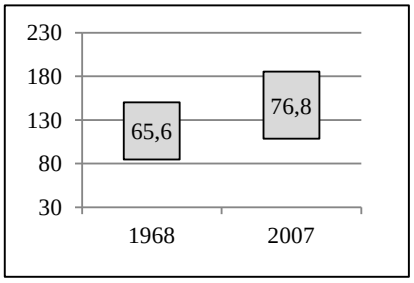

Figure 7: *Tonal range and Register*.

The other parameter under investigation was the vocalic and consonantal percentage in the utterance. Likewise the pitch movements, as well as the vowel percentage in the utterance increases with advancing age. In the corpus produced when Piero Angela was 40 years old, the vocalic portion amounts to 46%, while in the speech of the 80-year old speaker it reaches 51%. This datum enables us to clarify the components – vowels rather than consonants - on which the AR slowing down mostly depends. This phenomenon can be explained by the greater articulatory stability that characterizes vowels rather than consonants. The AR slowing down is, therefore, mainly due to the maintenance of static positions rather than to a variation of articulatory dynamics.

The variations of vocalic portion deserve more attention since this parameter plays a significant role in the rhythmic classification of languages. Indeed, according to a number of studies conducted on different languages, the traditional division in three rhythmic groups (syllable, stress, mora-timed languages) is related to vowel percentage and to another parameter, that according to [22] corresponds to ΔC (standard deviation of consonantal portions) and according to [23] to VtoV. In order to process the data of this corpus in the research framework of rhythmic organization of languages, the average %V and VtoV values obtained in Piero Angela's corpus were plotted with the ones obtained by [23]. Figure 8 shows the overall data relative to the different corpora. As it is clearly shown in the graph, the utterances produced by the 40-year old speaker lie in correspondence to the Italian TV news broadcast. On the contrary the mean VtoV and %V values of the utterances produced by the 80-year old speaker move to the right side of the graph, in the area occupied by Japanese, a mora-timed language. Thus, with advancing age, Italian speech seems to assume values more similar to mora-timed languages.

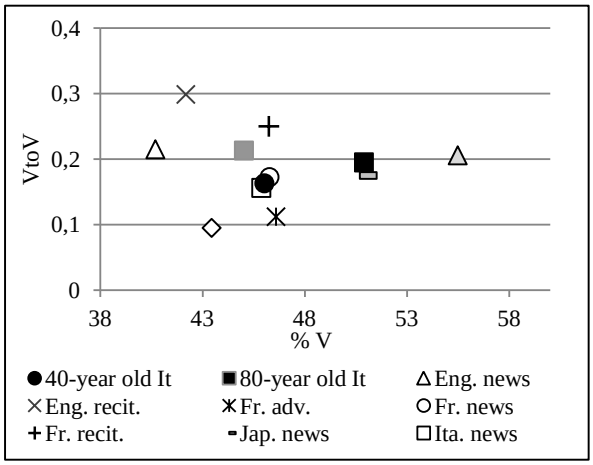

Figure 8: *%V and VtoV of different languages*.

This datum does not contrast the results of the above mentioned studies on the rhythmic features of languages, since neither the speakers involved in [22] nor the ones considered in [23] were 80 years old. Preliminary data on the speech produced by Japanese speakers of different age seem to confirm the trend which emerged for Italian: %V increases with advancing age (from 50.7 to 55.4%).

3. Conclusions

The spectro-acoustic analysis carried out on the corpus of read TV news broadcasts, produced by the same speaker at the age of 40 and 80 has demonstrated the existence of a relation between some rhythmic and prosodic features and the speaker's age. The old voice was characterized by a slowing down of AR and SR, by the rising of voice register and the widening of tonal range. The old voice also presents a higher percentage of vocalic portion (%V), and this increase makes Italian rhythm become more similar to the pattern of isomoraic languages. Thanks to the prosodic transplantation technique, the effect of these differences on a perceptual level was assessed. The judgments given to the transplanted voices suggest different considerations. Firstly, listeners are able to recognize the speaker's age relying solely on specific prosodic features. Secondly, on a perceptual level, the aging effect is more effective than that of making voices sound younger. In addition, the transplantation technique is therefore an effective procedure to the purpose of manipulating a speaker's age.

The data regarding the %V increase with advancing age suggesting the opportunity to extend the research on other languages belonging to other rhythmic groups.

Abstract

In this paper, we propose to compare expressive and neutral oral renditions of a children's tale in French by examining the segmentations performed by twelve high level French readers. We used a software dedicated to this kind of analysis (Analor) which takes into account different parameters (pause, pitch gesture, pitch jump) and their relative strength to determine pertinent prosodic units (phrases). The extraction of these phrases and their features enables us to observe the influence of both the type of oralisation (expressive or neutral) and punctuation signs on the organization of speech flow. Results show there are more prosodic phrases in the expressive readings (specially at comma locations), that their boundaries are more clearly demarcated, and that they have more varied contours than in neutral readings.

Index Terms: expressive prosody, neutral prosody, narrative, oral segmentation, phrasing

1. Introduction

Vocal expressivity, which we define as the capacity to express feelings, intentions and attitudes, is an important issue for research on oral communication and lies at the interface of computational linguistics, phonetics and psycholinguistics [1]. A number of prosodic resources can be used to impart expressivity to written text. [2] Some of these are universal features of all languages (variations in melody, rhythm and intensity, etc…) while others are language-specific (the nature of the variations, the use of melodic rather than temporal cues or vice versa). We focus in this paper on the prosodic process of grouping and phrasing in French performed by readers in a narrative task during a controlled study of oralized reading (Section 2). The aim of this study was to measure the variations in phrasing and prosodic grouping, and the nature of their correlation with punctuation signs[1], which distinguish two modes of oralisation, a neutral reading and an expressive reading.

Several studies confirm the influence of punctuation in the marking of breaks in oralized text [3], [4] and the variable durations of these breaks according to the type of punctuation sign [5] or the level of closeness of the sequence [6], [7]. However, other studies highlight the role of vocal expressiveness in the placement of these breaks, produced sometimes in places not oriented by punctuation marks or by discourse structure, but rather by the emotional qualities of the text [8], [9], [10]. Reading aloud is an activity which requires an emotional and physical involvement on the part of the reader [11], and we may assume that the structuring of breaks and intonation groups varies according to the degree of this involvement.

It is thus relevant to question the role of vocal expressiveness in the processes of segmentation in reading. Would the prosodic structuring of a text be less marked by readers who've been asked to read a story in a neutral manner ?

To answer this question, we tested 3 hypotheses: i) the number and location of phrase boundaries should be greater in the expressive reading condition; ii) the relative strength of phrase boundaries should be greater in the expressive condition; and iii) expressive reading should involve more pitch variation, i.e. specific contour types.

2. Corpus

2.1. Participants and task

Participants were 12 adults (6 men and 6 women ranging from 20 to 55 years in age) who considered themselves to be 'good readers'. They were asked to read aloud a children's tale (*the laughter of the frog* – 426 words, 23 full stops, 42 commas) in two styles: an expressive style, varying the tone of voice to convey emotion, and a neutral one, i.e. without expressing emotion.

(…) Dans sa folie des grandeurs, la grenouille avait asséché toute la planète. Les êtres vivants mourraient de soif et commençaient à suffoquer. (…)

Example 1.*Text extract from the tale*

The text was presented on a white sheet of paper in a single block, without paragraph breaks. Each reader was given the time he/she needed to familiarize him/herself with the tale and once he/she was ready, performed each of the 2 tasks (reading styles) as often as necessary until he/she was satisfied. The readings were recorded by means of a digital audio device (Roland BR600) with a sampling frequency of 44.1 kHz. The final corpus included 24 recordings (12 neutral readings and 12 expressive readings) with a total duration of 62 minutes.

2.2. Prosodic Segmentation

Each sample was segmented semi-automatically into prosodic phrases with the help of a software program called Analor[2] based on a method that has previously been tested [12]. The algorithm used by Analor is based on a global and multiparametric approach. The segmentation procedure is as follows: only melodic variations in time and breaks are used for segmentation into phrases, regardless of any segmental and syntactic data. Each break of at least 0.1 sec. is assigned a

[1]These markers co-exist with others (such as intonation contour variation, prototypicality of contours, melodic and tempo variation or vocal quality). They are considered easily observable indices for a model of vocal expressivity that precedes the phonetic level of analysis.

[2]http://www.lattice.cnrs.fr/analor

temporary marking and becomes a potential candidate for a phrase boundary. A break is a necessary but not a sufficient marker to locate a potential phrase boundary. In other words, the approach is global because the localization of a boundary can be envisaged only with respect to the combination of several parameters. Two other criteria are also used: (i) the detection of an ample melodic gesture; the trait [±ample] is fixed according to the melodic interval, measured in semitones, between the last extreme F0 value (before the boundary break) and the average F0 over the whole segment preceding the break; and (ii) the detection of a melodic jump which corresponds to the melodic interval which separates the points of F0 before and after the break (melodic resetting). An interesting characteristic of the algorithm is that the decision to place a boundary and its relative strength do not depend on the thresholds of each parameter taken independently but on the interaction between a set of parameters (Table 1, Figure 1).

PAUSE (seconds)	GESTURE (semi tones)	JUMP (semi tones)	Strength of parameter
x < 0,25	x < 2	x < 2	- 1
0,25 < x < 0,6	2 < x < 5	2 < x < 3,5	0
0,6 < x < 1	5 < x < 8	3,5 < x < 7	1
1 < x	8 < x	7 < x	2

Table 2.*Grid of the parameter values used to segment speech into phrases. The strength of the phrase boundary depends on the sum of the strength of each parameter. Each potential phrase that has a general index ≥ 0 must be validated by the experimenter.*

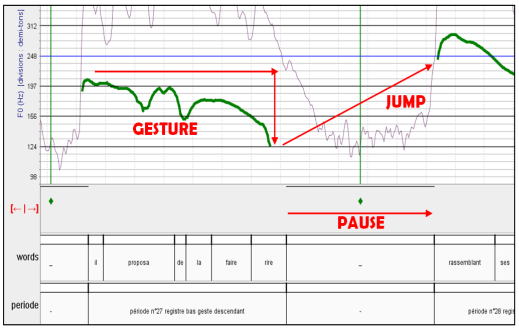

Figure 1: Screenshot of the software Analor and schematization of the criteria used for phrase segmentation

3. Data analysis

3.1. Analysis criteria

The comparisons between expressive and neutral readings were conducted, first, on the basis of the number of phrases produced by the subjects in the readings. We also compared the readings with regard to phrase boundaries taking into account text-based punctuation signs, i.e. 23 full-stops (excluding the final stop) and 42 commas. The tale contains 5 other punctuation marks, but these were excluded from analysis. The relative strength of phrase boundaries was also compared across all of the renditions, taking into account the punctuation signs. Finally, we quantified various types of general contours of phrases, according to the contour description provided by the Analor algorithm (flat, rise, fall). The contour of a phrase is considered flat if the amplitude of the gesture does not reach a minimal threshold (2 semitones (Table 1)) and it is considered as rising or falling if the absolute value of amplitude exceeds the given threshold.

Given the size of our sample, the non parametric Mann Whitney test was used to compare the averages.

3.2. Number and location of phrases and phrase boundaries

Figure 2 shows that, on average, readers produced many more phrases in the expressive reading (m=55.16, sd = 14.10) compared with the neutral reading condition (m=33.16, sd = 10.65). This difference is significant (U=11, p< 0.001). When we take into account the location of phrases and their correspondence with punctuation marks, it appears that full-stops almost systematically correlate with prosodic phrase boundaries in both conditions (m(exp) = 21.91, sd = 0.28, et m(neu) = 20.16, sd = 1.40). However, we find a significant difference between the expressive and neutral renditions at the comma level (U = 14, p< 0.001). The boundaries afforded by this punctuation mark are much less respected in neutral reading (m=8, sd = 6.68) than in expressive reading (m=21.66, sd = 7.61). Lastly, participants marked on average a slightly higher number of boundaries at unpunctuated locations in expressive reading (m=7.25, sd = 7.67) that in neutral reading (m=2.16, sd = 3.35) but this difference is not significant (p = 0.07).

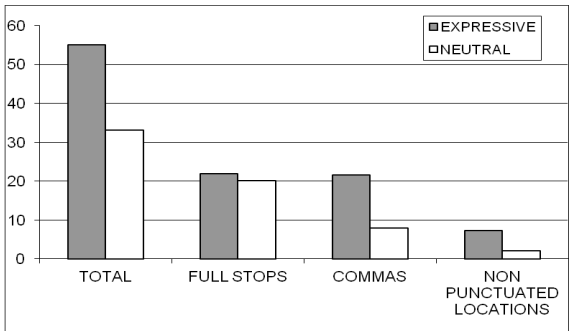

Figure 2: Mean number of phrases produced according to the versions and with respect to their locations

3.3. Strength of phrase boundaries

Based on the multiparametric index of boundary strength provided by Analor, it appears that the marking of boundaries is significantly stronger in the expressive readings (Figure 3) for all phrases (m(exp) = 2.40, sd = 0.46 and m(neu) = 1.41,sd = 0.54, U = 15, p< 0.001), with regard to full-stops (m(exp) = 2.83, sd = 0.63 and m(neu) = 1.65, sd = 0.66, U = 16, p < 0.01), and with regard to commas (m(exp) = 2.15, sd = 0.59,and m(neu) = 0.67, sd = 0.54, U = 4, p< 0.001). In both versions, boundaries are more strongly marked at full-stop locations than at comma locations (U(exp) = 31, p< 0.05 and U(neu) = 19, p< 0.01).

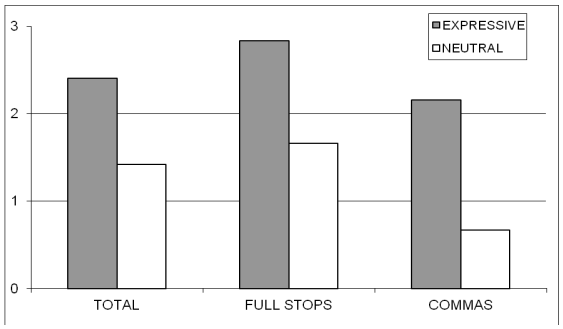

Figure 3: Mean index of cut strength according to the versions and with respect to their locations

3.4. Phrase contours

As shown in figure 4, the mean proportions of contour types are different in the two conditions. A higher proportion of flat contours is produced in neutral reading (m(exp) = 0.19, sd = 0.11, and m(neu) = 0.48,sd = 0.28,U = 26.5, p< 0.01), whereas a higher proportion of rising contours is produced in expressive reading (m(exp) = 0.17, sd = 0.12,and m(neu) = 0.04, sd = 0.05, U = 29.5, p> 0.05). Furthermore, a higher proportion of falling contours is produced in expressive reading, but this difference is only a trend (m(exp) = 0.63, sd = 0.12, and m(neu) = 0.46, sd = 0.27, p = 0.15).

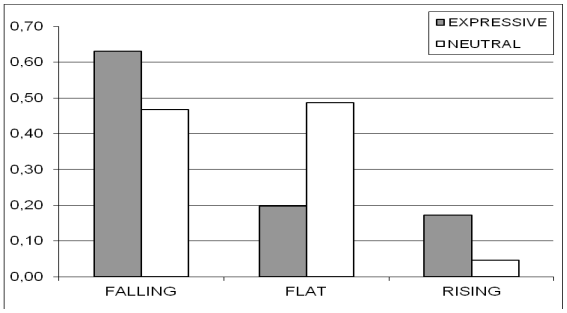

Figure 4: Mean proportions of contour types in the two versions

4. Conclusion and discussion

The aim of this study was to compare the prosodic grouping processes involved in expressive and neutral reading.

Our findings reveal a set of general factors that determine phrase segmentation in both conditions. Phrase boundaries, for instance, essentially coincide with punctuation marks and the full-stop is almost always a phrase boundary indicator. With regard to the strength of boundary markers, full-stops more frequently entail a segmentation than commas. This set of results was highly predictable as it illustrates the facilitative role of punctuation in segmenting a text into semantic units during oralisation. In addition, more than 45% of the phrases produced by the readers have a falling contour in both conditions. The high proportion of this contour type can be explained by the natural phenomenon of declination associated with the assertive modality of most of the clauses in the text.

However, our findings reveal a number of interesting differences between the expressive and neutral renditions of the text. It appears, first, that half of the commas give rise to prosodic boundary markers in the expressive condition as opposed to a little less than a quarter in the neutral reading condition. Readers thus use punctuation as a resource for conveying meaning and emotion in the oral rendering of written text. Furthermore, boundaries are more clearly marked (in terms of strength), whether they coincide with full-stops or commas, in the expressive reading condition.

These two observations point to a general principle associated with neutral reading, that of a minimal segmentation into prosodic units. The more frequent and marked segmentation in expressive reading, which we find in other genres such as political speeches, oratory or sermons, suggests that rhythm is used in oral discourse to support intersubjective engagement and emotional bonding. In effect, the neutral style can be considered an artefact of the experimental situation, and to be ecologically invalid, especially in a narrative genre where the plot itself pushes the reader to tell the story with emotion[1]. For this reason, the major implication of our findings is that expressive segmentation should be treated not in binary terms but rather as a continuous process of combining variable prosodic features.

Finally, the low frequency of flat contours in expressive reading compared to neutral reading shows that the prosodic structure of a text is made richer and more contrasted in the expressive rendition. These features may then facilitate the on line processing of prosody by the receiver and, it can be hypothesized, its comprehension and memorization. Further research should be undertaken to test this idea.

[1]Because lexical and syntactic properties of text carry intrinsic expressivity independently of prosody [13].

Challenges for Robust Prosody-based Affect Recognition

Heather Pon-Barry, Arun Reddy Nelakurthi

School of Computing, Informatics, and Decision Systems Engineering
Arizona State University, Tempe, Arizona, USA
ponbarry@asu.edu, anelakur@asu.edu

Abstract

Prosody-based affect recognition has great potential impact for building adaptive speech interfaces. For example, in intelligent systems for personalized learning, sensing a student's level of certainty, which is often signaled prosodically, is one of the most interesting states to interpret and respond to. However, robust uncertainty recognition faces several challenges, including the lack of gold-standard labels, and differences in expressivity among speakers. In this paper we explore the intersection of these two issues. We have collected a corpus of spontaneous speech in a question-answering task. Three kinds of certainty labels are associated with each utterance. First, speakers rated their own level of certainty. Second, a panel of listeners rated how certain the speaker sounded. Third, an externally crowdsourced difficulty score is generated for each stimulus (the question). We present a word-level prosodic analysis of individual speaking styles, as they relate to these three different measurements of certainty. Our results suggest that instead of learning one-size-fits-all prosodic models of affect, we might find improvement from learning multiple models corresponding to different speaking styles.

Index Terms: Uncertainty, affect recognition, affect labels, speaking style.

1. Introduction

An exciting goal in human-computer interaction is that of adding human-level emotional behavior to intelligent systems, that is, the ability to perceive a user's emotional state and adaptively respond to it [1]. In speech systems in particular, there has been a lot of work in recent years on detecting a broad spectrum of affective states in speech, including basic emotions [2, 3, 4], frustration [5], charisma [6], uncertainty [7, 8, 9], sleepiness and intoxication [10], and interpersonal stance [11].

There are multiple ways of measuring a speaker's level of certainty. In the existing work on automatic emotion recognition, the most common approach is to measure *perceived* emotion, as annotated by one or more human listeners, producing labels that are by definition subjective [12]. While we treat these labels as a gold standard, we understanding that the subjectivity makes for a challenging classification problem [13]. On the other hand, we can consider *self-reported* certainty, when speakers are asked to rate their own level of certainty. In our prior work, we found that perceived certainty was often *higher* than self-reported certainty [9]. In the same vein, related work on interpersonal stance (friendliness, flirtatiousness, etc.) found that in conversation dyads, self-reported affect was not strongly correlated with perceived affect [11]. In applications such as spoken dialogue systems for tutoring students, we are most interested in knowing a student's *internal* level of certainty.

Prior work has not addressed the question of whether the annotator perceptions or self-reports are an accurate reflection of internal certainty. There is no way to precisely measure internal certainty, but we attempt to address this issue by eliciting speech in a question-answering setting with materials that we hypothesize to be consistently easy or difficult for all individuals. We then generate difficulty scores for each stimulus via crowdsourcing.

In this paper, we present an exploratory analysis of the prosodic characteristics of individual speakers. We find that some speakers produce consistent prosodic expressions of their certainty level, mostly in their pitch, while other speakers show highly inconsistent patterns of speech. Our methodology involves extracting short audio segments of individual words from spoken answers to questions that varying in the speaker's level of certainty. Similar to recent work that has applied principal components analysis (PCA) to large sets of low-level acoustic-prosodic features [14], we identify a set of 10 principal components from a large set of word-level prosodic features. We then use the smaller set of prosodic features to learn several decision trees for each speaker and analyze the manner and consistency of prosodic expression as a way to gauage individual speaking styles.

2. Harvard Uncertainty Speech Corpus

The speech data that we use in this experiment comes from the Harvard Uncertainty Speech Corpus. This section gives an overview of the Harvard Uncertainty Speech Corpus (Section 2.1), the speech elicitation process (Section 2.2), and the methods of annotating and approximating speaker certainty from the hearer's perspective (Section 2.3), the speaker's perspective (Section 2.4), and according the difficulty of the question (Section 2.5).

2.1. Speech Data from Uncertainty Corpus

The Harvard Uncertainty Speech Corpus contains spoken utterances and level of certainty annotations from three question-answering domains [15]. In this paper, we use the *handwritten digit* section of corpus. The utterances were recorded in a lab, in a question-answering setting. The questions and answers are of the form below.

Q: Which train leaves Los Angeles and at what time does it leave?

A: Train seven leaves Los Angeles at 1:27.

In this experiment, we examine the first two words of such utterances, for example, "train seven" or "train two".

The Harvard Uncertainty Speech Corpus contains the audio corresponding the to answers (not the questions). A notable

feature of the utterances in the corpus is that when a speaker is uncertain, the uncertainty can be attributed to a particular *word or phrase* in the utterance. The entrire corpus contains 1700 utterances, roughly 150 minutes of speech. The handwritten digit section of the corpus contains 1100 utterances, about 90 minutes of speech. Detailed descriptions of the corpus are available in previously published works [9, 16].

2.2. Background on Method of Speech Elicitation

The speech elicitation materials are designed in a way that controls the difficulty of the stimulus. This is achieved by asking participants to engage in a task that necessitates speaking a spontaneous utterance that incorporates reading handwritten digits that vary in how legible they are. The digit images are drawn from the MNIST database of handwritten digits [17]. The materials for eliciting speech are designed so that participants would speak the selected MNIST digit aloud in the context of answering a question. The handwritten digit images are embedded in illustrations of train routes connecting two U.S. cities, where the handwritten digits indicate the train number. An example illustration is shown in Figure 1.

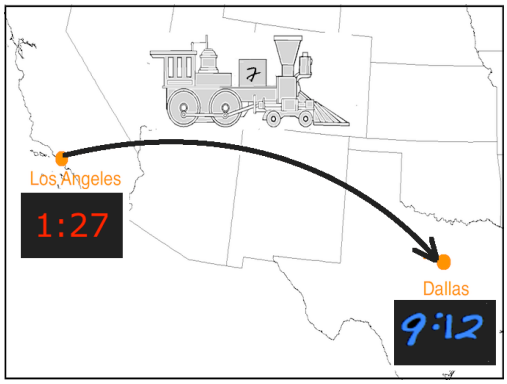

Figure 1: Example speech elicitation illustration featuring an ambiguous handwritten digit image, the train number.

We collected speech from twenty-two native English speakers. At the start of the data collection experiment, participants read a task scenario explaining why they are deciphering handwritten train conductor notes and answering questions about them. For each train route illustration, participants are asked a single question. The participants respond aloud, speaking spontaneously. Their word choice is influenced by a warm-up task where they are given answers to read aloud. This lets us have influence over the length and lexical content of the utterances without the participant explicitly reading aloud.

The method for eliciting uncertain speech is a modification the method used in a previous collection of affective speech [9]. In that work, we did not attempt to control the speaker's level of certainty. As a result, there was no way to verify whether a speaker's self-reported level of certainty was an accurate reflection of his or her actual certainty.

2.3. Certainty Labels from Hearer's Perspective

Each utterance in the corpus is annotated with the level of certainty from a hearer's perspective. We collected annotations from a panel of six human judges. Every annotator listened to and rated the entire set of 1100 utterances. They rated level of certainty on a 1 to 5 scale (1 = very uncertain, 5 = very certain). They did not see any contextual information such as the handwritten images. For each utterance, we consider the mode (average) of the six annotator labels to be the certainty label from the hearer's perspective. The distribution of certainty labels from the hearer's perspective in the corpus is shown in Figure 2.

The agreement among the six annotators highlights the subjective nature of the hearer-centric affect labeling paradigm. Across all pairs of annotators, we find an average pairwise agreement of 54.3%, average Cohen's kappa of 0.235, and average Spearman correlation coefficient of 0.494. If we look only at the pair of annotators with the highest agreement, we see much higher values: pairwise agreement of 74.1%, Cohen's kappa of 0.407, and Spearman correlation of 0.62.

2.4. Certainty Labels from Speaker's Perspective

Each utterance in the corpus is annotated with the level of certainty from the speaker's perspective. The speakers are asked, "How certain were you about the answer you just gave?" during the speech elicitation process. They rate their level of certainty on a 1 to 5 scale (1=very uncertain, 5=very certain). The distribution of certainty labels from the speaker's perspective in the corpus is shown in Figure 2.

2.5. Certainty Labels from Image Difficulty Score

We attempt to control the speaker's actual level of certainty by designing stimuli that are uniformly difficult or easy and we then use crowdsourcing to obtain a difficulty score for each stimulus. Each utterance in the corpus has a legibility score associated with the handwritten digit (the train number) that was used to prompt the question. We used Amazon's Mechanical Turk [18, 19] to collect human judgements from which we generate image legibility scores. Mechanical Turk is an online labor market that facilitates the assignment of human workers to quick and discrete *human intelligence tasks* (HITs). We showed Turkers a digit image and instructed them to identify the digit using a drop-down menu. Each digit was labeled by 100 human workers. Details of the HIT design are available in previously published work [16].

The legibility score for each image is defined as 1 minus the Shannon entropy of the human label distribution:

$$\text{Legibility} = 1 - \big[- \sum_{i=1}^{N} P(x_i) log P(x_i) \big]$$

Thus, scores fall in the range [0,1]. A score of 1 has an entropy of 0 and indicates high legibility (all 100 people choose the same label). The handwritten digit in Figure 1 has a legibility score of 0.75. The distribution of difficulty scores (legibility scores) for the stimuli used in eliciting the speech data is shown in Figure 2.

3. Experiment and Results

In this experiment we analyze the speaking styles of individual speakers. We explore whether these individuals are prosodically expressive regarding level of certainty, and if they display consistency in their prosodic expression. Because of design of the corpus, each speaker utters phrases such as "train one" or "train two" multiple times, with differing levels of certainty. Figure 3 shows the spectrograms of three utterances from the same speaker saying "train two" while feeling uncertain, neutral, and certain. Because the corpus contains such sets of lexically-identical phrases, in this experiment we compare

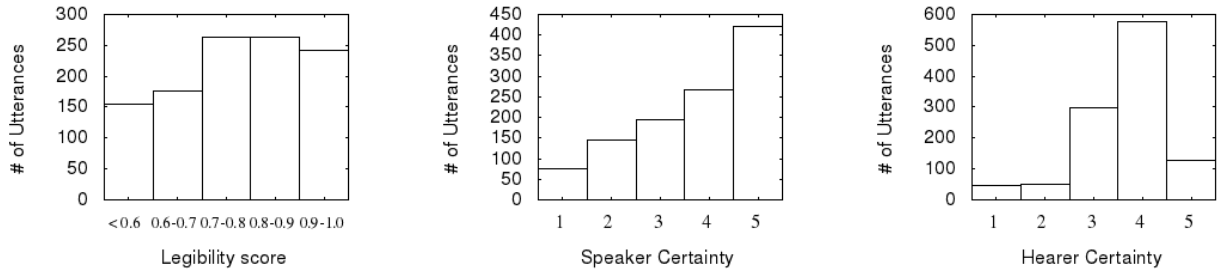

Figure 2: Three histograms: (left) distribution of difficulty scores for the stimuli that prompted the utterances in the corpus, (middle) distribution of certainty labels from the speaker's perspective, (right) distribution of certainty labels from the hearer's perspective.

word-level prosodic features. However, of the ten possible digits, only some are repeated with enough frequency to be analyzed. From the larger corpus, we identify a set of speakers and digits such that,

- each speaker utters each digit 3 or more times, *and*
- for each speaker-digit combination, the certainty labels are distributed among certain, neutral, and uncertain.

This yields a set of 408 utterances representing eight speakers and six digits. Table 1 shows the utterance counts for these eight speakers. For example, in our corpus, speaker a says "train one" five times and says "train two" eight times.

Table 1: Number of utterances that contain the phrases, "train one", "train two", "train three", "train five", "train seven", and "train nine", for a subset of speakers in the corpus.

	Num instances of "*train…*" per speaker						
Speaker	*one*	*two*	*three*	*five*	*seven*	*nine*	**Total**
a	5	8	4	7	8	8	**40**
b	4	8	6	6	9	10	**43**
c	4	11	4	6	6	12	**43**
d	3	8	5	6	8	12	**42**
e	3	10	5	6	7	8	**39**
f	4	7	7	5	7	11	**41**
g	3	6	5	6	9	8	**37**
h	6	7	3	7	9	7	**39**

3.1. Unit of Analysis

Because the corpus contains repeated instances of specific words, spoken with different levels of certainty, we perform prosodic analysis at the *word level*. The segments of interest are the train numbers, which correspond to the MNIST handwritten digits. The word-level audio segments are generated semi-automatically. We use the CMU Sphinx speech recognition toolkit to automatically transcribe each utterance and generate word alignments. The audio segments are manually verified and errors are manually corrected.

3.2. Prosodic features

Initially, we extract 230 prosodic features from each audio segment. We use the openSMILE feature extraction toolkit [20] with the `emobase` config file. The features include low-level descriptors (F0, F0-envelope, intensity, loudness, voice quality, and zero-crossing rate), functionals, and delta regression coefficients for smoothed feature contours.

We use principal component analysis to identify 10 principal prosodic components of the digit word segments in our data (using the entire corpus—word segments from all utterances of all speakers). PCA is performed using the WEKA toolkit [21]. The ranked results are aggregated and a set of 10 principal components are identified for further analysis. The resulting 10 features are listed below (delta features indicated by ^{d}).

1. F0 average^d
2. F0 range^d
3. F0 slope^d
4. F0 skewness^d
5. F0 envelope max^d
6. Intensity average^d
7. Intensity skewness^d
8. Intensity minimum
9. Probability of voicing^d
10. Zero-crossing rate^d

3.3. Speaker analysis

In order to understand how these features are related in predicting the level of uncertainty in utterances, we have made use of decision tree learning. Considering certainty labels from the speaker's perspective (3 classes), we learn separate decision tree classifiers for each speaker-word combination. That is, we learn a decision tree for [$speaker = a$, $word =$ "one"], [$speaker = a$, $word =$ "two"], and so on. In total, we learn six decision trees for each speaker. The maximum depth of decision trees is 3. We used the WEKA toolkit [21] implementation of C4.5 algorithm (J48).

For each speaker, we evaluate whether the learned decision criteria are consistent across all six words. In other words, we ask: for speaker a, are the informative prosodic features consistent for the word "one", the word "two", the word "three" and so on. We then do the same analysis for certainty labels from the hearer's perspective, and for the difficulty score approximation of certainty. Table 2 shows the speaker-specific consistency results. The 10 prosodic features are collapsed into three groups: pitch (#1-#5), intensity (#6-#8), and voice (#9-#10). Separate results are shown for the three approximations of certainty: labels from the speaker's perspective, labels from the hearer's perspective, and difficulty of the question (legibility

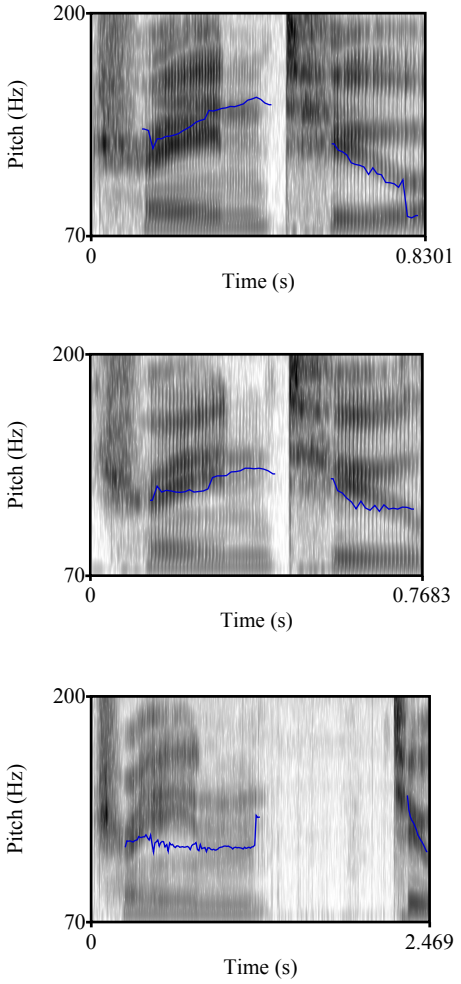

Figure 3: Three instances of a single speaker saying "train two" with varying affect: certain (top), neutral (middle) and uncertain (bottom). The pitch estimate (blue line) is overlaid atop the spectrogram.

score). For speakers that used consistent modes of prosodic expression, checkmarks indicate the class of prosodic feature that distinguished the certain, neutral, and uncertain words.

4. Discussion

We see two primary observations from this exploratory analysis. First, among the prosodic features that we analyzed, features related to pitch are the strongest differentiators between certain and uncertain affect, voice features are second strongest. Second, this analysis, though preliminary, suggests that some speakers consistently display their certainty through their prosody while others are inconsistent. We hypothesized that inconsistent speakers would be inconsistent across all three certainty metrics (speaker, hearer, and legibility). The results show only a small amount of support for this: speakers f and h are inconsistent under both the speaker and hearer metrics. The fact that there is no overlap between the inconsistent speakers in the bottom section of Table 2 and the other two sections indicates that the difficulty score metric may be too coarsely defined

Table 2: Speaker-specific prosodic modes for conveying uncertainty. Certainty is approximated in three ways: the speaker's perspective, the hearer's perspective, and the difficulty of the question.

	Speaker							
	a	b	c	d	e	f	g	h
Certainty labels: *speaker*								
Pitch	✓		✓	✓	✓			
Intensity					✓			
Voice	✓		✓		✓			
Inconsistent		✗				✗	✗	✗
Certainty labels: *hearer*								
Pitch		✓	✓		✓		✓	
Intensity								
Voice			✓					
Inconsistent	✗			✗		✗		✗
Difficulty of question								
Pitch	✓	✓		✓		✓	✓	✓
Intensity								
Voice								
Inconsistent			✗		✗			

(with two binary classes), or that it may not be as aligned with speaker and hearer certainty labels as we had posited.

We see that some speakers, e.g., speakers a and c, have similar manners of conveying certainty. Our next steps involve a clustering analysis to explore whether natural clusters can explain the variation seen among those speakers who convey their certainty in their prosody.

5. Conclusion

This paper presents an exploratory analysis of the prosodic characteristics of individual speaking styles, as they relate to three different measurements of certainty. We find that some speakers have consistent ways of conveying their level of certainty prosodically, while other speakers are inconsistent. Among the prosodic signals, pitch-related features are the strongest. Across the three different measures of certainty: speaker's perspective, hearer's perspective, and item difficulty, we find more varying speaker behaviors, suggesting the need for further analysis.

This work is of broad relevance to researchers studying affect recognition. Robustly recognizing affect, and especially subtle affective-cognitive states such as uncertainty, faces many challenges. It is not surprising that speakers have different ways of prosodically expressing affect. In this paper, we show that some speakers produce consistent prosodic signals of certainty, mostly in their pitch, while other speakers show highly inconsistent patterns of speech. Instead of using the same techniques for detecting affect in all speakers, there is great potential utility in adaptive affect detection. For example, if a person is very inconsistent in their speech signals, then an intelligent, multimodal system should direct its inference efforts toward signals from other modalities such as lexical content or facial expressions. On the other hand, if a speaker is prosodically expressive, adaptive systems in the future may dynamically determine which prosodic signals to weight more strongly.

Abstract

The aim of this paper is to examine cues for prosodic characterization of attitudes in Japanese. This work is based on previous studies where 16 communicative social affects were defined. The audio signal parameters (fundamental frequency, amplitude and duration) of previously recorded Japanese attitudes, are statistically analyzed. Interesting interactions among the parameters, the gender and the expression of specific attitude (e.g. politeness) were found, and we report on which parameters most significantly characterize each attitude.
Index Terms: speech, prosody, attitude, social affect, emotional speech, Japanese language

1. Introduction

The prosodic expressions of social affects, or attitudes as defined by [1], are a mean used by speakers to drive the illocutionary force of their intended speech acts [2] in face-to-face communication. Such choices are partly linked with the speaker's own proficiency in the spoken language, her/his personality, gender and the communication context which are also constrained at the linguistic level. Thus, each language has specific formulae or conventional prosodic variations for specific interaction contexts. Usually, studies investigating such kinds of prosodic variations rely on stereotypic stimuli [3, 4, 5, 6]. One common difficulty in studies which aim to compare the prosody of social affects is linked to a trade-off between the high sound quality required for acoustic analysis, the need for a neutral lexical content of the studied sentences (ideally identical sentences for all the studied affects), the search for spontaneity of the expressions, and a clear labeling of the communicative goals of the speaker. Most of the cited studies use laboratory corpora. Typically, adhoc sentences are recorded by speakers trying to read a sentence and reproduce a given expressivity. To enhance the spontaneity of these expressions and to facilitate the speaker's task, [7] proposes to place target sentences in affectively loaded texts. Similarly, [6] recorded attitudinally-neutral sentences embedded into dialogues that prepare the speaker to perform an adequate expression for the target sentence. The approach used during this research builds on these works. In order to study the expressive strategies used by speakers of varying linguistic backgrounds, communicative situations have been set-up so they can be plausibly used in different languages. The analysis method used in this paper also shares similar objectives to be applied to any language. We thus decided to use only low-level prosodic descriptors: the values of the fundamental frequency (F_0), the Root Mean Square (RMS) amplitude (computed on vowels) and the syllable duration. Using these features for statistical analysis with Repeated-Measure ANalysis Of VAriance (RM-ANOVA), we are able to determine to which extent each feature may contribute to the differentiation of attitudes. This paper is organized as follows: the framework we used for a speaker express social affects is described in Section 2. The recording set-up procedure and the feature extraction methods are respectively described in Sections 3 and 4. Finally, the results from the statistical analysis are presented in Section 5 and discussed in Section 6.

2. Social contexts for expression of attitudes

In order to immerse subjects in the context, a scenario was set up for each attitude, and the subject was requested to engage in a short dialogue that would lead to the production of target sentences with the native speaker. For the current experiment, 16 contexts have been selected, corresponding to a set of attitudes used in [8, 9] for different languages. Some of these contexts do not have lexical equivalents in all languages, as the corresponding communication situations have not been conventionalised in that particular culture. It is the case for example of the Japanese notion of *kyoshuku*, described by [10] as "corresponding to a mixture of suffering ashamedness and embarrassment, which comes from the speaker consciousness of the fact his/her utterance of request imposes a burden to the hearer". For instance, *Kyoshuku* has no lexical equivalent in English. Meanwhile, "walking on eggs" corresponds to a certain extent to this concept. The following 16 social affects were used in the present corpus: Admiration (ADMI)), Arrogance (ARRO), Authority (AUTH), Contempt (CONT), Doubt (DOUB), Irony (IRON), Irritation (IRRI), Neutral declarative sentence (DECL), Neutral question (QUES), Obviousness (OBVI), Politeness (POLI), Seduction (SEDU), Sincerity (SINC), Surprise (SURP), Uncertainty (UNCE), Walking on eggs (WOEG). They are defined by prototypical situations with the social relationship of the two interlocutors specified – as well as the communicative goal of the speaker (see [11] for details). For all situations, a short neutral target sentence has been used to record the respective prosodic expressions: "A banana". In order to elicit these target sentences in each context, small dialogues were written (cf. [6]), that take place in the prototypical context described above, and that end with the target sentence. During the recordings, each speaker (A) has an active interlocutor (B) who interacts with her/him in order to enhance the naturalness of the communication situation, and to ease the production of realistic expressions. Speakers are indeed not asked to produce an isolated

sentence with an identified attitude (e.g. seduction or authority), but rather to immerse in a scenario. For instance, the situation is the following for "walking on eggs":

- Your boss (Speaker B) has asked you (speaker A) to be in charge of setting up a room for a big conference. Your boss is a super compulsive guy who needs to have everything done just right, and gets easily angered if things are not perfect. Your boss walks into the room where the big conference is to be held, and in the wastebasket, there is a half-eaten banana. He is furious.

Currently, these situations have been adapted to three languages: American English, Japanese and French. The present paper focuses on the Japanese results, as performed by native speakers.

3. Recording procedure

A set of 19 Japanese native speakers (11 females, 8 males) have been recorded. Most speakers were recruited amongst university students and were paid for their performance. The recordings took place in a sound-treated room at Waseda University, Japan. The sound was captured by an *Earthworks QTC1* omnidirectional microphone, placed at one meter from the mouth of the speaker (this distance was chosen to limit the influence of the speaker movements on the sound level). The microphone level was calibrated before each recording session using a *Bruel & Kjaer* acoustical calibrator, thus the sound pressure level can be corrected after recording to a level comparable across all speakers. The target sentence "banana" was then manually searched for across the recorder corpus, isolated and extracted into individual files. Any speech utterances from speaker B occurring during the expressive gesture of speaker A performing the target sentence were removed from the sound track (none overlapped with their speech). Due to the interactive nature of the recording, some spontaneous changes were observed on the target sentences: typically "banana" sentence with interjections, such as "hmm", "er", "oh", etc., together with the target sentences. Each speaker recorded one utterance of the word for each of the 16 attitudes, resulting in a total of 304 stimuli. These were stored as 16 kHz, 16-bit WAV files. Each stimulus was trimmed to discard the beginning and the ending silence. The wave file of each stimulus was hand-labeled at a phonetic level using the PRAAT software [12].

4. Feature extraction

We characterized each stimulus with its F_0, amplitude and duration parameters.

4.1. Fundamental frequency

The F_0 parameter measured in Hertz is estimated using the SWIPE algorithm [13] with a 10 ms sampling interval. For statistical analysis (see Section 5), only F_0 values at time indices corresponding to the vocalic phonemes are kept, and averaged to give a mean F_0 value per vowel (3 values per stimulus). We also applied the MultiDimensional Scaling algorithm (MDS) [14] to the complete series of F_0 values normalized by the mean F_0 of the speaker (see Section 5.4). Thus, MDS allows a graphical interpretation of the distance between the attitudes which depends on the computed correlation between the F_0 series.

4.2. Amplitude

The amplitude is estimated using the RMS function where the signal is windowed to result in 20 ms frames with 50% overlap. Thus, the RMS amplitude is computed on each frame from the normalized values (in $[-1;+1]$) of the signal samples. As before, for statistical analysis, only RMS values at time indices corresponding to the vocalic phonemes are kept, and averaged to give a mean RMS amplitude value per vowel (3 values per stimulus).

4.3. Duration

Additionally, for statistical analysis, each syllable duration measured is computed as the sum of its consonant and vocalic parts, in milliseconds, based on the manual segmentation of the stimuli.

5. Results of the statistical analysis

The statistical significance of prosodic differences is measured between attitudes and gender, separately for the F_0, amplitude and duration parameters. For each parameter, each stimulus is considered as a series of three repeated measures, corresponding to the mean parameter value of the stimulus for the three successive vocalic phonemes. For each parameter, we conducted a RM-ANOVA, with attitude (16) $\times$ phoneme (3) as within-subject factors and gender (2) as between-subject factor. For the remainder of this section, $F(a,b)$ denotes the computed statistic which is assumed to follow a Fisher probability density function of parameters a and b. p denotes the p-value which results from the RM-ANOVA and M is used to denote the mean value of the considered parameter.

5.1. Fundamental frequency

The RM-ANOVA on F_0 values reveals a strong statistical interaction of attitude $\times$ time: $F(30,210)=8.12$, $p<0.001$, indicating that the temporal profile of F_0 varies significantly across attitudes. As shown in Figure 2(a), the interaction is most noticeable between F_0 values of the first and second vowel of each utterance: while the majority of attitudes are associated with lower-pitch in the second vowel ("V-shape"), attitudes AUTH, DECL, QUES and (to a lesser extent) SINC are associated with higher-pitched second vowels ("inverted V-shape").

To further characterize this behavior, we extract the normalized F_0 ratio between the second and first vowel of each stimulus (in % increase) - see Figure 2(d). A RM-ANOVA (with attitude (16) as a within-, and gender as a between-subject factor) reveals a main effect of attitude on this ratio: $F(15,225)=13.6$, $p<0.001$. Attitudes AUTH(+26%), DECL (+17%), QUES (+34%) show an increase in F_0 that is more important than the other measures ($p<0.001$, Bonferroni-corrected). Attitude SINC (+7%) also shows an increase in F_0 values more important than for CONT (-14%) ($p=0.01$, Bonferroni-corrected).

Most interestingly, the F_0 differences between attitudes have a marked interaction with gender: $F(30,210)=1.95$, $p=0.003$, indicating that different F_0 patterns are used by male and female to convey the same attitude. Remarkably, this interaction with F_0 is not characterized by the first (attitude $\times$ gender: $F(15,240)=1.36$, $p=0.16$), second (attitude $\times$ gender: $F(15,240)=1.83$, $p=0.03$) or third vowel individually (attitude $\times$ gender: $F(15,240)=0.38$, $p=0.98$), but rather on the difference between values on each vowel.

As seen in Figure 2(d), there are significant gender dif-

ferences in particular in the second-to-first F_0 ratio, both overall (attitude × gender: $F(15,225)=2.58$, $p=0.001$) and for individual attitudes ADMI (male: +5%, female: -11%, p=0.03), AUTH (male=+10%, female: +37%, $p=0.0008$) and QUES (male=+49%, female=+23%, $p=0.001$; all: Fisher LSD posthocs).

5.2. Amplitude

The RM-ANOVA on amplitude values reveals a main effect of gender: $F(1,17)=24.5$, $p=0.00012$, indicating that recordings by female speakers are louder than males; a main effect of time: $F(2,34)=88.51$, $p<0.001$, with first ($M=.00071$) and second vowels ($M=.00066$) both twice louder than the third vowel ($M=.00034$);and a main effect of attitude: $F(15,255)=1.99$, $p=0.015$, showing that some attitudes are generally louder than others, regardless of vowel and gender.

Attitudes ADMI ($M=.00063$), POLI ($M=.00060$), SINC ($M=.00060$) and WOEG ($M=.00059$) are louder than AUTH ($M=.00054$), CONT ($M=.00052$), IRRI ($M=.00052$), QUES ($M=.00054$), SEDU ($M=.00053$), SURP ($M=.00056$) and UNCE ($M=.0052$) at the $p<.05$ level (Fisher LSD test, non Bonferroni-corrected).

There is an interaction of time × gender: $F(2,34)=3.51$, $p=0.04$ - second vowels were more quiet for males than females -, but no interaction of attitude × gender: $F(15,255)=0.88$, $p=0.58$.

Most remarkably, there is a strong interaction of attitude × time: $F(30,510)=6.57$, $p<.001$, showing that, as for F_0, different temporal profiles of amplitudes are used to convey different attitudes (see Figure 2(b)), and, as for F_0, differences are particularly notable in the ratio of amplitude at the first and second vowels: while second vowels were quieter than first for the majority of attitudes, they were louder for attitudes AUTH, DECL and QUES.

However, contrary to F_0, there was no interaction of this effect with gender: $F(15,255)=0.33$, $p=0.99$ (attitude × gender interaction, RM-ANOVA on second-to-first amplitude ratio). Similar amplitude patterns are used by male and female speakers to convey the same attitudes (see Figure 2(e)).

5.3. Duration

The RM-ANOVA on syllable durations reveals a marginal main effect of gender: $F(1,17)=4.71$, $p=0.04$ - females were slower ($M=137$ ms) speakers than males ($M=117$ ms); a main effect of time: $F(2,34)=95.6$, $p<0.001$, with final syllables twice as long ($M=188$ ms) as the first ($M=99$ ms) and second syllables ($M=98$ ms); and a main effect of attitude: $F(15,255)=13.0$, $p<.001$, showing that some attitudes were generally slower than others, regardless of syllable and gender.

Attitudes AUTH ($M=162$ ms), CONT ($M=166$ ms), DECL ($M=171$ ms), DOUB ($M=155$ ms), QUES ($M=147$ ms) and SURP ($M=165$ ms) were slower than the others ($p<.05$, Bonferroni-corrected). This main effect of attitude was seen both on durations of the first syllable: $F(15,255)=11.09$, $p<.001$, second syllable: $F(15,255)=9.48$, $p<.001$ and third syllable: $F(15,255)=13.08$, $p<.001$.

There was no interaction of time × gender: $F(2,34)=1.57$, $p=0.22$, and no interaction of attitude × gender: $F(15,255)=1.17$, $p=0.29$. However, as mentioned below, there was a strong interaction of attitude × time: $F(30,510)=12.07$, $p<.001$, showing that, as for F_0 and amplitude, different patterns of successive syllable durations were used to convey different attitudes (see Figure 2(c)).

As for F_0 (but not for amplitude), this interaction is significantly related with gender: $F(30,510)=2.43$, $p=<.001$. The gender difference was mainly seen on the duration of the third syllable: $F(15,255)=1.89$, $p=0.02$ (see Figure 2(f)); gender differences were only marginal for the duration of the first syllable: $F(15,255)=1.68$, $p=0.05$, and not significant for the second syllable: $F(15,255)=1.04$, $p=0.4$.

5.4. Multidimensional scaling

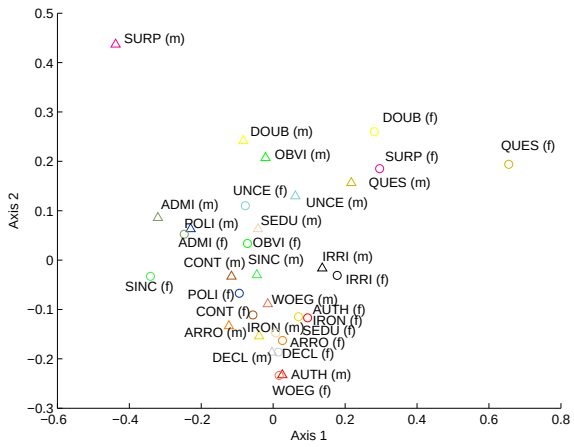

Figure 1: Result of the MDS algorithm based on the correlation distance of the F_0 profiles (circle: female, triangle: male).

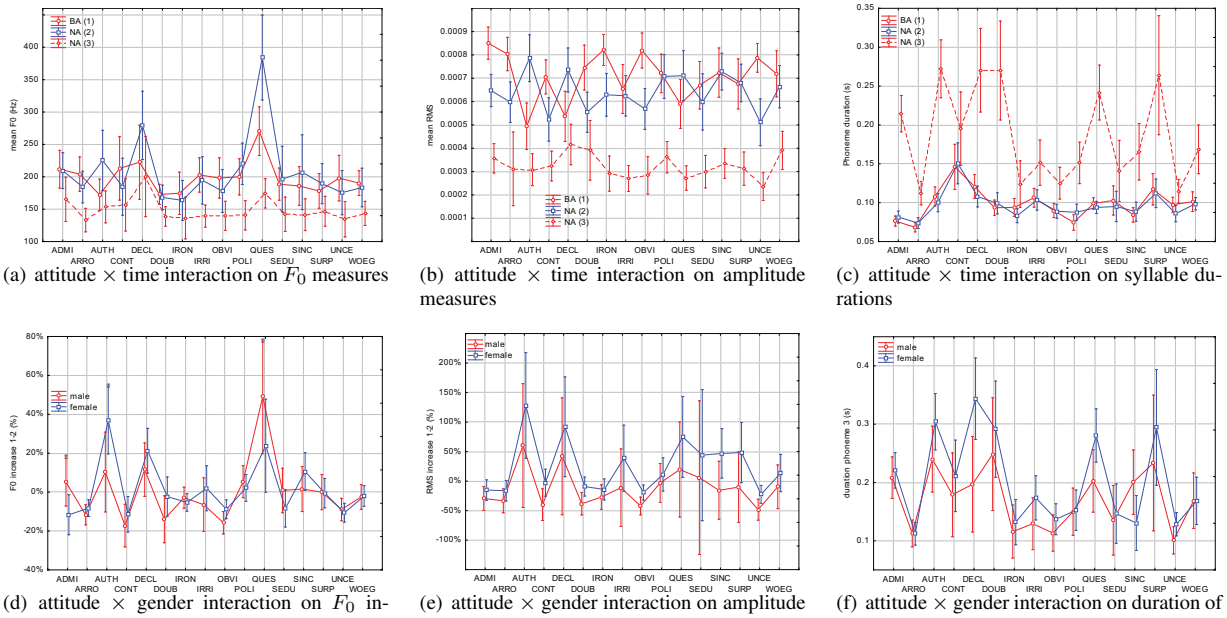
The result of the MDS algorithm [14] applied on the normalized F_0 profiles associated to the entire phrase "banana" and computed on the corpus is presented in Figure 1. This figure shows the center of mass for each attitude where male and female are separated. The distance between each point is associated to the correlation distance computed between the profiles associated to the attitude of each speaker. For the normalization, each estimated F_0 profile is divided by the averaged F_0 related to the speaker to obtain a modulation function centered on the unity. For the duration, all the estimated profiles are rescaled to a series of 100 frames fitting the mean duration of the corpus which is 531.25 ms

6. Discussion

This study on Japanese spoken language investigated acoustic characteristics of various social affects in order to identify what are the similar and different prosodic patterns for various attitudes. For this study we used the F_0 and the amplitude parameters which are objective signal parameters used to describe the prosody of each expressed attitude. Statistical results show that the interaction between attitudes and gender is observed only for the F_0 parameter. It indicates that the gender differences of attitudinal expressivity are more characterized by F_0 rather than amplitude or duration. However, we have observed that female expressiveness is not only characterized by a higher pitch but also by a higher amplitude and longer syllable durations than males. We also identified that Japanese politeness expressions (ADMI, POLI, SINC, WOEG) are louder than others, including impoliteness expressions (AUTH, CONT and IRRI). Concerning the duration parameter, the Japanese language is



(a) attitude × time interaction on F_0 measures

(b) attitude × time interaction on amplitude measures

(c) attitude × time interaction on syllable durations

(d) attitude × gender interaction on F_0 increase

(e) attitude × gender interaction on amplitude increase

(f) attitude × gender interaction on duration of syllable 3

Figure 2: Differences in F_0 temporal profiles between attitudes 2(a) and gender 2(d). 2(a): mean F_0 value (in Hz) for each vowel of (b)a-(n)a-(n)a for the 16 attitudes. 2(d): difference of mean F_0 between the second and first vowels (in % increase) for the 16 attitudes and for both genders. Error bars in 2(a) and 2(d) correspond to 95% confidence intervals. Asterisks in 2(d) mark significant gender difference ($p<0.05$, Fisher LSD posthoc). Differences in RMS amplitude temporal profiles between attitudes 2(b) and gender 2(e). 2(b): mean amplitude value for the three vowels of (b)a-(n)a-(n)a for the 16 attitudes. 2(e): difference of mean amplitude between the second and first vowels (in % increase) for the 16 attitudes and for both genders. Error bars in 2(b) and 2(e) correspond to 95% confidence intervals. Differences in syllables duration between attitudes 2(c) and gender 2(f). 2(c): duration of each of the three syllables ba-na-na for the 16 attitudes. 2(f): duration of the third syllable for the 16 attitudes and for both genders. Error bars in 2(f) and 2(f) correspond to 95% confidence intervals.

well known to be mora-timed which means that each mora (taking account of two moras for long vowels, geminate obstruents and nasal /N/) is of similar duration because of the compensation of segmental variation of duration inside the mora-structure [15, 16]. However these results show an important temporal variation among attitudinal expressions. A variation between the two first vowels and the 3rd vowel was especially observed (i.e. 3rd vowel was almost twice as long as 1st and 2nd vowel). It suggests that social affects may change duration adjustment of Japanese rhythmic structure, and it confirms a previous work [17] which finds that the duration of this 3rd vowel is an important factor to make a difference in various attitudinal expressions. Moreover, a correlation between attitude and time based on the F_0 values was observed. Standard Japanese is described as a pitch accent language which is characterized by a rising F_0 at the beginning of the phrase, and an important pitch fall after an accented vowel [18]. The recorded sentence "Banana" has an accentual nucleus on the 1st mora. Thus, we expect to observe F_0 rising on the 1st vowel with a fall at the end of the 1st vowel. However results show that the phrasal initial rising of F_0 until the peak (F_0 max) vary according to attitudes [19]. Our assumption is that the timing of F_0 peak whether it comes on the 1st or the 2nd vowel is correlated with speech rate and amplitude. According to our data , it seems that some attitudinal expressions (AUTH, QUES and DECL) where F_0 peak comes later (on the 2nd vowel) are related with slower speech rate and with an amplitude peak which comes later (on the 2nd vowel) as opposed to the majority of attitudes which are associated with lower pitch in the second vowel ("V-shape"). MDS analysis for F_0 values of all attitudes identified 3 different categories: polite expressions, impolite expressions and dubitative expressions. The first category consists of 4 impolite expressions (AUTH, ARRO, IRON, IRRI) plus 2 other attitudes (DECL, WOEG). The second category is composed of 4 polite expressions (ADMI, SINC, POLI, SEDU (males only) plus 2 attitudes (OBVI, UNCE). It is important to note that WOEG which is akin to the Japanese polite expression of *Kyoshuku* is located in the category of impolite expressions. These results confirm previous work on Japanese politeness expressions [9, 20]. The expression of WOEG may be differentiated from impolite expressions because it does not have the same voice quality characteristics to the Japanese (polite) expression of *Kyoshuku* [9]. Contrary to the similarity of F_0 values of SEDU for males and females given from RM-ANOVA (see Figure 2(d)), MDS analysis identified that female values for this attitude are quite different from the male ones according to Figure 1, the female speakers' circle is located in the category of impolite expressions, which is different from the male one which is located in the politeness category. Although the pitch of SEDU is similar to impolite expressions, the voice quality of this attitude is softer, and therefore SEDU may not be perceived as impolite expression. For future work, a comparison with non-native speakers will also be done to examine prosodic similarities among different languages.

Abstract

Two experiments investigated the role of intonation in perception of basic emotions. In the first experiment, pitch contours of stimuli from a corpus containing portrayals of anger, joy, fear and sadness were manipulated with respect to range, mean and smoothness. In the second experiment, pitch contours of identical words portraying different emotions were exchanged. In each experiment, the emotional category and intensity of the original and manipulated stimuli were evaluated by two separate groups of 20 participants. Results of the first experiment show mainly that pitch mean and range should vary congruently to portray activation correctly, and demonstrate the interaction in varying these two parameters. Results of the second experiment show that a pitch contour conveying high activation is not sufficient in conveying the appropriate emotion, if the other paralinguistic cues are not also in accordance. A pitch contour indicating low activation, on the other hand, is apparently a more powerful cue and thus less reliant on other cues.

Index Terms: emotion, speech, intonation, perception

1. Introduction

It has long been acknowledged that pitch has a central role in production and perception of emotional speech [1], with more recent studies indicating that pitch mean and range are strong indicators of Activation or Arousal [2]. Many studies have shown, however, that other prosodic parameters such as intensity, timing and voice quality, are also involved in this process [3, 4,5]. It is therefore interesting to try and isolate the contribution of each of these factors to perception of emotion. Several previous studies have explored this issue using resynthesis, manipulating various prosodic or spectral properties and examining the effect on recognition scores [5, 6,7]. This is of interest for producing emotional speech in text-to-speech systems, however such tools can also be used studying the acoustic cues themselves.

In this study we present two experiments which attempt to investigate the contribution of pitch to emotion perception in a controlled manner. However we chose to perform manipulations on recorded emotional speech rather than text-to-speech synthesis. Both experiments employ a corpus of emotional speech which has been analyzed extensively in several other studies [8]. It is composed of short sentences and single-word (nonsensical and meaningful) emotional utterances with neutral content, recorded from 4 speakers and conveying 4 emotions: Anger, Joy, Fear and Sadness.

In experiment 1, the pitch contours of the different utterances were manipulated to exaggerate or diminish the pitch movements, in order to determine how this influenced the detected emotion and its intensity. In the second experiment, pairs of pitch contours from identical words uttered in different emotional expressions were exchanged, in order to examine which cues would be dominant: the pitch contour or the remaining acoustic cues.

The next section describes in some detail the corpus employed here, followed by detailed descriptions of each experiment, and a conclusion.

2. Emotional Corpus

A full description of the emotional corpus, detailing how it was recorded and evaluated can be found in previous work by the present authors [7]. In brief: stimuli were recorded in a professional recording studio by four professional actors (two female, and two male). The stimuli included nonsense monosyllabic utterances, nonsense polysyllabic words, Hebrew words and Hebrew sentences. None of the words and sentences had any linguistic emotional content. The stimuli represented four basic emotions: anger, joy, fear and sadness. The stimuli were validated by a panel of 20 independent judges, receiving an overall average recognition rate of 79.0% (SD=15.9%).

3. First Experiment

3.1. Objectives

The objectives of this experiment were to determine the effect of several properties of the pitch contour on the perception of emotion: 1) *Small pitch movements*: normally produced pitch contours contain major pitch movements known to signify both pragmatic and affective information, such as a final rise indicating a question. However, there are many smaller pitch movements which may have a significant but less obvious role [9]. Removing the small pitch movements, while retaining the large ones, may enable a controlled investigation of their perceptual importance. 2) *Pitch range*: this parameter has long been considered an important property of the pitch contour, usually considered to be an indicator of Activation or Arousal [2]. By stretching or compressing the pitch contour, the pitch range can be shifted considerably, without damaging its overall shape. 3) *Pitch mean*: This is also considered an important indicator of emotion, though it is not clear whether it is a global feature, independent to some degree of the speaker's normal mean, or must be normalized to each speakers individual mean. Once again, shifting the pitch mean can help determine its perceptual value.

3.2. Methods

In order to keep the listening task manageable, 92 utterances were selected from the original emotional speech corpus. The selection was balanced to ensure nearly the same number of utterance per emotional category (23 or 24 per category) and per utterance type (21-24). All the selected stimuli were originally identified correctly at a rate of over 68%. Each of these utterances was then manipulated in four ways:

1. Smoothing: removing any small pitch movements. This was carried out using Praat software's "stylize" manipulation with a parameter of 2 semitones.
2. Increase of pitch range by a factor of 2.
3. Decrease of pitch range by a factor of 2
4. Shifting of the pitch mean: Globally, pitch means for anger and sadness were low and means for joy and fear were high, both for men and women. Their overall averages were 260Hz for women's utterances, 167Hz for men's utterances. Thus, all stimuli were shifted to these mean values, for women and men respectively.

All manipulations were performed in Praat software. The net result was a collection of 460 stimuli: the original 92, and four manipulations of each.

The experiment was implemented as a Matlab GUI. For each stimulus, participants had to choose one of five emotions: anger, sadness, joy, fear or neutral, and rate the emotional intensity on a scale of 1 to 3. Despite the fact that the corpus did not contain neutral stimuli, the neutral category was included to account for cases in which the emotional content was possibly lost due to the above manipulations.

The participants were a group of 20 women, aged 20 to 30 (M=26). All participants had no reported hearing problems, 12-16 years of education, and were native Hebrew speakers.

3.3. Results

In the interest of brevity, only the main results of this experiment are presented here.

3.3.1. Identification of emotions

Table 1 shows the average recognition score per stimuli, for each emotion and each type of manipulation, in percents. Figure 1 shows the same results graphically. Evidently, baseline recognition scores (i.e. for non-manipulated stimuli) were very similar, over 80%, for all the emotion types.

Observing each row, it becomes obvious that the different types of manipulation had different effects on recognition of the various emotions.

The main findings from Table 1 are as follows: **Anger** recognition was reduced significantly ($p<0.05$) by shifting the pitch (in this case to higher levels) and *reduction* of the pitch range. **Joy** recognition was reduced significantly by pitch shifting (to lower levels in this case) and *reduction* in pitch range. **Sadness** recognition was reduced significantly by *increasing* the pitch range. **Fear** recognition was lowered greatly by pitch shifting (to lower levels).

*Table 1. Average **recognition** scores (%) per emotion and manipulation type. Asterisks mark statistically significant differences.*

Emotion	Original	Stylized	Shifted	0.5 x range	2 x range
Anger	84	86	73*	74*	80
Joy	81	74*	69*	53*	84
Fear	81	77	51*	76	71
Sadness	84	86	84	87	72*

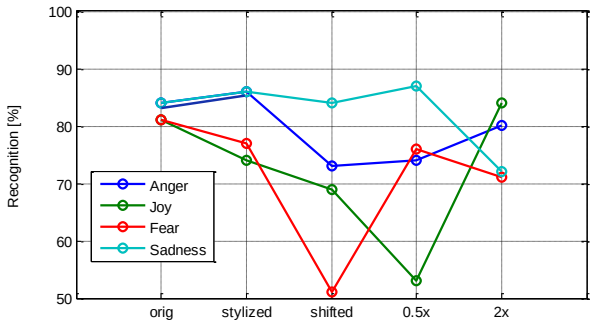

Figure 1: *Recognition scores of Table 1*

3.3.2. Ratings of emotional intensity

Table 2 shows mean intensity scores per emotion, for each manipulation. Anger and Joy scores fell when pitch range was reduced. Joy scores increased when pitch range was increased, whereas this had the opposite effect on Sadness. Finally, pitch shifting reduced intensity scores for Joy and Fear. This is in line with the fact that it reduced their recognition scores also.

*Table 2. Average emotional **intensity** scores per emotion and manipulation type (normalized to a 10-point scale). Asterisks mark statistically significant differences.*

Emotion	Original	Stylized	Shifted	0.5 x range	2 x range
Anger	6.1	6.3	6.1	5.4*	6.
Joy	5.7	5.6	5.2*	4.8*	6.6*
Fear	6.9	7	5.3*	6.9	6.5
Sadness	6.5	6.3	6.4	6.4	5.7*

3.4. Discussion

The results above show several interesting trends. In the original stimuli, the two emotions with high activation, Anger and Joy, demonstrated opposing tendencies with regard to average pitch. Thus, shifting them to the overall average (reducing pitch in Joy and increasing it in Anger) caused recognition rates to fall for both. As activation is commonly acknowledged to be associated with high pitch range [Banziger], recognition rates of both these emotions also fell when pitch range was reduced.

Sadness and Fear also employed opposing tendencies in the original corpus, with regard to average pitch: Fear being high and Sadness low. However, shifting the average pitch had a large effect on Fear, but no effect on sadness. Nevertheless, since these emotions have relatively low activation, *increasing* the pitch range for these emotions resulted in lower recognition rates.

Pitch stylization had some interesting effects also. It affected Joy most significantly, reducing recognition rates. This may indicate that recognition of Joy relies to some extent on small pitch movements as well as large ones. On the other hand, stylization increased recognition of Anger and Sadness slightly, though not significantly. Possibly this type of manipulation removed some small pitch movements that might in fact cause the emotion to sound more ambiguous in these cases.

The trends for intensity scores are roughly similar to those found for recognition scores. Emotions with high activation (Anger and Joy) were adversely affected by *reducing* pitch range, though less affected by *increase* in range. Pitch shifting had a similar effect on intensity as on recognition, though not in all emotions.

Overall, this experiment reveals that pitch mean and pitch range behave somewhat independently. Range appears to signify activation. Thus, reducing the range for emotions with high activation (Anger and Joy) appears to confound the listeners. However, reducing the pitch range for emotions with low activation (Sadness and Fear) does not have an identical effect, only marginally changing the recognition of both.

Increasing the range had no effect on emotions that had a large pitch range to start with, but reduced the recognition rates for emotions with low activation (Fear and Sadness) where a large pitch range was not expected.

Shifting the pitch mean adversely affected nearly all emotions, probably because shifting was done towards the overall average, thus reducing the degree of emotional content. This raises the question whether listeners were able to normalize their expectations of average pitch to the speakers, or whether speakers are preconditioned towards some overall global average in this respect. Interestingly, Sadness was not at all affected by this manipulation.

To summarize, the results show that the parameters of pitch range and mean and their interactions have important significance in production and perception of emotions, which are highlighted in this experiment.

4. Second Experiment

4.1. Objective

The objective of this experiment was to examine the degree to which the specific pitch contours associated with each emotional production were responsible for the correct perception of the emotion.

4.2. Methods

The original corpus was scanned for utterances which could be "paired": i.e. words or nonsense words uttered by the same speaker while expressing two or three different emotions. 104 such utterances were found. For these utterances, the pitch contour of one emotion could be synthesized onto the utterance the other one or two remaining utterances. The final corpus was thus composed of:

1. 104 original utterances
2. For pairs of utterances uttered in *two* different emotions, the pitch contour of one utterance was synthesized onto the other utterance, and vice versa, producing two new stimuli.
3. For triplets of emotions uttered in *three* different emotions, each combination of cross synthesizing pitch contour and utterance were created, producing six new stimuli

The net result was a corpus of 268 stimuli: 138 nonsense words (54 original and 84 synthesized), and 130 Hebrew words (50 original and 80 synthesized).

All manipulations were performed in Praat software. This experiment was also implemented as a Matlab GUI. For each stimulus, the participant had to choose one of five emotions: anger, sadness, joy, fear or neutral, and rate the emotional intensity on a scale of 1 to 3.

The participants were a group of 20 women, aged 20 to 30 (M=26.4), separate from the group that had participated in the first experiment. All participants had no reported hearing problems, 15-19 years of education, and were native Hebrew speakers.

4.3. Results

The average recognition score for all non-manipulated stimuli was 15.2 out of the possible 20, which is slightly lower than in experiment 1. The entire confusion matrix for these stimuli appears in Table 3. All values on the diagonal are in the vicinity of 15, with a relatively even distribution of errors. This indicates that on average, the emotions in the original, non-manipulated stimuli were fairly easy to recognize.

Table 3. *Confusion matrix of recognition scores for the original stimuli (%)*

Perceived / Produced	Anger	Joy	Fear	Sadness	Neutral
Anger	75	7	2	1	14
Joy	12	77	2	1	8
Fear	1	1	80	18	1
Sadness	7	0	10	72	11

For the manipulated stimuli, two confusion matrices can be calculated: one for identification of the stimuli according to the original emotion of each stimulus, and the second according to identification of the emotion represented by the synthesized pitch contour of each stimulus. These two matrices are presented in tables 4 and 5.

Table 4. *Confusion matrix of recognition scores for the manipulated stimuli, identified in accordance with the original emotions (%).*

Perceived / Produced	Anger	Joy	Fear	Sadness	Neutral
Anger	36	15	21	17	11
Joy	13	36	14	15	22
Fear	5	4	47	34	11
Sadness	7	5	28	46	13

Table 5. *Confusion matrix of recognition scores for the manipulated stimuli, identified in accordance with the synthesized pitch contour (%).*

Perceived / Produced	Anger	Joy	Fear	Sadness	Neutral
Anger	10	19	25	24	22
Joy	23	18	25	21	13
Fear	12	14	39	29	6
Sadness	18	11	20	36	16

Table 4 indicates that on average, changing the pitch contour caused recognition rates to fall, though they remained above the chance level (4/20) for all the emotions. Emotions Fear and Sadness remained more immune to changes of the pitch contour.

The first two values on the diagonal of Table 5 are very low. This indicates that imposing a pitch contour of Anger or Joy on utterances that originally conveyed other emotions, had very little success in causing these utterances to "shift" towards Anger or Joy. On the other hand, the second two values on the diagonal of this table are much higher, well above chance. This indicates that imposing the pitch contour of Fear or Sadness had a clear effect in shifting the perceived emotions towards these two.

Finally a more detailed analysis was carried out. Each combination of original and F0 emotion was analyzed separately, scoring perception according to 1) the original utterance; 2) the pitch contour. Results are presented in Table 6 and Figure 2.

Table 6. *Recognition scores for each cross-manipulation of original emotion and F0 contour emotion (%). Four blocks of rows are denoted with shading: hi activation to hi, hi to low, low to hi and low to low*

Row #	Original emotion	F0 emotion	Score according to original	Score according to F0	N
1	Anger	Joy	48	26	16
2	Joy	Anger	49	14	16
3	Anger	Fear	23	40	17
4	Anger	Sadness	38	28	11
5	Joy	Fear	35	32	11
6	Joy	Sadness	23	28	14
7	Fear	Anger	49	5	17
8	Fear	Joy	52	10	11
9	Sadness	Anger	50	12	11
10	Sadness	Joy	37	13	14
11	Fear	Sadness	40	52	13
12	Sadness	Fear	52	43	13

Some interesting observations can be made based on this table. For example, rows 1 and 2 show that emotions with high activation (Anger and Joy) are not easily "taken over" by swapping each other's pitch contours. However, rows 11 and 12 show that the opposite is true for emotions with low activation. Rows 2 - 6 indicate that Anger and Joy are more readily taken over by pitch contours of Fear and Sadness. Rows 7 – 10 show that Fear and Sadness are *not* easily taken over by Anger and Joy.

4.4. Discussion

The observations regarding the confusion matrices strengthen the notion that pitch is an important cue of emotion, though not the sole one. Imposing a "wrong" pitch contour reduced recognition score of the original emotion by approximately half, though emotions with high activation (Anger and Joy) appear to be more severely affected than emotions with low activation (Fear and Sadness).

Conversely, when looking at the same manipulated stimuli in order to observe when the imposed pitch contour "took over" the perceived emotion, a gross asymmetry can be observed. On average, the pitch contours of the highly active emotions had no discernible effect at all in taking over the perceived emotion. On the other hand, pitch contours of the emotions with low activation were moderately successful in taking over the perceived emotion.

Our conjecture is therefore that a pitch contour conveying high activation is far from being sufficient in conveying the appropriate emotion, if the other paralinguistic cues are not congruent. A pitch contour indicating low activation, on the other hand, is apparently a more powerful cue and thus less reliant on other cues.

The detailed analysis in Table 6 also raises some interesting asymmetries, showing that pitch contours can more easily draw one emotion to the other than the reverse. Line 3 shows that Anger is rather easily turned into fear, for example, but line 7 shows that the opposite is not true. Joy is easily converted to Sadness (line 6), but again the opposite is not true (line 10).

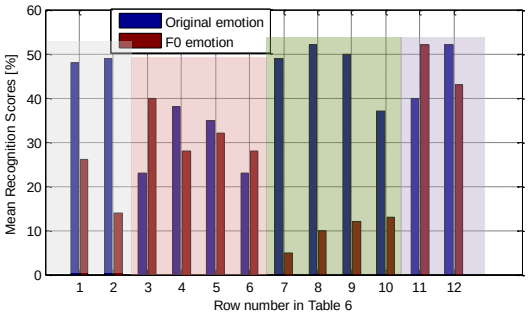

Figure 2: *Recognition scores of Table 6.* Groups of bars are color coded to fit the rows in the table.

5. Conclusions

Arriving at a clear and definite picture of the cues behind the production and perception of emotions is a daunting and likely impossible task. However, studies such as the present one can provide insight into the relative perceptual importance of these cues. Pitch has been long been acknowledged to be a central cue in emotion recognition, however this study quantifies its role to a certain extent, and underlines the fact that it has different influence on the perception of different emotions. The corpus used here offers a unique opportunity to study such effects in isolation, an opportunity which is not afforded by many emotional corpora. Presumably, manipulations of further cues, such as voice quality, could lead to results with even a higher degree of refinement in separating the effects of different cues to emotional perception.

6. Acknowledgements

The authors would like to thank Nina Gilad, Amit Lavi, Michal Rubinstein and Ravit Tahar for their assistance in running the experiments.

Abstract

This paper tests previous findings for polite speech of low pitch, low intensity, higher number of hesitation markers and filled pauses against those parameters in a different socio-cultural background. Two similar groups of (19+13) participants, from Austria and from Germany, were recorded. The adopted experimental approach used 16 tasks aiming at different speech acts in situations that evoke either polite or informal speech. The analyzed acoustic and electroglottographic signals reveal main effects for lower pitch, lower intensity and HNR only for the German group. Open quotient values differ only for female speakers. In both groups significantly lower word rate and lower speaking rate as well as higher rates of filled pauses and hesitation markers are found in formal (polite) conditions. However individual speakers can show indifferent or opposing behavior for a given parameter with compensatory utilisation of other parameters in order to express politeness (formality).
Index Terms: polite speech, voice quality, pauses, hesitations

1. Introduction

While looking at expressions on the sociopragmatic level of speech [1] a number of phonetic and other paralinguistic differences between polite vs. informal speech registers have been found for situations talking either to a senior person or to a peer. We adapt the view that the concept of polite speech covers here typically a transmission of a social message of deference, submission and distance, where politeness (polite behavior) is considered to be a vehicle to ensure stability of social hierarchies. In the model of Brown & Levinson [2] this is categorized as negative politeness strategy. Such speaking style is different from the speech of, e.g., shop assistants or other service personel, that seeks an exaggeration of displayed interest, approval, or sympathy with the interlocutor, which is identified as positive politeness [2]. And in fact, Ito [3] and Ofuka [4] found for Japanese female speakers that high pitch register and higher degrees of breathiness correlate with higher degrees of perceived politeness. Higher pitch range in connection with perceived politeness are reported for British English and Dutch by Chen et al. [5] but also for a number of Spanish Varieties in Latin America (cf.[6]). However, for Korean females a pitch lowering was found [7] in polite speech, which was confirmed in a independent production study and also found for male speakers [8]. In a recent study it was shown that English and Korean listeners can detect the intended politeness purely based on prosodic expressions (in Korean), even if only presented with minimal material like a sentence [9]. Accuracy would increase for native and non-native listeners as they become familiarized with the voices. Similarly a reduction of pitch range in Catalan [6] has been found to prompt a perception of politeness. These findings do not meet the assumptions of high pitch as known from the predictions by Brown & Levinson [2] or the frequency code hyphothesis of Ohala [10, 11], but suggest a more differentiated hypothesis with regard to the phonetic profile of politeness. Additionally it brings into play other biologically motivated sound symbolisms in human and non-human vocal behavior, namely the effort code hypothesis by Gussenhoven [12], since here other voice quality parameters apart from pitch are used. Hence this paper seeks to contribute more rigorously to the question of cross-linguistic validity of such findings and seeks to replicate the previous study [8] with a different cultural and linguistic background. In order to address also the cultural pragmatic aspect, we conducted the same experiment in two linguistic expressions of cultures (Austria and Germany) [13, 14] of the same language (German). If a more universal usage of a "frequency code" holds we would – given the results for Korean [8, 9, 15] or Catalan [6] – expect similarily for polite speech: lower F0, lower F0 range, lower intensity, lower intensity range, more tensed VQ with parameters indicating this (i.e. acoustically, lower harmonics-to-noise ratio (HNR), or electroglottographically, lower open quotient). Further we would expect for polite speech more hesitation phenomena (onset hesitation, lengthening, hesitation 'markers') and more signals of interruption (audible breath intakes etc., cf.[8]).

2. Data and Methods

2.1. Participants and Procedure

The current data set comprises recordings of 13 speakers (11 female/2 male) from East Central German and of 18 speakers (8 female/10 male) from Western Austria. Recording sessions were carried out in the phonetics lab of the MPI EVA Leipzig and in the sound attentuated room of the Media Center of University of Innsbruck. For best replication of the previous study, we were aiming at students of the humanities as participants which were not freshmen any more but still in the age of 20 to 30. The latter ensured that our participants already had commuciation experience in hierarchies and asymmetrical relations, but were not too advanced in their carrier. To ensure consistency of procedure, participants were first ask to read aloud a written text in order to get acquainted with the setup. After clarifying the general procedure the participants were prompted with different situations via a screen. The 16 situations described demanded either a mailbox task, where a participant would be asked to leave a message for her friend or her boss on a voice

mail box. Or the task was a discourse completion task (DCT), where a participant would be asked to start a conversation, like *'Remind your professor to upload the power point files after the lecture'*. Linguistically the scenario descriptions were culturally adapted for the local areas in Austria and Germany so that infrequently used phrases and non-typical names were avoided.

2.2. Recordings and Measures

The recordings of the acoustic (headset microphones AKG C420 III and audix HT5) and electroglottographic signals (Glottal enterprise EG2) were accomplished by means of a multitrack recorder sound device 788T in a PCM format of 44.1kHz 16bit. *Praat* [16] was used as annotation tool and for acoustic and EGG measures. Manual annotation and labeling was carried out in order to assess word rate, occurence of hesitation markers as well as audible and silent breath intakes. Syllable estimation [17], f0, f0 variance, f0 range, intensity (RMS), intensity range, HNR as well as noise-to-harmonics ratio (NHR), as well as jitter (local, RAP) and shimmer (local, APQ3) [16, Manual] measures were based on the periodic parts of the microphone signal. The amplitude difference H1-H2 had not been chosen, since especially for analyzing running speech these have been lately critized to be heavily vowel dependent [18]. The EGG-signal served for the open quotient, i.e. duration of open phase by total period. These quotients were based in part on the DEGG-method where the first derivative is used for estimation of the instants of closing and opening (cf. [19]).

2.3. Notes on Statistics

We used *R* [20] with the packages *lme4* [21] and *glmmADB* [22] to perform a linear mixed effects analysis of the relationship between the individual parameters and the supposed attitude (polite vs. informal). In a first step we set attitude and gender as fixed effects into the model, in a second step we added group (Austrian, German) to the fixed effects. As random effects, we had random intercepts for speakers and tasks, as well as random slopes for the effect of attitude by speaker and by task. Visual inspection of residual plots served as check for deviations from homoscedasticity or normality, including overdispersion by particular random effects (task, speaker). P-values were obtained by likelihood ratio tests of the full model with the effect in question against the model without the effect in question. Likewise models with interaction (e.g. attitude*gender) were tested against such models without interaction (e.g. attitude+gender). For the count data (pauses etc.) we were using with negative binomial and zero.inflation=TRUE.

3. Results

3.1. Polite vs. Informal: Overall

3.1.1. General Observations

All participants reacted eagerly to solve the experimental tasks quickly and freely. Specifically the mail box task proved to be appropriate, especially in initiating the experiment and gaining near real-life utterances for most of the time. The formal vs. informal distinction was realized by all participants. It was not only that participants would choose the correct grammatical forms (e.g. du 2SG 'you; thou' vs. Sie 'you' 3SG) for addressing the imaginary interlocutor, but they would also use more passive or subjunctive constructions. With regard to pronunciation we almost always observed a shift away from close-to-standard patterns into to more areal or colloquial patterns in informal situations. This was more clearly obvious for the Austrian group, since the (spoken) standard for all German speaking countries is derived from more Northern German pronunciation habits, hence there is a greater phonetic distance between the two varieties and therefore the two situational styles/registers.

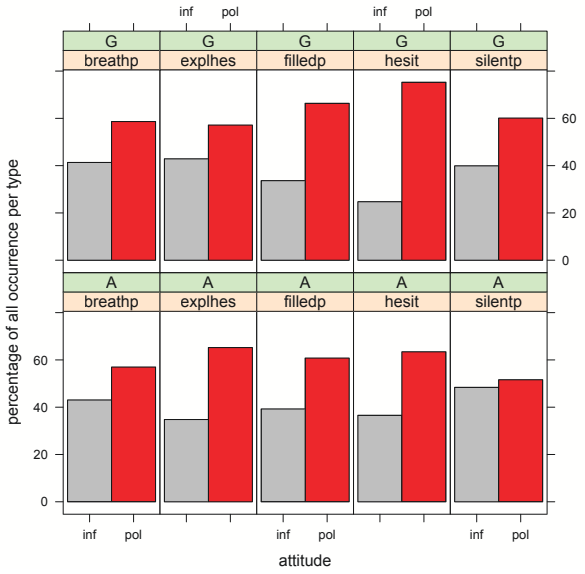

Figure 1: *occurrence of breath, silent and filled pauses as well as explicit and other (lengthening) hesitation markings, grouped by country (*Austria; Germany*)*

3.1.2. Hesitation Phenomena and Rates

One of the most striking phenomena is the occurence of hesitation phenomena throughout the corpus. In order to group the different appearances of these phenomena in a meaningful way we defined five types. First, we separated pauses into *silent pauses* and (audible) *breath pauses* (in and out). Then we would treate conventionalized hesitation markers – also known as non-lexical conversational sounds (cf. [23]) or fillers – like "ä","äh","ähm" ('hm, mh , em' etc.) as *filled pauses*. In contrary such coventionalized explicit phrases that contain lexical items like "ich denk", "glaub ich" ('I guess, I think') or conjunctions like "u:::nd", "dann:: ", "weil::" ('and, well, because' etc.) – functioning as discourse markers – were grouped as *explicit hesitations*. Although one can observe all kinds of combinations of the conventionalized markers, phrases and conjuctions plus a phonetic lengthening (like "u:::nd", "dann:: ", "weil::" or "und ähm", "weil ähm", "dass ähm") we nonetheless treated these lengthening behavior as one *hesitation* category. Silent pauses would also comprise instances of breath holding, i.e. a pause with oral or glottal closure, with a more or less sudden release. These cases were also treated under the same category, *hesitation*.

Overall we find higher counts and percentages for all types of hesitation marking and pauses in the formal (polite) condition. Breathing pauses (inhales) show a significant main effect (attitude=polite, Est. +0.363 ±2.99 SE, p=0.0028) with no (gender) interactions. However one needs also to take into account that the answers in the polite condition have a longer duration. The relation of effective duration and total duration of a task reflects the role of pauses per task similar to the rela-

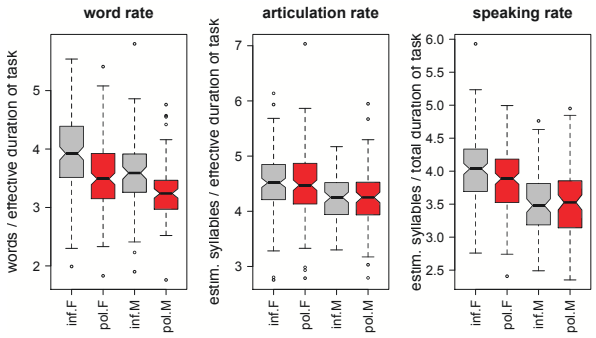

Figure 2: *Overall rates for all female (F) and male (M) speakers in polite (pol) and informal (inf) condition*

tion of speaking rate vs. articulation rate (-0.025s ± 0.01154, p=0.037). Closely related are the results of word rates (p=0.03), since here a higher number of pauses corroborates the lower rate of words (per task duration). Moreover the lower 'wordiness' may even be more pronounced since here all non-lexical markers have not been excluded yet.

3.1.3. Pitch, Intensity and Voice Quality Measures

Average f0 values display only a minimal overall main effect of -0.41st and ±0.217, i.e. lower f0 in the polite condition. Only half which comes out significant for interaction (attitude*gender) for the German subgroup (-0.44st ±0.273, p=0.012). Further only mean intensity differences reach significance in interaction (-1.24dB ±0.460, p=0.02746). The only acoustic voice quality parameter showing significant effects reflects the variance of HNR within a task: overall HNR SD is lower for polite speech with interaction effect (0.28dB ±0.116, p=0.019), in the Austrian (0.17dB ±0.109, p=0.023) and the German group (here only as main effect, 0.14dB ±0.098, p=0.015). This points towards a more non-homogenous use of voice quality on the breathiness-tensedness dimension. Taking into account correction for multiple testing we note that this result is corroborated by the results for open quotients (OQ; Fig. 3), where we see lower values in polite situations (mean OQ: 0.013 ±0.0114, p=0.0364; OQ SD: 0.0105 ±0.0041, p=0.043; here only reported for interaction with country since only female speakers were compared). These findings suggests a higher tensedness (or lower breathiness) for polite speech and thus far parallel the results for Korean [8].

3.2. Group specific behavior

3.2.1. Overall gender specific behavior

Gender specific main effects are found for parameters that are expected and well known to differ between genders (sex). These concern mainly pitch and voice quality (jitter, shimmer), where f0 range seems to be strikingly higher for male speakers in both conditions. As often observed, we find higher articulation rates for female speakers (Fig. 2; with interaction, 0.31words/s ±0.160, p=0.00014). More interesting in this regard is that word rates show a signficant effect with interaction for lower rates in polite speech with male speakers (0.013words/s ±0.080, p=0.039).

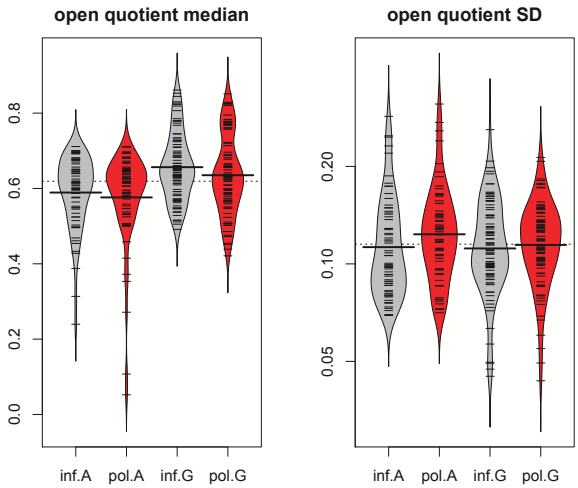

Figure 3: *open quotient measures for female participants from Austria (A; N=8) and Germany (G; N=11)*

3.2.2. German in Austria vs. German in Germany

Apart from a general trend for open quotients, which appear to be very small but significantly higher for female speakers from Germany (mean OQ:-0.0024 ±0.01806, p=0.039) than for female speakers from Austria, meaning that there comes into play a difference between these groups, perhaps pointing towards a general use of breathiness in the speaker population from Germany. Other measures where we find group (country) effects but also main effects for attitude are mean intensity values (-6.46dB ±1.542, p=0.00011) and HNR SD values (0.79dB ±0.3106, p=0.0053). With regard to the nature of these measures such differences may be easily explained by the influence of conditions (e.g. mic or booth) in the two recording sites.

3.3. Task specific behavior

The individual task categories (eight scenarios) that we were testing for phonetic aspects comprise a number of different speech acts, i.e. types of messages that have to be conveyed by the paticipant. These required urgently requesting an action (task 11, 12), requesting something critical (task 2,6), requesting something essential (task 1), apologizing for being late, making a compliment (task 5), and correcting a (minor/major) mistake (task 3,4). Indeed we observe, more often especially for task 5 (*compliment*) but also for task 6 (*minor request*), behavior that deviates from that of other tasks. For mean HNR measures in task 5, showing the lowest values in the dataset, a three way interaction of attitude, gender and task becomes marginally significant (-1.42dB ±0.737, p=0.0545). Moreover, mean HNR measures show for task 2 and 12, lower values for males and females whereas the other tasks display the contrary trend, e.g. males in task 3 (1.48dB ±0.521, p=0.0045). Strikingly the two groups behave almost symmetrically (s. Fig. 4) and we are not yet able to discard a particular task as behaving consistently different.

3.4. Speaker specific behavior

While looking at strategies of individual speakers we report in Table 1 individual slopes for a selection of parameters that show partially an opposing behavior (cf. [24]). For example

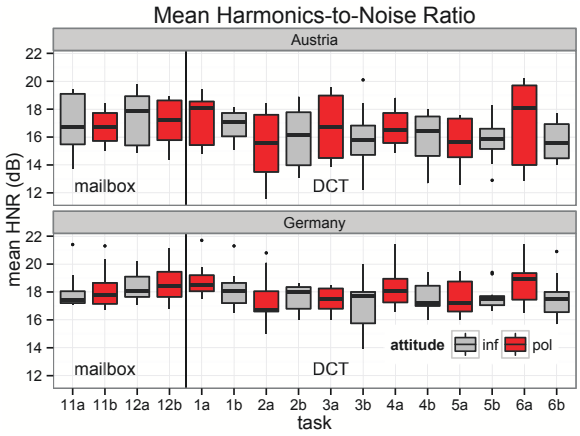

Figure 4: *taskwise HNR behavior (females only)*

speaker GM01 illustrates the complementary use of high intensity range difference but countertrend f0 range. At the lower end we find speaker AM02 with the opposite behavior. Simlarily HNR seems to be more strongly employed (e.g. by GM01). By contrast, all speakers exhibit the same trend for the pause quotient (effective task duration by total task duration).

4. Discussion

On the one hand the current results for speakers of two German varieties show tendencies for the use of hesitations and pauses as well as for the use of pitch, pitch range, intensity, intensity range, and HNR, that match those results for Korean in [8]. On the other hand, the two speech registers appear to be less distinct, given the lower number of significant differences, which can be assumed to mirror the fact that for German politeness or formality register is linguistically but also culturally less entrenched. Certainly we must stay aware of the reality of the experimental nature of the investigated speaking behavior. The general assumption here is that participants will simulate from the same source of acquired culturally transmitted and evolutionary conditioned behavioral pattern as they would in a non-experimental situation of a similar situation 'in situ'. The latter would then supposedly evoke higher arousal levels and lead to stronger difference between the attitudes (formal/informal). We cannot exclude at this moment that individual speakers may also fail to express deference and submission widely in favour of other expressions, such as friendliness or fear, while still being formal. This could in case of friendliness be interpreted as pursuing a positive politeness strategy, or in case of fear, as an exaggeration of the urgency message. Both may remain disrespectful and therefore potentially impolite if not addresssed to peers or if failing formality even with addressing a peer – a distinction that remains to be tested yet.

5. Conclusions

Since languages vary in their entrenchment of pragmatically relevant registers (such as different degrees of politeness) into the grammar, moreover the paralinguistic expression may vary between speech communities. Small scale samples, as ours, may not give enough power to estimate the actual group differences that interact with gender specific effects. Within communities we observe speakers using the multidimensional space of possible parameters (pitch, loudness, voice quality, fluency; cf.[25]) in its own particular way but also in the degree of expression. Already previous results for Korean [8] contradict the findings for Japanese and English [3, 4, 5, 7] where politeness was associated with higher pitch (and more breathiness). Although with our German speaking participants we find more non-homogenous behavior of subjects, our findings are still very similar, since we find clear trends for (less breathy) voice quality and higher rates of pausing/hesitations in polite speech. But we can also confirm the previous observations of Shin [7], who found no pitch differences for German. Given that we were using here still a parsimonious approach, using 'holistic' rather than detailed measures – an in-depth analysis of the actual moments of expression for pitch [6], intensity or breathiness/tensedness will certainly gain more insigths. In order to achieve ecological validity we will also turn these production data into a perception experiment.

Table 1: *Random slopes per speaker from polite condition sorted by f0 range values; pausequot (effective task duration / total task duration)*

Abstract

The study of the acoustic expression of emotion is, in general, the analysis of whether prosodic variables such as intonation (F0), speech rate, pauses, rhythm, intensity and duration, are reliable clues for the characterization of the emotional states of the speaker. The present paper aims to verify whether an association exists in Brazilian Portuguese between the basic emotion of "anger" and the prosodic variable "speech rate", as the literature often suggests there is for other languages. The corpus consisted of fragments of spontaneous speech recorded from a radio program. The fragments were selected on the basis of a perceptual test. For the production analysis, only excerpts that were identified by more than 75% of the participants of the perceptual test as associated to the categories "anger" and "neutral" were selected. The results demonstrated that, for the data that were used for the analysis, there is a general reduction in speech rate when utterances are associated with the emotion of "anger", if compared to utterances spoken in a "neutral" mode by the same speaker, contrary to what literature often indicates for other languages.

Index Terms: speech rate, anger, spontaneous speech

1. Introduction

1.1. Speech and emotion

There are several ways in which human emotions can be expressed at the time of communication: through the facial expression of the speaker, the verbal content of the utterance and the acoustic features of the speech, observed through the behavior of prosodic parameters such as intensity, duration, fundamental frequency (F0) and voice quality.

All these parameters collaborate to speech intelligibility and promote the understanding of the expression of emotions in human communication. [1], however, consider that the prosodic characteristics alone may warrant the recognition of emotions expressed by humans.

According to [2], real-world applications, notably those based on human–computer interaction, depend on coming to terms with the ways people express emotion. In order to contribute to the improvement of recognition and synthesis speech systems, [3] found to be of vital importance to speech technology to determine the vocal changes produced by emotional factors in various languages and cultures. Thus, [3] has analyzed the emotion and speech recognition in nine countries from three different continents and found that segmental and suprasegmental aspects, in each of the languages that were analysed, contribute significantly to the production and the perception of the emotional categories.

The classification and the concept of emotion are, however, quite controversial in the literature [4]. [5] asserts that the definitions of emotion are as varied as the researches that address it. The classification of emotions is particularly controversial because of its spontaneous, involuntary and unpredictable feature.

Despite the lack of general agreement in the literature, there are common basic aspects that several papers share on the subject, such as the fact that emotions are almost always directed to the object, that they are activated by internal or external stimuli and that they consist of momentary states of people [5]. It also seems to be a consensus among the researchers that emotion can be broken down into three basic categories: sadness, happiness and anger ([5], [6]).

Each of the emotions, as classified by the literature, is associated with specific prosodic features that individualizes them. [5], [7] and [8], in studies of the Dutch, French and German languages respectively, sought to associate emotional patterns in these languages with acoustic parameters such as pitch levels, vocal range, global average intensity and total utterance duration. In all of these studies, the authors observed that sadness is generally characterized by a lower F0, a lower voice and a slower rate, whereas anger and joy have a higher F0, a louder voice and a faster speech rate.

[9], on the other hand, points out that not always the speakers of a language expresses emotions in the same way with the same activation levels. Then, each of the basic emotions can generate different levels of activation in the speaker, depending on its manifestation. For example, [5] observed that irritation causes a low level of activation in speaker, while fury affects the speaker more intensely.

[10] asserts that there may be very subtle differences in the way basic emotions are manifested for individual speakers. The author, however, does not make reference to different emotions, but to subtypes of the same emotion. In that way, [10] considers "fury" (hot anger) and "irritation" (cold anger), for example, as being two different manifestations of the same emotion: anger.

According to [2], there are inconsistencies for several emotions and emotion-related states that have been studied. These, however, may reflect inconsistent procedure or different interpretation of emotion categories, or variations in terms of the type of data that was used in the analysis: real or simulated. Others, though, seem likely to reflect real differences in the vocal expression of emotion, from speaker to speaker, from culture to culture, and across genders and situations. [2] points out that comparisons between languages and cultures are limited, but they suggest substantial differences.

There are still very few studies on prosodic characteristics of emotions and emotion-ralated events in Brazilian Portuguese. [9], for example, investigated how the expression of three primary emotions affects the characteristic melodic contours of four speech acts in Brazilian Portuguese spoken in Rio de Janeiro. In order to test that, the author used an interaction between four speech acts (assertion, question, request an order) and four emotions (three primary emotions: sadness, happiness and anger, plus the "neutral" form). She

intended to answer whether these two categories – speech acts and emotion – are really independent prosodic dimensions or whether the interaction between them causes substantial changes in intonation patterns that's been found for speech acts alone.

The author found that speech acts and emotional patterns appear to be independent categories in terms of production. With regard to the perception, however, there is some overlap between the two categories. She concludes that intonation and voice quality should be seen as complementary categories, both necessary for the recognition of emotional states of the speaker. It must be pointed out, however, that [9] analyzed utterances produced by two actors from the southeastern area of Brazil. Most of the few studies addressing the prosody of emotions in Brazilian Portuguese is based on the southern and southeastern dialects, and uses monitored utterances produced by actors.

[11] presented a method for speech expressiveness, which combines a dimensional analysis of speech expression, a Principal Component Analysis technique, as well as a multiple regression analysis. The author used as the corpus for his study recordings of a radio show called Programa do Chupim, aired by Rádio Metropolitana de São Paulo, based on a southeastern area of Brazil. He concluded that if utterances are analyzed chronologically, they reveal clear expression changes, from an automatic acoustic analysis, what implies that acoustic parameters are sufficient for the detection of emotion in speech.

[12] analyzed the prosody and expressivity of speech through emotions expressed in a poem spoken by a professional actor from southeastern Brazil. [13], investigated the melodic contour associated to the emotion of anger in theatrical speeches, based on samples of three professional actresses from southeastern Brazil, collected in laboratory condition. [14] also analysed monitored speech with the goal of improving synthesized speech produced by a TTS (text to speech) system, by adding to it emotional information from an acoustic perspective. The model used by them was based on a southeastern dialect of Brazilian Portuguese.

It is, however, unclear to what extent monitored speech truly reflects an emotion that is characterized as involuntary and unpredictable. This is, actually, one of the most important limitations in studies of emotional speech [15]. In this direction, [16] emphasized that high levels of activation are not often found in the case of elicited emotions from control conditions.

1.2. Speech rate

One of the very first references to empirical research on speech rate dates back to [17], who summarizes his findings as follows: "it takes about twice as long to read (aloud, as fast as possible) words which have no connexion as letters which make words… When a passage is read aloud at a normal rate, about the same time is taken for each word as when words having no connexion are read as fast as possible." This study dealt with several languages, such as English, French, German, Italian, Latin and Greek, as he was also concerned with the different rate employed by the same speaker while speaking a foreign language. According to [17], the rate at which someone speaks a foreign language is determined by the familiarity that the person has with the language: the more familiar a person is with it, the faster the speech.

[18] was perhaps the first to introduce objective methodology for the study of rate in speech. Using a rather peculiar method of measurement that relied on soot marking from flames, he compared polysyllabic words with monosyllabic words, using the syllable per second unit of measure – a unit most widely employed today. In his experiment, he demonstrated that, for a given passage containing the same amount of syllables, polysyllabic words are read faster than monosyllabic words. He claims that this is due to the amount of meaning that is carried out in passages containing monosyllabic syllables: the larger the amount of meaning that is conveyed in a message, the longer the speaker will take to utter it.

Meaning is also considered to be a determining factor for the establishment of speech rate in [19]. It compared the repetition of nonsense syllables with the production of syllables articulated within words and found that nonsense syllables are often produced at a slower rate than those syllables that are part of real words. He also noted that people tend to be affected by curiosity when reading a passage of unknown content, which would result in a deliberate acceleration of the speech as a result of this curiosity.

[20] introduced developmental considerations to the study of speech rate, by investigating the speech of kindergarten children. They found that while boys tend to speak less than girls, they do so in a faster rate. [21] considered other external factors. According to these authors, emotions such as anger, fear, and indifference are closely related to fast speech rate, whereas contempt and grief are associated to slow rate.

[22] confirmed the hypothesis that meaning has a decisive influence on speech rate, by demonstrating that the more meaning there is invested in an utterance, the slower the articulation rate is. According to him, this has also to do with the emotional state of the speaker: psychological tension – a result of the demanding task of interpreting new meanings – would be the most immediate reason for speech rate variation.

On the basis of the overview presented above, it may be concluded that there is a historical tradition in the studies on speech rate to relate its observed variation to both semantic and emotional aspects associated to different speech activities. The study on speech rate, as an acoustic correlate of emotion, is still incipient for Brazilian Portuguese, as the literature review presented above indicated. Most of the few studies carried on so far focus on intonational characteristics in speech expressiveness.

One of the few studies for Brazilian Portuguese that addresses the acoustic parameter of speech rate as a correlate of emotion is that of [9]. According to her findings, there isn't a straightforward relation between duration and different basic emotions: duration may vary as a function of individual speakers. (See also [23]).

1.3. Research question

The main objective of the present study is to investigate whether speech rate is a reliable acoustic correlate, in Brazilian Portuguese, of a basic human emotion: anger. The rationale for this study lies in the scarcity of such investigation, despite the fact that the literature often relates the acoustic parameter of speech rate to human emotion ([5], [7], [8], [9]).

Contrary to most of the very few studies on the prosody of emotion in Brazilian Portuguese, the present investigation uses spontaneous material, representative of a dialect that has been neglected so far in this kind of investigation: that spoken in the northeastern area of Brazil.

2. Methods

The data used in this study consist of eighteen small fragments of recordings of spontaneous speech, extracted from a radio program called "A Hora do Mução". It is a popular practical joke program, in which the radio broadcaster Rodrigo Vieira Emerenciano embodies the character Mução. The radio broadcaster calls people in the northeastern area of Brazil, from suggestions made by friends and relatives of the victim, in order to annoy them by constantly making reference to a physical characteristic or a nickname of the victm. One of the advantages of this kind of interaction, in radio program, is the possibility of obtaining high levels of arousal of affective responses, due to the critical events introduced by the program presenter.

In the recordings, there is a clear difference between the speech of the called parties in the first half of the phone calls and their second half, when the reason for the calls is known (i.e. the practical joke is in action). In the second half of the calls, the speech of the called party is clearly linked to the expression of anger.

The recordings of this radio program are, therefore, an excelent material for the type of analysis proposed here because they make it possible to compare, for each individual speaker, prosodic features associated with neutral speech to those associated with the expression of anger.

Furthermore, contrary to what happens with most of the data used in research about the relationship between prosody and emotion, the recordings used in the present investigation reflect the speech associated with a spontaneously occurred emotion, what makes it ecologically valid. It must also be pointed out that telephone speech is ideal for the study of vocal signs of emotion, because contrary to face to face interactions, it doesn't present any visual information that could distract the analysis ([2], [24]).

The excerpts of the recordings were selected from a perceptual test conducted with forty graduate students in Arts at Federal University of Alagoas. The data that was used in this perception test consisted of fragments of recordings available on CD "Pegadinhas do Mução" [25], which were selected based on the following criteria: (i) sound quality (intelligible and noiseless signal), (ii) sex the speaker (all excerpts were extracted from recordings featuring men only, in order to avoid the inclusion of a variable that could confound the interpretation of the results), and (iii) content of lexical information (the extract were selected by taking into account their contents: for obvious reasons, they shouldn't offer any evident clues of anger – or any other emotion, for that matter). Regarding this last criterion, however, it must be pointed out that previous studies have demonstrated that prosody processing is segregated from linguistic semantic processing, probably because both depend on partially dissociated neural mechanisms ([26], [27]).

We understand that the corpus is reduced, however, the difficulty in obtaining data from spontaneous speech justifies this limitation. Moreover, we could not use excerpts of the recordings containing insults and in the case of emotion "anger", this occurs very often.

Transcriptions of the selected excerpts from recordings of three practical jokes, made with three different men, all speakers of northeastern dialects, along with their corresponding audio files were presented in slide-show, at random, to the participants of the perceptual test. For each excerpts, the participant had to identify an emotion related to it. The options were the three basic emotions: "anger", "happiness" and "sadness", as well as "neutral". The participants were instructed to listen to each stimulus as often as they wished before answering the form.

For the production analysis, only excerpts that were identified by more than 75% of the participants of the perceptual test as associated to the categories "anger" and "neutral" were selected.

There is a variety of units of measurement that are employed in the research on speech rate. The units range from sounds per unit of time ([22], [28], [29], [30]), to words per unit of time ([31], [32], [33], [34], [35]), to syllables per unit of time ([34], [36], [37]) and finally to beats per unit of time [35]. This plethora of units of measurements employed in the literature not only reflects a serious methodological flaw – as discussed in [37], but also makes the essential task of comparing results among various studies impossible.

The best-suited unit of measurement for speech rate, according to many authors, is the syllables per unit of time ([38], [39]). [36], for example, defines speech rate as the "rate of syllable succession." This is the unit adopted by [34], [38], [40], [41], [42], [43], [44] and [45], to name a few. Even though, as [39] points out, this unit of measurement has also the disadvantage of not taking into consideration the processes that may result in syllable omission, that are often found in rapid speech, such as assimilation and segmental deletion, what would obviously not be covered in this unit of measurement.

Therefore, the present study opted for a measure that is mostly used in the temporal research of speech for the sake of comparability. It does recognize the pitfalls related to this choice, but assumes that they are not so serious as to invalidate the analysis. Speech rate will be interpreted in this study using the measurement of syllables per second.

3. Results

Figure 1 below shows average speech rates of the speech samples that were selected for analysis, based on the perceptual test. It is broken down by emotion ("neutral" and "anger") and speaker (a total of three).

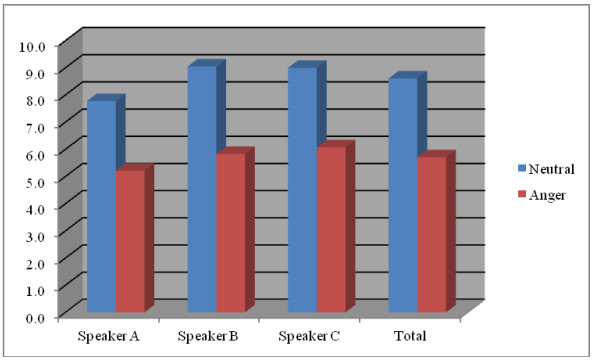

Figure 1: *Average speech rate (in syllables per second) of "neutral" and "anger" utterances, broken down by speakers.*

We used the mean for comparison between utterances associated with each emotion because we found that the difference between it and the median was insignificant, which allows us to state that there is no significant distortion in the mean rates found in analyzed excerpts and, therefore, can be considered a reliable measure for this data.

The results shown in Figure 1 clearly indicate that speakers employed a slower rate of speech in utterances associated to the emotion of anger, if compared to those considered to be neutral, both individually as well as a group. Speech rate of the excerpts labeled as "neutral" was, in average, 3 syllables per second faster than those that were labeled as associated to the emotion of anger.

A series of paired-samples two tailed t-tests were conducted to assess the significance of the differences in speech rate between "neutral" and "anger" expressions for each speaker and for the total sample. Table 1 below shows the results of these tests:

Table 1. *Results of t-tests, broken down by speaker and by total sample.*

Sample	Results
Speaker A	[$t(5) = 7.02$, $p < 0.0009$]
Speaker B	[$t(5) = 11.08$, $p < 0.0001$]
Speaker C	[$t(5) = 6.77$, $p < 0.0011$]
Total sample	[$t(17) = 13.86$, $p < 1.08E-10$]

Table 1 evidences that for all speakers, speech rates differ significantly between the two conditions: "neutral" and "anger". It also indicates that the differences are significant when subjects are regarded as a group. Results in Table 1 show a low probability of the results being a fortuity, as indicated by the values of p.

4. Discussion

This study set out to investigate whether speech rate is a reliable acoustic correlate, in Brazilian Portuguese, of a specific basic emotion: "anger". It followed the tradition of studies that explore how speakers use prosody to encode discrete emotions, such as happiness, anger, disgust, etc.

Emotional prosody in Brazilian Portuguese has been studied very scarcely so far. The few papers that address the issue deal almost exclusively with simulated emotion and are based on data representative of dialects spoken in the southeastern area o Brazil. In order to contribute with the still incipient research on emotional prosody in Brazilian Portuguese, the present investigation used spontaneous recordings representative of dialects spoken in northeastern Brazil.

According to the literature, the emotion of "anger" is characterized acoustically by fast speech rate, high voice intensity, high F0/pitch level, much F0/pitch variability, rising F0/pitch contour, fast voice onsets, and microstructural irregularity ([5], [7], [8], [9]).

What the general results from the analysis of speech rate reported here suggest is that there are possible dissonances between what the literature establishes as a prosodic pattern associated with the emotion of "anger" and what has been identified as a pattern for the same emotion in Brazilian Portuguese, based on spontaneous speech material. The results demonstrate that there is a general reduction in speech rate when utterances are associated with the basic emotion of "anger", if compared to utterances spoken in a "neutral" mode by the same speaker. Statistical analysis indicate that this difference is not a fortuity or due to individual characteristics of the speakers, because the samples of each speaker were analyzed individually, as well as a group, and very similar characteristics with regards to this speech rate's variable in the expression of anger was found.

It is known that emotions are manifested in a continuous way, in varying dimensions, depending on the level of activation / stimulation [9]. The emotion of "anger", for example, can be expressed on a scale ranging from a mild "irritation" to a "wrath".

In this paper, however, we didn't consider the varied levels of activation, but rather the basic emotion "anger". We are of course aware that, depending on where in the continuum a given emotion is located, its corresponding acoustic characteristic may vary [46]. Notwithstanding, faster speech rate is commonly associated to any level of activation in the scale of "anger" [10].

The difference in terms of speech rate as a correlate of the emotion of "anger" reported here, as compared to the results reported elsewhere, may be interpreted as a result of the specificities of data that were used for the analysis: spontaneous material, derived from telephone speech, uttered by male speakers of scarcely studied dialects of Brazilian Portuguese. As [2] points out, variations in this kind of study may reflect differences in the vocal expression of emotion, from speaker to speaker, from culture to culture, and across genders and situations. In order to find out whether this is systematically the case, further investigation needs to be done, with a larger corpus contemplating all possible variables that are potentially important for any attempt to generalize.

5. Conclusion

According to [47], communication of emotions is crucial to social relationships and survival. It is, thus, essential to understand all the aspects related to it, including its acoustic properties. It has been suggested, however, that signs of emotion in speech is not consistent across individuals and occasions, what calls for systematic descriptions of their properties for proper comparisons between languages and cultures.

The analysis presented here allowed us to infer that in spontaneous speech data representing the variety of Portuguese spoken in northeastern Brazil, there is not an association between the basic emotion of "anger" and an increase in speech rate, as the literature often indicates for other languages. Instead, many excerpts identified as being representative of the emotion "anger" by the participants of the perception test were enunciated with a speech rate slower than that in the excerpts perceived as "neutral".

Contrary to most studies on the prosody of emotion, the present study opted to use spontaneous material for the analysis, because, as [10], we believe that if research continues to be almost exclusively concerned with the simulation of emotion, nothing much will be gained in terms of getting to understand to what extent we are operating within a closed system of association or translation rules that may be only indirectly tied to the underlying biology of emotion.

The present paper stands as a contribution to the acoustic characterization of emotional patterns in Brazilian Portuguese. We plan for future investigation to enlarge the corpus, as to reflect other variables, and to include other prosodic parameters in the analysis, such as variation in fundamental frequency, pause and intensity. Perceptual tests with stylized samples of the corpus are also planned, as we understand that it is fundamental to describe what prosodic parameters are relevant from a perceptual perspective.

Abstract

This study focuses on confusions made by French L2 learners vs. native subjects in the perception of 11 audiovisual Mandarin Chinese social affects. Two groups of French L2 learners of Mandarin Chinese were selected according to their Chinese level : 9 beginners (A1) vs. 10 intermediate learners (A2). Subjects evaluated the 11 social affects in audio, visual and audiovisual condition. Comparison of confusions between learners of level A1 vs. A2 indicates few significant differences, mostly in audiovisual condition and without a clear gain for one group over the other. The comparison of French L2 learners pooled together vs. native speakers reference sheds light on major confusions to be targeted by specific methods and exercises. Cross-modality comparisons suggest a limited contribution of informations conveyed by acoustic prosody in the identification of audiovisual social affects by L2 learners.

Index Terms: social affects, attitudes, audio-visual perception, L2 prosody, Mandarin Chinese

1. Introduction

The face to face interaction functions of prosody are the main vector of the "socio-affective glue" that builds the communication channel [1] and are expressed following different cognitive processing levels [2]: from involuntary controlled expressions (emotions) to the voluntary control of the social affects of the speaker [3,4]: intentions, attitudes, social cues etc). During the face-to-face communication, people express their affects within the audio-visual speech prosody [5], and as social affects are constructed socially for and by the language, and prosodic realization of one specific social affect in a specific language may be ambiguous or unknown in the learner's language [6], the cross-cultural approach looks more convenient to spotlight the cultural specifications of the expression of social affects. Meanwhile, the social affects are generally learned in childhood within the language community in question and they can also be learned by the learners of a foreign language or a second language if they are different from the social affects in their mother language. But it is preliminarily necessary for foreign learners to recognize first the social affects expressed in the target language. Some studies have shown that the foreign language learners did not perceive the attitude expressed in the target language in the same way with the native people, and the attitudinal prosody needs to be taught in the L2 class [7, 8].

For these reasons, we intend in this study to examine in a cross-cultural context the perception of the audio-visual expressions of Chinese social affective prosody by both native subjects and French learners of Mandarin Chinese. The largest part of the analysis focuses on differences between native Chinese listeners and French learners for the perception of the same social affect, investigating the potential influence of the learners' language skill on their perception of these social affects. The relative contribution of the acoustic vs. visual modalities is also compared across groups of subjects. Finally, consequences for L2 teaching of differences in the perception of social affects between learners and native speakers will be discussed.

2. Method

2.1. Selection of social affects

A large audio-visual Chinese corpus (acted speech) of 19 social affects (each expressed on a set of utterances varying within length, syntax and tone location) was initially validated in an acoustic only perception experiment [9].On the basis of an acoustic cross-perception experiment by French naive listeners [10], 11 social affects were selected among the 19. These social affects were observed problematic for both native and foreign listeners during the previous perception experiments because of their "attractivity" (cumulated percentage of confusions from other attitudes to each one) and showed great difference in perception behavior between native subjects and foreign ones. Hence, they are supposed to be also problematic and difficult for French learners of Chinese in their face-to-face communication with native speakers. The 11 social affects selected are composed of the attitudes, intention or opinion of the speaker about what he says; the characteristics of the social relation implied in the interaction (e.g. "politeness") and the socio-cultural context of interaction (e.g. "infant-directed speech"). Table 1 presents the 11 Chinese social affects and their abbreviation.

Table 1. *Summary of the 11 social affects selected*

Social affects and abbreviation	
declaration (DECL)	obviousness (OBVI)
question (QUES)	neutral surprise (NEU-S)
irritation (IRRI)	politeness (POLI)
doubt (DOUB)	authority (AUTH)
contempt(CONT)	infant-directed speech (IDS)
disappointment (DISA)	

2.2. Audiovisual corpus

The audiovisual speech corpus is based on a 4-syllable long sentence, which is constructed to bear a literally neutral meaning but could be expressed with all social affects studied.

This sentence was performed with 11 social affects by one native Chinese female speaker, who speaks an unmarked standard Mandarin Chinese. The audio part of the corpus has been validated in [9], where all of 11 attitudes have been recognized over chance level. The sentence used in this experiment was better recognized for all social affects and considered the most representative of a prototypical expression of the targeted social affect. This sentence is "四天三夜" (si4 tian1 san1 ye4, "four days and three nights" in English). Thus, 11 short videos were used in the present experiment.

2.3. Subjects

A first group consisted of 30 Chinese native listeners (12 males and 18 females, mean age = 33.3) as the reference group of "optimal" performances of Chinese perception. Two groups of L2 learners are composed according to their results to a test of placement in Chinese language according to CECRL (the Common European Framework of Reference for Languages), taken at the beginning of the term. One group was composed of 9 French learners of Mandarin Chinese whose acquired Chinese level is A1: beginners, having taken less than 100 hours of teaching (1 male and 8 females, mean age = 20.7). Another group was composed of 10 French learners of level A2 – having taken less than 200 hours of teaching (3 males and 7 females, mean age = 22.3). All 19 French subjects study the Mandarin Chinese as foreign language in the LANSAD (Languages for the specialists of other disciplines) Department of University Stendhal-Grenoble 3.

Subjects in each group were divided randomly into two sub-groups of equal size with a different presentation order: audio only → video only → audiovisual in one sub-group, and video only →audio only →audiovisual condition in the other.

2.4. Perceptual evaluation protocol

Before the test, subjects were briefly presented the setting of the experiment and a description of each attitude with examples of situations in which it can happen. They took the test in a quiet room with closed headphone, using a graphical user interface developed with LiveCode® for stimuli presentation and answers collection. Each stimulus was presented once, in a different random order for each subject.

The Chinese audiovisual corpus was presented to subjects in three different conditions:

- Audio only (AU): in this condition, images were hidden. Subjects were instructed to listen to what the speaker said before answering.
- Video only (VI): in this condition, the sound was turned off. Subjects were instructed to carefully watch the facial and body movements of the speaker.
- Audiovisual (AV): in this condition, both modalities were presented simultaneously. Subjects were instructed to watch the facial and body movements of the speaker and at the same time to listen to her voice

For each stimulus presented, subjects were asked to judge which attitude was expressed by the speaker, by choosing among the eleven labels proposed.

3. Results

Subjects' answers were pooled into a confusion matrix for each group of listeners x presentation condition. In each presentation condition, confusion matrices cells values were compared against chance level, and between groups using chi-squared tests for comparison of proportions.

3.1. Native subjects performance

As expected from previous studies on this corpus with Chinese and completely naive French listeners, the native listeners performed better than French learners for all modalities of presentation of social affects. In audiovisual condition, they recognized significantly over chance level (9%) all attitudes except "contempt" (recognition rate: 33%). "Declaration" and "irritation" were significantly recognized over chance in all three conditions.

3.2. A1 vs. A2 learners

A first analysis was performed comparing confusions of L2 learners with level A1 vs. L2 learners with level A2, revealing few inter-group differences. The largest part of significant differences was found in audiovisual presentation condition. Compared to group A1, the group A2 confused significantly less question with obviousness and doubt with neutral surprise, outperforming both native subjects and A1 learners in their identification of the expression of doubt. Surprisingly, a better performance of group A1 was found in the identification of authority. However, a comparison with native subjects reveals that the confusion pattern observed in group A2 for expressions of authority is similar to native subjects confusions, authority being largely confused with obviousness.

In audio-only condition, the expression of doubt was significantly less confused with disappointment by learners of the group A2 compared to group A1. In visual-only condition, learners in group A2 confused significantly less contempt with irritation than group A1, but they confused significantly more doubt with irritation.

3.3. Native subjects vs. French L2 learners

Results reported supra do not picture a clear advantage in performances of the group of A2 learners vs. A1. In order to get more insight into major differences between native Mandarin Chinese subjects and French L2 learners, answers in groups A1 and A2 are pooled altogether in a 'L2 learners' group (19 subjects) in the following analysis.

Table 2, 3 and 4 summarize confusions by the 30 native Mandarin Chinese listeners and French L2 learners respectively in audio-only, visual-only and audiovisual presentation condition, all learners answers pooled. Each cell in the confusion matrices has two values, native subjects' performance (top) and L2 learners' performance (bottom). Values significantly different from chance level are flagged by stars on the right part. Stars on the left part of a cell indicate a significant difference between the group of native speakers and the group of French L2 learners.

For instance, the cell corresponding to neutral surprise (NEU-S, 3rd column, 3rd line) in the matrix diagonal in audio-only condition (Table 2) indicates that native Mandarin Chinese subjects identified neutral surprise at 60%, which is significantly higher than chance ($p<.01$), while L2 learners did not identify it better than chance (16%, $p>.05$). The left part of this cell also reports that the ratio of correct identification of audiovisual neutral surprise is significantly higher ($p<.01$) in the native subjects group than in the L2 learners group.

Table 2. *Confusion matrix for 11 Chinese social affects of 30 Chinese native listeners (top position in cells) vs. 19 French listeners (bottom position in cells), in audio-only condition. Lines: presented attitudes; columns: recognized attitudes. Stars indicate significant differences (chi-squared test for proportions). Left part of cells: native Mandarin Chinese speakers vs. French learners performance; Right part: comparison with chance level for both groups of listeners: *: p<.05; **: p<.01.*

- For audio only modality: native subjects recognized significantly better neutral surprise and politeness than French learners; the native subjects confused more authority with obviousness and disappointment with declaration than French learners; on the other hand, French learners confused more contempt with question and question with obviousness than native subjects.
- For video only modality: native subjects recognized better contempt than French learners (A1: 0%, A2: 0%); French learners identified mistakenly more obviousness with declaration, contempt with irritation, and disappointment with doubt than native subjects.
- For audiovisual modality: native subjects identified better neutral surprise than French learners, who, on the contrary, recognized better infant-directed speech; native subjects confused more declaration with obviousness, doubt with question and contempt with doubt than French L2 learners. However for L2 learners, neutral surprise was more confused with irritation, question with obviousness and contempt with disappointment.

Identification rates and confusions were also compared between presentation conditions using chi-square tests, for each group of subjects. For the sake of concision, those results are not reported extensively in this paper. Cross-condition comparisons indicate different multimodal strategies for the identification of social affects between groups. While native subjects tend to rely more on acoustic cues (with neutral surprise, question and infant-directed speech significantly better recognized in audio condition, and only disappointment better recognized in visual condition), this tendency is only partly reproduced in L2 learners performance (with question and infant-directed speech better recognized in audio condition, and doubt, politeness and obviousness better recognized in visual condition). Most differences between native subjects and L2 learners are found in the comparison of audiovisual vs. audio-only condition: while native subjects show a significant gain in audiovisual condition for authority and disappointment, L2 learners significantly benefit from the audiovisual information for declaration, doubt, politeness and obviousness.

4. Discussion and conclusion

This paper investigated the perceptual behavior of 19 French learners of Mandarin Chinese vs. 30 native listeners for 11 Mandarin Chinese social affects, presented in three different conditions: audio-only, video-only and audiovisual conditions. Meanwhile it also examined the correlation between the listeners' language skill and their perceptual behavior.

According to the results of analysis, the perception of all subject groups for the audiovisual modality shows the best scores for almost all attitudes [7]. Though differences were found between groups of learners with different level, the French learners in A2 level showed no clear advantage over the learners in A1 level. However, significant differences were found between native Chinese speakers and French L2 learners as a whole: the native listeners recognized better "neutral surprise" in both audio only and audiovisual modalities, and it was more confused with "question" in audiovisual modality by French learners; "politeness" was better recognized by native subjects in audio only modality; although "contempt" was relatively better recognized by native subjects in video only modality, in fact, the recognition rate of native subjects was not satisfactory (23%); "infant-directed speech" was unexpectedly better recognized by French learners than by native subjects. Limited differences in audio-visual condition between native Mandarin Chinese subjects and French L2 learners suggest that in a face-to-face communication context, L2 learners might compensate their relative inability to identify the acoustic prosodic correlates of social affects by relying more extensively on visual cues.

Meanwhile, French learners showed more difficulties in recognizing "politeness" in audio only condition, "question" and "contempt" in video only condition. "Politeness" was mostly confused with "declaration", that may be because of their similar prosodic characteristic. The facial expression of "question" was considered similar with that of "declaration", because both of them are basic communicative functions expressed by utterance modalities and are neutral in terms of affective sate. Acoustically, "question" was more confused with "neutral surprise" by French learners. These observations suggest that L2 teaching of Mandarin Chinese for French learners could benefit from integrating specific exercises on social affects, particularly concerning their acoustic realization with a focus on "neutral surprise" and "politeness".

Abstract

The cross-disciplinary study (phonetics and film study) aims at highlighting the coordination between posture and prosody in two versions of "The Great Gatsby". The central aim of the study is to understand how prosodic variations are related to gesture in different acting schools. Formal and functional analysis of gesture and their relation to prosody, shows striking contrast between the acting styles.

Index Terms: prosody, gestures, postures, acting schools.

1. Introduction

In this paper a methodology and preliminary results of coordination between gesture and prosodic variations of two actors' productions are presented. The goal of this study is to assess the expression of emotion through speech and gestures according to two well known acting schools.

In human communication, gestures have been the subject of investigations in fields like sociology, psychology, 'natural history' tradition of interaction studies; linguistics etc. [1] describes gestures as an integral part of speech, "a close examination of the coordination of gesture with speech suggests, these two forms of expression are integrated, produced together under guidance of a single aim". Their semantic and pragmatic functions, parallel those of speech [2]. In the same way as speech, gestures are categorized in functions and forms. A number of function categories have been proposed in different domains. We have deemed adequate to apply a semantic and expressive approach instead of a structural or syntactic one, as the study deals with emotions. Our theoretical framework will be based on the semantic and expressive functional category of gestures presented by [2]: *Iconic* (the gesture gives an image of the shape or action, e.g. hands apart showing something huge), *metaphorics* (the gesture gives an image of an abstract concept, e.g. when speaking about arts), *deictics* (or pointing gestures, showing something), *emblems* (lexicalised gesture) and *effectives* (conveying emotions). Gestures have different forms, "…all gestures can be categorized according to their temporal and spatial characteristics" [3]. They can be described either as *dynamic* or *static* [3]. Forms of gesture differ from one culture to another (a head nod to say "yes" is different in Bulgaria than in most of the other European countries, they use the "no" head movement instead); they are combined most of the time with vocal cues. For example a high pitch and intensity plus hands gesticulation can represent anger. We will investigate if there is a correlation between forms of gestures and acoustic cues in the two versions of the "Great Gatsby".

2. Prosodic analysis

In the field of emotions, different prosodic cues have been used to describe emotions and to find relevant information [4], [5]. In previous studies combination of several parameters, have been studied: duration, amplitude, fundamental frequency, intensity, pitch, speech/syllable rate etc. But fundamental frequency contours are considered as the most relevant cue in perceiving emotions. In our experiment, analysis relies on fundamental frequency contours (minimum, median, maximum) as well as combined to gestures.

3. Acting schools

Emotions and attitudes in films are imparted mainly through the instructions of the film's director but also through the actor's acting styles and personality. The two versions of the "Great Gatsby", hence fore (GG1 for Jack Clayton, 1974 film and GG2 for Baz Luhrmann, 2013), reveal a visible difference in the aesthetic, acting styles and the use of voice techniques. The direction of GG1 and GG2 corresponds to different acting schools: the "American Academy of Dramatic Arts" and the Actors Studio/Method Acting respectively [6, 7, 8]. The former was founded in 1884 in New York, where working on voice was a predominant aspect of the actors' training. Actors indicate their emotions mainly through the use of voice variations, while body movements and gestures were considered as secondary. It is considered as an "intellectual" school of acting based on the text/script with a rather static attitude. The latter is a more recent school founded in 1947 and is mainly based on psycho-physiological exercises where actors are trained on how to show feelings through motion. In Method Acting School, postures and gestures are predominant; emotions are shown through the body which totally embodies the character [8, 19, 10].

4. Methods and Materials

4.1. Materials

The material analyzed is drawn from "The Great Gatsby" 1974 (GG1) scene 10 (from 1:36:07 to 1:41:09) and 2013 version (GG2) chapter 9 (from 1:30:33 to 1:37:36). The scene shows the confrontation between Tom and Jay Gatsby in the presence of Tom's wife and two friends. They were all lounging in armchairs as it was a very hot day, everybody was sweating and one could feel the tense atmosphere., This scene has been used in this study as a source for examples of different gestures and their correlation with prosody (mainly f0 variations). We have decided that it would be more interesting to concentrate on the husbands' reactions as they reveal a larger number of body movements.

4.2. Measurements

The method of analysis employed in this study is as follows: small segments of the scene were scanned in the aim of picking out postures and gestures with the corresponding speech units. Gestures and the associated pitch variation levels were annotated. A screen shot for each movement was segmented and plotted out on a chart for both versions. The movements were then labelled using the set of terms proposed by [2] for describing the functional and formal categories. In this study, we concentrated on the movements of the hands, arms head and trunk. Facial expressions were not included. The data was then labelled using Praat software [9], and an adapted human annotation scheme of lINTSINT [10]. Four tiers were labelled: orthographic, prosodic for inflection points of F0 contour. The tag assigned to each inflection point is relative to its predecessor and successor along the contour. The tag set is: M (medium), T (top), B (bottom) (for the speaker's voice range), H (higher), L (lower), U (up-step), D (down-step) and S (same). Corresponding F0 values to each inflection point is indicated in the third tier. The fourth tier shows the correlative gestures [11].

5. Results and discussion

Overall results show striking differences both in terms of acting style, gestures and emotions. In GG1 the nervous emotional tension in the confrontation scene is conveyed by the film-making techniques and the final cut rather than by the actors. Jay Gatsby (Robert Redford) was slouching in an arm-chair with a listening position, almost during the entire scene with limited gestures and using a monotonous calm voice. This static "peacock" attitude, contrasts with the husband's one, who was voluble and mobile, sitting down, standing up, pacing up and down the room, his hands in his trouser pockets, walking behind Jay Gatsby trying not to show his anger. Bruce Dern (husband) started hostility and provocation by asking: *"I'd like to know what kind of row you're trying to cause."* He was standing up facing Jay Gatsby; the utterance was accompanied by a slight trunk bend and a low pitch (110Hz) with no voice variation (27 Hz). In GG2, when Joel Edgerton asks J. Gatsby: *"What kind of a row you trying to cause in my house anyway"*, he was standing away from J. Gatsby, hands crossed, very little pitch variation (69Hz) but a F0 increase on *"are you*" which correspond to his (T at 151Hz). In the second utterance the husband was annoyed by his wife's question asking him to have some self control. In GG1 and GG2, they both replied *"self control!"* as if surprised. A difference in attitude and pitch variation between the two is obvious (see figure 1 and 2). A higher pitch level (in GG2, and larger variation (165Hz) was observed with a down step at the end of the utterance, although he had a static attitude, standing up and hands crossed. Whereas in GG1, the husband speaks with calm low voice but there is an audible step-up in the terminal pitch at "control" (205Hz) and a head nod at the same time. In a last attempt to conquer his wife's heart again, he supplicated her in a whispery charming voice "*And not that day that I picked you up in my arms and carried you...*" Here the action of *"carry"* is said with a slight rise at the beginning of the utterance, then almost the same pitch but "carry" is showed by *an* iconic gesture and a rather long pause (1.51 ms) before the end. This gives account of his despair, as if he was weighing his words and expecting a positive reply after the effect of his seductive voice. The husband in GG2 version used a very low pitch with a range of (B at 78Hz and T at 126 Hz), hands always crossed as gesture. The scene ends up by the husband provoking J. Gatsby; "*certainly not for a swindler…*" in GG1, with a left head tilt, a (B at 87Hz) and no increase in F0. J. Edgerton's reaction in GG2 *"certainly not for a common swindler like you*", his attitude was still static, but one can perceive the intensity in his voice when he called J. Gatsby *"a common swindler», but* with a small increase in F0. In this confrontation scene, we have noticed that the acting style and the use of gestures and voice variations are completely different in the two versions (see table 1). In GG1, there is a real contrast between J. Gatsby (Robert Redford's) static listening position and Bruce Dern who was mobile and demonstrating his speech with several gestures (n° 15: stop gesture, n°18 deictic/pointing…) [11], thus giving more strength to his speech. The expected fist fight and "blast" did not take place in this version. This might explain the small pitch variations in his voice (see table 2). Jay Gatsby's attitude in GG2 is totally different; Di Caprio delivered a "neurotic" version in this scene, showing clearly his irritability and highly nervous state through micro- gestures and postures, for instance: shaking his foot, leaning his head, walking forward to and backward from the window, helping himself to a drink several times, shouting etc. In the confrontation scene, Joel Edgerton, embodies the role of a deceived husband, ready to fight, although he stood stiff and edgy far away from J. Gatsby with his hands crossed for most of scene. But emotions were perceived more in his acting style when comparing pitch contours. (See table 2). As he does not show many gestures in this scene, he acts using his voice, with perceived pitch variations or even with sarcastic laughter (twice) "*you must be crazy"*. This static attitude or posture corresponds to the classical school of acting and contrasts with Di Caprio's Actors Studio/Method and its dynamic approach. In GG1, Bruce Dern's acting style and emotions, are conveyed more through gestures (with clear trajectories), than through the use of vocal cues. He embodied the role according to the Modern Actors method school.

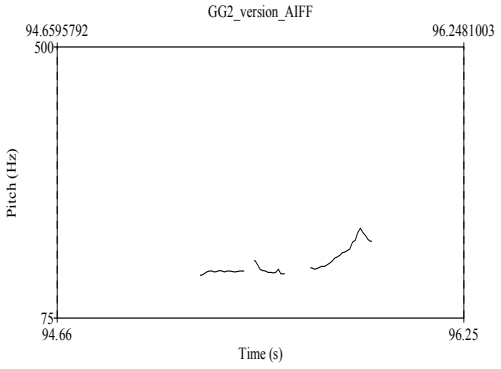

Figure 1: *"Self-control!" GG1*

The coordination between gesture and prosody is different in the two versions. In GG1, Bruce Den's gestures are combined with slight changes in pitch; however F0 values do not show systematic marked cues. His gestures sometimes correspond to a Top level like in GG1 *"self control*", to a rise *"not that day"* or even to a Bottom value *"like you"*. In GG2 the use of voice is predominant, with pitch variations reaching the Top range of the speaker but combined with static gestures.

6. Conclusion

As can be seen from the results the coordination between postures and voice variations in acting engenders the film's atmosphere in general and brings a significant difference in the actor's role. Pitch variations associated to postures allowed Di Caprio according to the "Acting Method" to personify a "neurotic" character in the confrontation scene, thus bringing out a more energetic acting style and a greater impact on the audience. The outcome of Joel Edgerton's performance (from the same "Acting method") is surprisingly "classical", using more voice variations with limited and static postures to embody the role of a deceived husband. Alternation enabled him to convey his emotions passing from provocation, supplication, seduction, and denigration which led to the final blast of anger. The tension in the confrontation scene in GG1 is realized by film-making techniques such as: framing, cutting, silence… a "Koulechov effect" where editing the different film plans created an atmosphere of tension, which was not really conveyed by the actors' performance. However the coordination between postures and pitch variations increased the dynamics to the interactions in the confrontation scene. The coordination between gestures and prosody seems to be clear in differentiating the two acting schools, although no recurrent acoustic cues were found in this study. In this new field of research; implementation of more methodological tools will broaden the scope of the coordination between prosody and gestures in film studies.

Explorations in the prosodic characteristics of synchronous speech, with specific reference to the roles of words and stresses

Fred Cummins[1], *Judit Varga*[2]

Abstract

We examine the prosodic characteristics of read speech produced alone or in synchrony with a co-speaker in English. Previous work has demonstrated a marked difference between these two speaking conditions in Mandarin, but not English. We employ word lists that are either simple sequences of trochees, or complex lists with regular stress alternation but irregular word boundaries. Inter-onset intervals are examined and no major differences between solo and synchronous interval sequences are found. Viewed from the perspective of two generative models, however, there is weak evidence for some small difference in the dependence of interval duration on serial position.

Index Terms: synchronous speech, stress timing, word lists, joint speech

1. Introduction

Synchronous speech is a laboratory variant of the more general phenomenon of joint speech, where speakers utter the same words in unison [1, 2]. Familiar ethological examples include collective prayer, and the chant of protesters. In a synchronous speaking task, novel texts are typically employed, and subjects do not have difficulty in reading these while keeping in time with one another. The speech so produced is perhaps best characterized as unmarked. To conform to the task demands, speakers must shear their speech of unpredictable temporal variation, stemming, for example, from dramatic expression, or idisyncratic phrasing. This results in speech in which linguistic contrasts are preserved, but many sources of variability that serve to make phonetic analysis both rich and complex are otherwise absent. Synchronization among speakers has since been employed by several researchers as a means for eliciting speech suited to phonetic analysis [3, 4, 5, 6]. Most such work has been done on English, although O'Dell and colleagues (2010) have employed the same methods in studying Finnish speech rhythm and Kim and Nam (2008) examined Mandarin Chinese.

Underlying the use of synchronous speaking to elicit phonetic data is the strong assumption that there is no additional source of alteration to the speech introduced by the device of having speakers synchronize. It is known that synchronous speech tends to be relatively slow in rate, though within the range of rates adopted by speakers when speaking alone [1]. At issue is rather whether there is any form of systematic prosodic alteration to synchronous speech other than a relatively slow speaking rate. To date, this has been tested only informally, by listening to synchronous speech and noting that indeed, it sounds like unremarkable English speech.

In a recent study comparing English and in Mandarin Chinese, we observed that Chinese synchronous speech appeared to exhibit an exaggerated syllable timing compared with speech produced by one person at a time (hereafter, "solo speech") [7, Sample recordings available in Supplementary Materials online]. Sentences were produced almost as if they were lists of unconnected words, and this was evidenced by a slight difference in PVI calculated based on syllable onsets. We hypothesize that there is an interaction between the means that best satisfy the demands of synchronization, and the phonological structures of the language, such that the relatively simple syllable and word forms of Chinese lend themselves to regular, temporally predictable production in a way that the more complex phonological structures of English do not. Additional evidence for this hypothesis was found in that synchronization among Chinese speakers was more resistent to perturbation induced by having slightly mis-matched texts than their English counterparts, for whom such intervention frequently led to complete cessation of speaking [7]. A follow up study including a wider variety of languages is currently underway.

We here return to the question of whether English speech produced synchronously is, in fact, unaltered, compared to solo speech. Several consideration reveal this question to be more complex that it appears at first blush. Solo speech, and joint speech, are each produced with great amounts of variability due to context, purpose, and the identity and concerns of the speakers. Neither variety admits of reduction to a simple unmarked form that can stand for all others. Synchronous speech, more narrowly circumscribed, may, indeed appear as a largely invariant speaking style, as novel texts are used that are divorced from any ongoing behavioral context, and the additional constraint of remaining in synchrony prevents the overlay of any overly dramatic or expressive phrasing. With what should it then be compared? What kind of (solo) speech might serve as a gold standard? Put like this, the question is clearly unanswerable. However if we limit the domain of possible texts radically, we may make some meaningful comparisons between the two styles. This is the approach adopted here, where we use simple word lists of 8 unconnected words.

By using simple word lists, we make use of texts that admit of very little variability when read either alone or together. This serves to constrain the potential variability of the solo speech. But using invariant word lists represents a drastic simplification. In order to then re-admit some potential temporal complexity, we contrast simple word lists (8 trochees) with complex lists in which the relative sequence of stresses and word onsets is non-coincident, such that either word onsets or stress onsets may form the basis of regular timing, but not both. If synchronization is facilitated by enhancing an underlying regularity (as we suspect in Chinese) then we might observe a more

regular sequence of either word onsets or stressed syllable onsets in synchronous productions of complex lists compared to solo productions.

The use of word lists allows us to also evaluate the temporal characteristics of the speech in terms of models of sequential production. Two highly influential models are the Wing and Kristofferson model of interval timing [8] and the hierarchical timing model of Rosenbaum [9]. The Wing & Kristofferson model has found frequent application in teasing apart sources of variability in tapping studies [10, 11, and many others]. It assumes that overt behavior is shaped by a distinct timing process (the central clock) which influences the movement of effectors. Both clock and peripheral physiology are assumed to be potential sources of variability in observed behavior, but the assumptions of the model permit decomposition of that variability into distinct clock and peripheral sources, which may be subject to distinct pathologies, or independent perturbation. The model rests on the assumption that the two sources are independent, and this assumption is warranted only if the lag one autocorrelation of an interval sequence lies between zero and -0.5 (for full justification, see Wing and Kristofferson, 1973). We test this below.

Rosenbaum's model looks for evidence of hierarchical structure in short regular sequences that would suggest constraints on timing that are not strictly sequential (as in Wing & Kristofferson's model). Hierarchical execution of movement plans involves the depth-first traversal of a tree, and would lead to a dependence of interval duration on serial position within sequence. For short sequences of 8 taps, this leads to alternating short-long patterning from binary grouping at the lowest level, with additional short-long alternation at higher levels of composite units of two or four taps. As our word lists consist of short sequences of 8 accents or stresses, we ought to look for any sign of non-sequential, hierarchical influences that would be indicated by a non-monotonic dependence of interval duration on serial position. Such non-sequential effects would be compatible with some form of hierarchical production model, while a specific pattern in which interval lengths are ordered as $\{4\} > \{2,6\} > \{1,3,5,7\}$ would fit the specific form of the model adduced on the basis of sequences of 8 taps in the 1983 paper.

2. Methods

25 dyads (50 speakers) took part in the study. Speakers were either relative strangers (12 dyads) or were highly familiar couples (13 dyads). All familiar dyads were of mixed sex, while among the strangers, 7 were mixed, 2 were male-male and 3 were female-female. Ages ranged from 21 to 56, and all were native speakers of Hiberno-English. Subjects were recruited on the campuses of two Dublin universities, and ethical approval was provided by the School of Psychology at Trinity College Dublin.

Subjects were recorded as part of a larger data gathering exercise. Relevant to the present study, they each read 4 word lists alone ("solo") and 4 word lists together ("sync"). Each group of 4 comprised 2 simple trochaic lists and 2 complex lists (see below). Solo readings were done before synchronous in all cases. Readings were done using head mounted microphones, and recordings were made to parallel audio channels.

Half the wordlists were simple, in which case they consisted of 8 trochees, selected so that stressed syllable onsets were of simple CV form, with C $\in$ {b,d,g}. Sample simple list: *banter, body, dagger, guinness, batty, dancer, bingo, gutter*. The other half were complex. In complex lists, there was a regular alternation of stressed and unstressed syllables (half began with a stressed, half with an unstressed element), but word boundaries were selected to be irregular, due to varying numbers of syllables per word. Sample complex list with a weak initial syllable: *deny, debunking, boot, divide, deduction, bike, barbaric, ban*, with a strong initial syllable: *bad, debugging, body, boot, debacle, banter, bog, degrading*. Both word onset and stressed syllable onsets were constrained to be of CV form with C $\in$ {b,d,g,v,n,m,l}. Each list in each condition was unique and was spoken exactly once. A total of 11 lists were discarded due to speech errors or mispronunciation.

Word onsets and stressed syllable onsets were located in time using a P-centre estimation algorithm, first presented in Cummins and Port (1998). This identifies the time of an onset as the halfway point through a local rise in the amplitude envelope of the bandpass filtered signal (with cut offs at 500 and 2000 Hz). This algorithm works well when syllable onsets are suitably constrained, as here, and in a very few cases where no appropriate local rise was found, manual measurement was made (less than 1% of data points). This provided a sequence of 8 word onsets and 8 stressed syllable onsets for each list. For simple lists, these coincide, providing a single set of 8 onsets, or 7 successive intervals. For complex lists, these provide 2 alternate ways of looking at the list, as 7 intervals demarcated either by word onsets or by stressed syllable onsets.

3. Results

We have three kinds of interval series: trochaic, complex calculated from word onsets, and complex calculated from stressed syllable onsets. We first examine the distribution of interval durations in the solo and synchronous conditions, for each kind of series. Fig. 1 provides an overview of the distribution of interval durations as a function of serial position. The first thing to note is that there is no obvious macroscopic difference in the central values or serial characteristics of the synchronous and the solo data. As has been documented before, the variability across speakers seems to be reduced in the synchronous case [13]. Fig. 2 shows the distribution of the interval durations for each series in each condition. It is clear that the solo distributions are right skewed, while the synchronous distributions are more compact and more nearly symmetric. The reduction in variance is confirmed by one-sided F-tests which verify reduced variability in the synchronous condition for the trochees (F(643,643)=2.7, $p < .001$), the word onsets in complex lists (F(643,587)=1.9, $p < .001$) and stress syllable onsets in complex lists (F(615,587)=2.8, $p < .001$).

The complex lists were designed so that word onsets and stress syllable onsets did not coincide for every word. In order to see whether subjects imposed regularity on the word or stress onsets, we calculated the normalized Pairwise Variability Index for successive interval durations within each series. This provides a measure of variation among successive intervals, and is minimized in isochronous series, and maximized in alternating long-short series. The nPIV is calculated as

$$\mathrm{nPVI} = 100 \left[\sum_{k=1}^{m-1} \left| \frac{d_k - d_{k+1}}{(d_k + d_{k+1})/2} \right| /(m-1) \right] \quad (1)$$

Fig. 3 shows the nPVI scores for each series type and condition. In both solo and synchronous conditions, the intervals formed by successive word onsets in the complex lists are con-

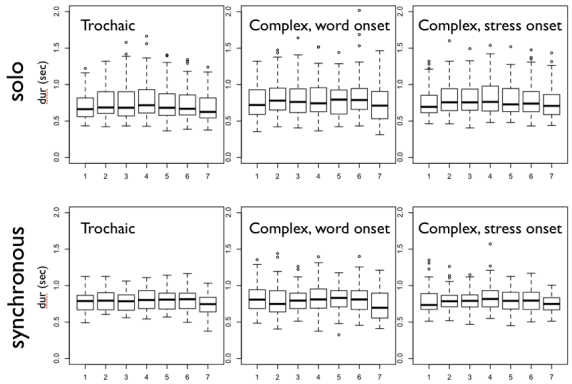

Figure 1: *Interval duration as a function of serial position.*

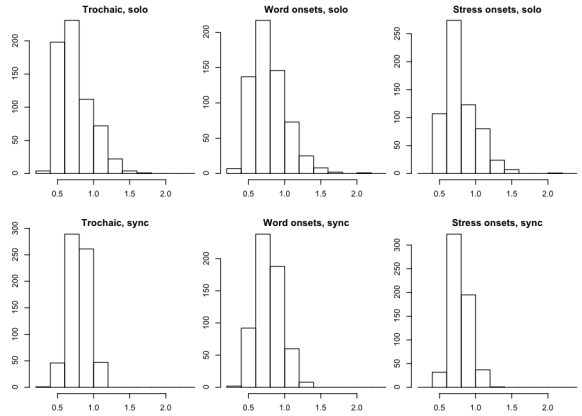

Figure 2: *Histograms of interval durations.*

siderably less regular (higher nPVI) than those formed by the stress syllable onsets. There is no evidence here of any increase in regularity (lower nPVI scores) in the synchronous condition compared with the solo.

We now turn to analyses that examine the assumptions and predictions of the two generative models, the hierarchical production model of Rosenbaum [9], and the clock model of Wing and Kristofferson [8]. The hierarchical production model makes the general prediction that serial position will influence duration, and, for sequences of 8 events, or 7 intervals, it predicts the relative durations based on tree-traversal distance of a hypothetical underlying metrical tree.

In order to investigate the effect of serial position on interval duration in the solo lists, a repeated-measures ANOVA was carried for each of the three series with familiarity (two levels) as a between subjects factor, and serial position and repetition as within subject factors (7 and 2 levels, respectively). For the trochees, there was a main effect of serial position ($F(6,264)=6.6$, $p < .001$) and a main effect of repetition ($F(1,44)=4.2$, $p < .05$). For the word onsets in complex lists there was only a main effect of serial position ($F(6,252)=3.8$, $p < .01$), and similarly for the stressed syllable onsets in complex lists there was only a main effect of serial position ($F(6,252)=3.7$, $p < .01$). A similar analysis for the synchronous lists is complicated by the fact that the utterances of two speakers speaking in unison can not be considered at all indepen-

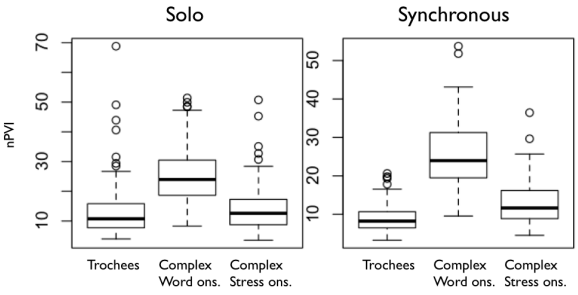

Figure 3: *nPVI scores for each series type and condition.*

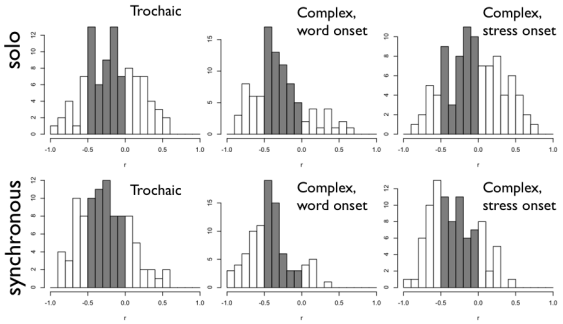

Figure 4: *Histograms of lag 1 autocorrelations.*

dent of one another. We therefore conducted a similar analysis for the first and second speaker separately, and report only those findings that were consistent across both speakers. There was a main effect of serial position only for the trochaic series ($p < .001$), but not for either the word onsets or the stressed syllable onsets.

There are thus effects of serial position in the solo data, but not in the synchronous data, except for the maximally regular trochaic series. For the solo data, this is in accordance with the general premise of the model of Rosenbaum et al., but does not test the predictions of the specific form of that model described in Rosenbaum et al. (1983), which predicts that interval 4 should be the longest, followed by intervals 2 and 6, with intervals 1, 3, 5 and 7 somewhat shorter. This structure is not evident in the aggregate data, and there is not enough data per subject or dyad to test this on a by-subject/by-dyad basis. However, simple calculation of the index of the longest interval in each series does not support the Rosenbaum predictions, as Interval 4 is the longest interval in no more than 30% of series in the trochaic solo series, and less in all other cases.

Turning now to the Wing and Kristofferson model, it is predicated upon an assumption of the separability of variance in timing due to two independent sources: a central clock or timekeeper, and a peripheral effector system. This hypothetical independence is possible only if the lag 1 autocorrelations within each series fall in the range [-0.5, 0]. Lag 1 autocorrelations outside that range violate the assumptions of the model. In the many studies that have employed this model, the proportion of the data violating this constraint, and hence the validity of the model, has varied greatly form case to case.

Fig. 4 shows histograms of the lag 1 autocorrelations for each series. Only those series falling within the grey bins ac-

cord with the basic assumptions of the Wing and Kristofferson model. The proportion of series that violate those assumptions ranges from 41% to 55%, and violations are found both above and below the bounds of [-0.5, 0]. The serial production model of Wing and Kristofferson is thus not appropriate for interpreting these data. Violations are as common in the solo data as they are in the synchronous case.

4. Discussion

The principal question addressed in this small study is whether systematic differences between speech produced alone or in synchrony with a co-speaker can be found in English. Such differences have been found in Chinese, where synchronous speech has been found to be more list-like, with regularization of inter-syllable onset intervals [7]. In order to constrain the kind of prosodic change that might be observed, lists were employed, both simple trochaic sequences, and complex sequences in which either word onsets or stress syllable onsets might for the basis for any hypothetical regularization during synchronous production.

One difference we expected to find, and did, is that interval timing is less variable between subjects in the synchronous condition. This difference does not imply any systematic change to the prosodic features of any given utterance, however.

At first blush, there appears to be little in the way of variation in the prosodic features of synchronous utterances compared to solo utterances. In both cases, trochees are produced with a low pairwise variability, and the complex lists are produced with similar regularity in the sequence of stressed syllable onsets (but not word onsets). This is itself valuable empirical evidence that stress feet, in the sense of Abercrombie,[1] and not lexical units, constitute temporally extended constituents that may, under specific conditions, form the basis of isochronous sequences in English speech. This is in line with observations from the speech cycling paradigm in English [12], and contrasts with observations made under similar constraints in Korean [14] and Japanese [15].

We then examined the appropriateness of two generative models of sequential interval production that might be called to task in accounting for these data. The simpler model of simple sequential production based on the hypothesis of a modality-independent timer is provided by Wing and Kristofferson (1973). The presuppositions of that model were found to be very inappropriate for the present data set, with almost half of all observations showing non-local serial dependencies that violate the assumptions of the model. This was true for solo and synchronous data in equal measure.

When we viewed the data through the lens of the hierarchical production model of Rosenbaum, however, we observed some possible differences between solo and synchronous interval sequences. A liberal application of this model, that captures the notion of hierarchical production, but remains agnostic about the precise form of control or implementation underlying such production, predicts only that there will be position dependent differences among interval durations that are not a simple function of the immediately preceding neighbor (as in Wing and Kristofferson). This was true of both simple and complex lists in the solo condition, but only true of the simpler trochaic lists in the synchronous condition. The more rigorous prediction that falls out of positing a specific binary tree underlying production, that accounted very well for tapping data in the original study, did not well describe the present data.

Given the failure of the more specific model to capture for form of the non-local dependency of interval duration on serial position, we must be cautious in drawing strong conclusions. The difference betwen solo and synchronous data we observed is slight, and not yet well characterized. Prosodic differences between solo and synchronous speech in English are slight, if they exist at all, and at this stage, it appears that synchronous speech may still be a valuable way of eliminating variability from English speech while leaving linguistic contrasts unaffected. On the basis of our experinece with Mandarin, however, it is clear that this assumption does not generalize to all other languages, and that even in the case of English, further investigation is warranted.

[1] The Abercrombian stress foot is the interval from one stressed syllable onset to the next, including any and all intervening unstressed syllables. It assumes a simple binary stress distinction that may or may not be an appropriate characterization of English stress, and that certainly does not generalize to all languages.

Effects of native dialect on Mandarin listeners' use of prosodic cues to English stress

Zhen Qin, Annie Tremblay

Department of Linguistics, University of Kansas, United States

Abstract

This study investigates the effect of native dialect on the use of prosodic cues to English stress by Standard Mandarin (SM) listeners, Taiwanese Mandarin (TM) listeners, and English listeners. Both SM and TM use fundamental frequency (F0) to realize lexical tones, but only SM uses duration together with F0 to realize lexically contrastive full-full vs. full-reduced stress patterns. Native English listeners and second language learners of English who spoke SM or TM as native language and were at similar proficiencies in English completed a sequence-recall task. English disyllabic non-words that differed in stress placement were resynthesized to contain only F0 cues, only duration cues, or converging F0 and duration cues. The results showed that SM-speaking learners used duration more than TM-speaking learners to recall English non-words. Native dialect is suggested to be considered in second language speech processing models.

Index Terms: lexical stress, prosodic cues, native dialect.

1. Introduction

Languages differ in the extent to which prosodic cues contribute relevant information for lexical access. Second-language (L2) learners weigh prosodic cues to stress as a function of how these cues are used in the native language (L1) (for discussion, see [1]). The present study investigates how the L1 dialect influences Mandarin-speaking L2 learners' use of prosodic cues in the processing of English stress.

In English, although prosodic cues such as fundamental frequency (F0), intensity, and duration signal stressed syllables in accented words [2,3,4], listeners make limited use of these cues, as English stress is also signaled by segmental information (e.g., full vs. reduced vowels; for discussion, see [1]). Although English listeners can use prosodic cues to English stress [5,6], their word recognition is not inhibited by errors in stress placement unless these errors also result in segmental (i.e., vowel quality) changes in the word [7,8,9,10,11].

Prosodic cues have a greater functional load in Mandarin than in English, in part because Mandarin is a tonal language in which lexical identity is signaled primarily by F0 cues (e.g., [mā] 'mother,' [má] 'hemp,' [mǎ] 'horse,' and [mà] 'scold') [12,13]. While all dialects of Mandarin share this tonal system, some dialects differ in whether or not they also have lexical stress. For example, Standard Mandarin (SM) has a stress pattern that contrasts full-full and full-reduced disyllabic words (e.g., respectively, ***dongxi*** 'west and east' vs. ***dong****xi* 'stuff') [14,15]. Whereas words with the full-full pattern are stressed on both syllables, those with the full-reduced pattern are stressed only on the first syllable (word-initial/trochaic stress). The reduced vowel in the latter carries a neutral tone rather than a lexical tone and it is shorter than the full vowel [14,15]. These two stress patterns are thus signaled with duration and F0, with these two cues perhaps contributing to lexical access in SM [16,17]. By contrast, Taiwan Mandarin (TM) does not have this stress distinction: Words have the full-full pattern, and the second syllable of disyllabic words is not reduced (e.g., ***dongxi*** 'west and east' or 'stuff') [13]. Given the absence of the full-reduced stress pattern in TM, F0 may play a more important role than duration for lexical access in TM [18].

Research on Mandarin listeners' use of prosodic cues when processing English words has yielded inconsistent findings. Some speech perception studies found that, like native English speakers, Mandarin-speaking L2 learners of English from mainland China but tested in the US relied more on segmental cues than on prosodic cues to English stress and did not differ from native English speakers in their use of F0 and duration cues to English stress [19]. Other research, however, suggests that Mandarin-speaking L2 learners of English from mainland China and tested in China could use only F0 cues to English tress [20]. Finally, and perhaps more surprisingly, it has been shown that Mandarin-speaking L2 learners of English from Taiwan but tested in the US could use duration alone in the perception of English stress [21].

These inconsistent findings may stem, at least in part, from the different proficiency of the Mandarin-speaking L2 learners of English that were tested: The L2 learners who lived in the US [19,21] are likely to be more proficient than those who lived in China [20]. Once proficiency is controlled for, it is unclear whether the L1 dialect would influence L2 learners' processing of English stress. Whereas the above studies examined L2 learners who spoke different Mandarin dialects [19,20 vs. 21], they did not investigate whether the particular properties of these dialects—specifically, whether or not the L1 dialect has lexical stress—would affect L2 learners' encoding of English stress. L1 effects on L2 learners' use of prosodic cues to stress are well documented [22, 23, 24]; much less is known about the effect of L1 dialect on non-native listeners' use of such cues in speech processing.

To fill this gap, the present study investigates the use of F0 and duration cues to English stress by English listeners and L2 learners of English who speak SM or TM as L1 dialects and are at a similar proficiency in English. For F0 cues, given that SM and TM have similar tonal systems, we predict that the SM and TM groups will not differ from each other in their use of F0 to encode stress in English words. For duration cues, since SM has a lexical stress contrast signaled in part by duration cues, we predict that SM listeners will perform better than TM listeners in the use of duration cues to English stress. Finally, because SM does not have a reduced-full stress pattern, we predict that SM listeners will differ from TM listeners only on words that are stressed on the initial syllable—not on words that are stressed on the final syllable.

2. Methods

We conducted a sequence recall task adapted from [22,23]. This paradigm requires listeners to encode phonetically variable stimuli that differ in stress placement and hold them in short-term memory for a brief amount of time. Given the

memory load it imposes, this paradigm taps into L2 learners' abstract phonological knowledge and is thus ideally suited for investigating the effect of L1 dialect on the use of prosodic cues in the encoding of L2 stress.

2.1. Participants

Participants included 15 L2 learners of English who spoke SM (mean age: 24.2; SD: 4.0) or TM (mean age: 25.7; SD: 3.4) as L1. Their results were compared to those of 15 native English listeners (mean age: 21.3; SD: 3.9). The two groups of L2 learners did not differ in their age of acquisition of English (p>.1) or in their proficiency in English (p>.1), assessed with a cloze test [25]. No participant had any speech or hearing impairments.

2.2. Stimuli

The stimuli were minimal pairs of English non-words that differed in stress placement (e.g., ['fʌði] vs. [fʌ'ði]). The non-words had a $C_1V_1C_2V_2$ structure. To exclude segmental cues of stress such as vowel reduction, /ɪ/, /ʊ/ and /ʌ/ were used in V_1 position and [i] was used in V_2 position, as they are not reduced to schwas in their respective positions in English. For C_1 and C_2, only fricatives were used to avoid providing segmental cues to stress. In total, four segmental non-words (/sɪvi/, /zʊθi/, /fʌði/, and /hʌfi/) were used. All stimuli were produced by a female native speaker of American English (Midwest). She read each non-word four times in the carrier sentence "Say _ again." Two tokens were selected from the four repetitions of each word type. The stimuli included a total 16 tokens (4 segmental words × 2 stress patterns × 2 tokens). Any given sequence (described in the next section) never contained the same token twice.

As shown in Table 1, the non-words with initial vs. final stress differed significantly in F0 (p<.01) and duration (p<.01) ratios of the first syllable (σ1) to the second syllable (σ2).

Table 1. *Acoustic characteristics of non-words with initial stress and non-words with final stress.*

	F0						Duration					
	Word-initial			Word-final			Word-initial			Word-final		
	σ1	σ2	ratio	σ1	σ2	ratio	σ1	σ2	ratio	σ1	σ2	ratio
Mean	226	162	1.4	174	192	0.9	163	293	2.2	140	328	3.0
SD	22	15	0.1	7	12	0.1	76	26	0.9	73	32	1.4

This study investigates the use of F0 and duration cues to the perception of English stress. The stimuli were resynthesized such that stress would be conveyed by both F0 and duration ("F0+duration cues" condition), by F0 alone ("F0 cues" condition), or by duration alone ("duration cues" condition). The non-words were first normalized for intensity at 70 dB. The F0 and duration cues were then manipulated in PSOLA [26] such that the non-words would have the average F0 and/or duration of the natural stimuli reported in Table 1. Thus, in the conditions where F0 conveyed stress placement, the F0 of σ1 and σ2 would be that corresponding to the averages in Table 1, and in the conditions where duration conveyed stress placement, the duration of σ1 and σ2 would be that corresponding to the averages in Table 1. In the condition where F0 was the only cue to stress placement, the duration of each syllable corresponded to the average duration across stress patterns but not across syllables (i.e., 156 ms for σ1 and 310 ms for σ2). This was done in order to preserve word-final lengthening in the words. In the condition where duration was the only cue to stress placement, the F0 of each syllable corresponded to the average F0 across both syllables and stress patterns (i.e., 189 Hz).

2.3. Procedures

The sequence-recall task had two main phases: a familiarization (or association) phase and a testing phase.

In the familiarization phase, participants were trained to associate 1 and 2 (on a keyboard) with, respectively, words with initial stress and words with final stress. This was done using real words (i.e., *trusty* vs. *trustee*). Participants received feedback on whether or not their responses were correct. After 18 trials, an association test was conducted, in which participants were required to correctly identify the stress pattern of the tokens they heard (as 1, word-initial stress, or 2, word-final stress). Only the participants who received an accuracy score equal to or higher than 95% were invited to complete the testing phase.

In the testing phase, participants were asked to recall sequences of four tokens by pressing 1 and 2 in the correct order. Each test trial began with the auditory presentation of a sequence that included two stress-initial tokens and two stress-final tokens with the same segments (e.g., [fʌ'ði] ['fʌði] ['fʌði] [fʌ'ði]). Each sequence consisted of four different tokens from the same cue condition (F0+duration cues, F0 cues, or duration cues). To shorten the duration of the experiment, three of the six possibilities of number ordering (i.e. [1122], [2211], [1212], [1221], [2121], [2112]) were used for two segmental non-words, and the other three possibilities were used for the other two segmental non-words. The order of sequences and of tokens within each sequence was randomized across participants. The experiment included 36 experimental sequences (4 segmental words × 3 conditions × 3 orderings).

The non-words in the sequences were separated by an interstimulus interval of 50 ms (see [22,23]). The last interstimulus interval in the sequence was followed by the prompt "OK" to prevent participants from using echoic memory to recall the sequences. The inter-trial interval was 1,500 ms. Participants completed a practice session of 12 real-word sequences (e.g., *trustee trusty trustee trusty*) to ensure that they would understand the paradigm before the actual experiment.

2.4. Data analysis

Logit mixed-effects models were conducted on the participants' sequence-encoding and word-encoding accuracies. The sequence-encoding accuracy was computed to examine the overall effect of prosodic cue on the processing of English stress; the word-encoding accuracy was computed to compare the processing of English stress for words with initial stress vs. words with final stress. The models were fitted in R, using the lmer( ) function from the lme4 package for mixed-effects models (for discussion, see [27]).

Model 1 analyzed the sequence-encoding accuracy of the three groups in the first three conditions, with cue condition (F0+duration cues vs. F0 cues or duration cues), L1 (English vs. SM or TM), and the interaction between the two as fixed variables. In this model, the F0+duration cues condition and the English group were used as baselines. Model 2 analyzed only the L2 learners' corresponding sequence-encoding

accuracy, with L1 dialect (SM vs. TM) instead of L1 as fixed variable. The baseline for L1 dialect was SM.

Models 3-4 analyzed the participants' word-encoding accuracy in the first three conditions but separately for words with initial vs. final stress, with cue condition (F0+duration cues vs. F0 cues or duration cues), L1 (English vs. SM or TM), and the interaction between the two as fixed variables. The baselines were the same as in Model 1. Models 5-6 analyzed only the L2 learners' word-encoding accuracy in the first three conditions separately for words with initial vs. final stress, but with L1 dialect (SM vs. TM) instead of L1 as fixed variable. The baselines were the same as in Model 2. In all the models, participant and item were crossed random variables.

If our predictions are correct, we should find significant interactions between the effect of duration cues (as compared to the F0+duration baseline) and the effects of L1 and L1 dialect in the sequence-encoding results, with TM listeners showing a larger difference between the duration cues condition and the baseline condition than the English and SM listeners. In the word-encoding results, we should find similar results only for non-words with initial stress.

3. Results

3.1. Sequence-encoding accuracy

The accuracy of the sequence encoding in the three cue conditions is shown for the three groups in Figure 1.

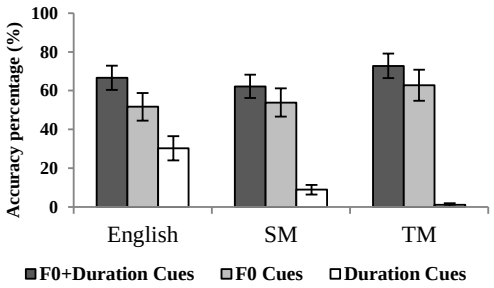

Figure 1. *All participants' mean sequence-encoding accuracy (and standard errors).*

A first logit mixed-effects model was conducted on the participants' sequence-encoding accuracy. The results, reported in Table 3, showed significant effects of cue for F0 and for duration, as well as significant cue (duration) × L1 interactions for both the SM and TM groups. This indicates that both the SM and TM groups showed a larger difference between the F0+duration cues condition and the duration cues condition than the English group did.

Table 2. *Model 1: Logit mixed-effects model on all participants' sequence-encoding accuracy (df=1612).*

Variable	Est.	SE	*z*	*p*
Cue (F0)	–0.7	0.24	–7.1	<.01
Cue (Duration)	–1.8	0.25	–3.2	<.001
L1 (SM)	0.2	0.85	–0.5	>.1
L1 (TM)	0.5	0.47	1.0	>.1
Cue (F0) × L1 (SM)	0.4	0.33	1.1	>.1
Cue (Duration) × L1 (SM)	–1.5	0.42	–3.6	<.001
Cue (F0) × L1 (TM)	0.2	0.35	0.5	>.1
Cue (Duration) × L1 (TM)	–4.8	0.86	–5.5	<.001

A second logit mixed-effect model was conducted on the L2 learners' sequence-encoding accuracy. The results, shown in Table 4, revealed a significant effect of cue for duration, as well as a significant cue (duration) × L1 dialect interaction. This indicates that TM listeners showed a larger difference between the F0+duration cues condition and the duration cues condition than the SM listeners did.

Table 3. *Model 2: Logit mixed-effects model on the L2 learners' sequence-encoding accuracy (df=1615).*

Variable	Est.	SE	*z*	*p*
Cue (F0)	0.4	0.23	–1.7	>.1
Cue (Duration)	–3.3	0.34	–9.6	<.001
L1 dialect	0.7	0.48	1.5	>.1
Cue (F0) × L1 dialect	–0.2	0.34	–0.6	>.1
Cue (Duration) × L1 dialect	–3.3	0.90	–3.7	<.001

To summarize, as we predicted, the SM and TM groups do not differ from each other in the use of F0 cues to encode sequences of English non-words. However, TM listeners differ from both English listeners and SM listeners in the use of duration to encode English non-word sequences.

3.2. Word-encoding accuracy

As mentioned above, word-encoding accuracy was also analyzed to compare listeners' performance on words stressed on the initial syllable and words stressed on the final syllable. Figure 2 displays the accuracy of the individual word encoding for the three cue conditions, with the top panel showing the accuracy for non-words with initial stress and the bottom panel showing the accuracy for non-words with final stress.

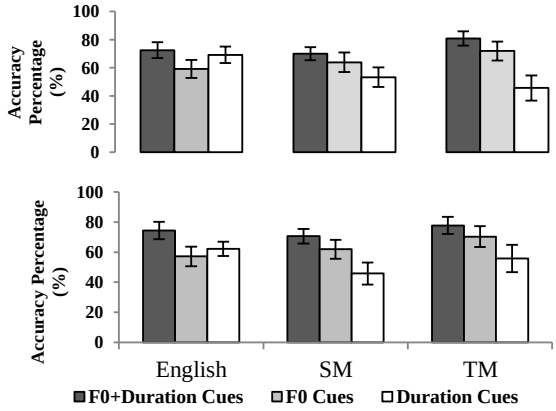

Figure 2. *All participants' word-encoding mean accuracy (and standard errors) for non-words with initial stress (top panel) and non-words with final stress (bottom panel).*

Third and fourth logit mixed-effects models were conducted on the participants' word-encoding accuracy separately for non-words with initial stress and non-words with final stress. The results are reported in Table 4. For non-words with initial stress, the model revealed significant effects of cue for F0, as well as significant cue (duration) × L1 interactions for both the SM and TM groups. This indicates that for non-words with initial stress, both the SM and TM groups showed a larger difference between the F0+duration cues condition and the duration cues condition than the English group did. For non-words with final stress, the model revealed significant effects of cue for F0 and duration, as well

as significant cue (duration) × L1 interactions for both the SM and TM groups. This again indicates that for non-words with final stress, both the SM and TM groups showed a larger difference between the F0+duration cues condition and the duration cues condition than the English group did.

Table 4. *Models 3-4: Logit mixed-effects model on all participants' word-encoding accuracy (df=1612).*

Word-initial stress				
Variable	Est.	SE	*z*	*p*
Cue (F0)	–0.7	0.17	–4.0	<.001
Cue (Duration)	–0.2	0.17	–1.0	>.1
L1 (SM)	–0.2	0.26	–0.7	>.1
L1 (TM)	0.4	0.27	1.6	>.1
Cue (F0) x L1 (SM)	0.4	0.23	1.6	>.1
Cue (Duration) x L1 (SM)	–0.6	0.23	–2.5	<.05
Cue (F0) x L1 (TM)	0.2	0.25	0.6	>.1
Cue (Duration) x L1 (TM)	–1.5	0.24	–6.2	<.001
Word-final stress				
Variable	Est.	SE	*z*	*p*
Cue (F0)	–0.9	0.17	–5.2	<.001
Cue (Duration)	–0.7	0.17	–3.8	<.001
L1 (SM)	–0.1	0.50	–0.2	>.1
L1 (TM)	–0.6	0.50	1.2	>.1
Cue (F0) x L1 (SM)	0.5	0.24	1.8	>.05
Cue (Duration) x L1 (SM)	–0.6	0.24	–2.4	<.05
Cue (F0) x L1 (TM)	0.4	0.26	1.4	>.1
Cue (Duration) x L1 (TM)	–0.8	0.26	–3.0	<.01

Fifth and sixth logit mixed-effects model were conducted on the L2 learners' word-encoding accuracy separately for non-words with initial stress and non-words with final stress. The results are reported in Table 5. For non-words with initial stress, the model revealed a significant effect of cue for duration, a significant effect of L1 dialect, and a significant cue (duration) × L1 dialect. This indicates that TM listeners showed a larger difference between the F0+duration cues condition and the duration cues condition than the SM listeners did for non-words with initial stress. For non-words with final stress, the model revealed significant effects of cue for duration and F0, but no interaction between either cue and L1 dialect. This means that TM listeners did not differ from SM listeners in their use of duration cues in non-words with final stress.

Table 5. *Models 5-6: Logit mixed-effects model on L2 learners' word-encoding accuracy (df=1615).*

Word-initial stress				
Variable	Est.	SE	*z*	*p*
Cue (F0)	–0.3	0.16	–1.8	>.05
Cue (Duration)	–0.7	0.16	–4.7	<.001
L1 dialect	0.6	0.23	2.7	<.01
Cue (F0) x L1 dialect	–0.2	0.24	–0.9	>.1
Cue (Duration) x L1 dialect	–0.9	0.23	–3.9	<.001
Word-final stress				
Variable	Est.	SE	*z*	*p*
Cue (F0)	–0.4	0.17	–2.6	<.01
Cue (Duration)	–1.2	0.17	–7.2	<.001
L1 dialect	–0.7	0.58	1.3	>.1
Cue (F0) x L1 dialect	–0.1	0.26	–0.3	>.1
Cue (Duration) x L1 dialect	0.2	0.26	–0.8	>.1

In summary, the SM and TM groups pattern like each other in the use of F0 to encode stress in individual English non-words, irrespective of whether stress is word-initial or word-final. However, as predicted, SM and TM listeners differ from each other in the use of duration cues to word-initial stress, a stress pattern that exists in SM, but not in the use of duration cues to word-final stress, a stress pattern that does not exist in SM.

4. Discussion and Conclusion

Our results showed that the SM- and TM-speaking L2 learners of English did not differ from each other in the use of F0 cues to process English stress. We attribute these results to the presence of lexical tones in Mandarin, which are signaled primarily by F0 cues.

However, TM listeners differed from both English and SM listeners in the use of duration cues to English stress, with TM listeners being relatively less accurate than the other two groups in the duration cues condition as compared to the F0+duration cues condition. These results were found in the participants' sequence-encoding accuracy and their word-encoding accuracy for non-words with initial stress. These findings are exactly as predicted: In SM but not in TM, duration is used to encode a stress distinction (i.e., full-full vs. full-reduced). This in turns allow SM listeners to use duration for encoding English stress. Importantly, SM does not have a reduced-full stress pattern, and it is precisely in this word-final stress condition that SM and TM patterned similarly.

The results also showed that SM listeners differed from English listeners in the use of duration cues to English stress. One possibility is that the greater occurrence of vowel reduction in English than in SM may lead English listeners to be more sensitive to duration cues than SM listeners. Alternatively, SM may have relatively few words that contrast in stress placement, potentially leading SM listeners to rely less on duration cues as compared to English listeners [13].

Our results are consistent not only with the proposal that non-native listeners weigh prosodic cues to stress as a function of the role of these cues in the L1 [1], but also with more general cue-weighting accounts of L2 speech perception [28,29]. Learning to process English stress depends in large part on the prosodic cues used to realize stress and on whether these cues are similarly used to access words in the L1. The present study also suggests that not only the L1, but also the L1 dialect, plays a crucial role in determining whether non-native listeners can use specific prosodic cues to encode English stress. L2 speech processing models should thus consider the influence of L1 dialect, which may impact how prosodic cues are weighted in L2 processing.

5. Acknowledgements

We would like to thank Yu-fu Chien for help with the data collection in Taiwan; Dr. Allard Jongman, Dr. Joan Sereno, Dr. Jie Zhang, as well as the members of LING 850, for their valuable comments on this research; and all participants.

Abstract

The distribution of preboundary lengthening within the phrase-final word is controversial. In CV syllables immediately preceding a prosodic boundary, the acoustic duration of the syllable onset C is less involved than that of the following rime V in the lengthening phenomenon. Moreover, preboundary lengthening might be extended to the stressed/accented rime within the phrase final word. On the other hand, articulatory the constriction gesture for the onset consonant can be lengthened despite not being immediately adjacent to a boundary. In this preliminary study, we explore the effects of prosodic boundary and prominence in Italian, at both acoustic and articulatory level. Bilabial consonants in CV onset position were examined. The consonants were inserted in unstressed (word final) and stressed (penultimate vs. antepenultimate) syllables occurring close to prosodic boundaries of different levels. In final syllables, the acoustic duration of the onset consonant was not affected by the prosodic boundary manipulation whereas the closing gesture duration showed a pattern of lengthening which was stronger for higher level prosodic boundaries. In non-final syllables, no acoustic/articulatory effect was found for onset consonants but only on the stressed vowels in penultimate position. Structural, phonological and phonetic constraints might be at work in determining preboundary lengthening.

Index Terms: preboundary lengthening, articulatory movements, onset duration, Italian, prosodic hierarchy, pi-gesture.

1. Introduction

Acoustic studies in different languages have found that segments in a phrase-final word (i.e., close to a prosodic boundary edge) undergo final ("preboundary") lengthening [1]). Prosodic phrasing also influences articulatory gestures of segments close to the phrase edge, with gestures being slower and less overlapped before a major prosodic boundary [2,3]. [2] invokes the activation of a prosodic (or π-) gesture, whose function is to slow down the timing of the co-occurring articulatory gestures for boundary-adjacent segments. As [1] put it, this gesture indicates "the onset and offset of a time period during which the clock that controls the timing of other gestures ticks more slowly".

An important issue concerning preboundary lengthening is how its precise distribution is determined within the phrase-final word. Though the magnitude of the effect is larger on the syllable immediately adjacent to the boundary, a few acoustic studies has also showed that preboundary lengthening can also affect syllables which are away from the boundary (see [1] and references therein). According to [1], there are at least two possible approaches to account for such a phenomenon.

The *Structure-based* view predicts that the distribution of (acoustic) final lengthening is conditioned by linguistic structure. For instance, within the same syllable (e.g., a word-final CV), only the syllable rime (the vowel V) would be affected by lengthening. Moreover, the leftward extension of preboundary lengthening would be conditioned by the position of the stress within the phrase-final word. For instance, the *Word Rime hypothesis* [1] predicts that preboundary lengthening would start from the rime of the stressed syllable up to the rime of the word-final syllable, while the syllable onset consonant in both the stressed and final syllables would be unaffected by preboundary lengthening (cf. also [1] for a model of multiple targets of preboundary lengthening).

The *Content-based* view, on the other hand, predicts that the actual portion undergoing lengthening is structurally variable since it results from a lengthening gesture of fixed duration. In particular, [3] claimed that in English, the half-point of the π-gesture is temporally anchored to the boundary itself, and that its temporal activation is fixed. As a consequence, the π-gesture can overlap with earlier or later portions of the last word within a phrase depending on structural complexity (e.g., presence or absence of a coda consonant) and intrinsic gesture duration (e.g., presence of lax vs. tense vowels) of the phrase-final syllables. Note that, articulatory studies conducted within the Content-Based view, such as the ones supporting the π-gesture hypothesis, report preboundary lengthening of articulatory constriction movements for the onset consonant of final syllables [3] and of prominent syllables in non-final position [4], though the effects appear to be speaker dependent.

The magnitude of phrase-final effects is not only modulated by syntagmatic factors, but also by paradigmatic ones. Given that prosodic structure is hierarchically organized, phrase-final effects are predicted to be stronger before higher-level boundaries at both acoustic and articulatory level [5, 6]. In Italian -the language under investigation here- the number of phrasing levels is still controversial. Whereas both the intonation (IP) and the intermediate phrase (ip) are well attested, a third level of phrasing has been tentatively proposed, the Accentual Phrase (*AP*) (see also [7] for evidence for this level in French). Specifically, in Neapolitan Italian, [8] found that a tone is inserted at the right edge of the *AP*, which is differently specified in questions (H_{AP}) and in statements (L_{AP}). Also, [9] found that the duration of the accented syllable cumulatively increases with prosodic boundary strength, thus suggesting an interaction between prosodic phrasing and accentual prominence in Italian.

In the present study, we test whether preboundary lengthening affects the production of the consonant in syllable onset position in Italian. If the Structure-based view is correct, its duration in word final CV syllables will be constant since only the syllable rime (V) undergoes lengthening. Alternatively, the syllable onset will be sensitive to vicinity to a prosodic boundary and the effect will be greater for higher level boundaries. More specifically, the effect of prosodic boundary on both acoustic onset duration and articulatory closing movements will increase from the syllable to the *IP*-level. If the *π*-gesture is anchored to the phrase edge, we expect also greater amplitudes and lower velocity of preboundary closing movements. Moreover, in line with the *Word Rime hypothesis*, preboundary lengthening should start from the stressed/accented vowel, independent of its position within the word (i.e., penultimate vs. antepenultimate).

The target words were inserted in both statement and question utterances, since we know that Neapolitan Italian questions and statement temporal structure is different both at a global and local [10] level. As a consequence, we expect that the effects of prominence and prosodic hierarchy on the acoustic and articulatory parameters will also differ across sentence modality.

2. Corpus and methods

The target consonant was /m/ which was always in onset position in the syllable /ma/. The consonant was preceded and followed only by /a/ to guarantee relatively large articulatory movements. Moreover, the syllable /ma/ appeared either in final or non-final position within the word (e.g., ABRAma, TaMAra[1]). Six trisyllabic words were included. They were always proper names. When the position of /ma/ was word-final, the target syllable was unstressed (ABRAma, PAnama). When /ma/ was in non-final position, the target syllable could also bear a stress. To control for the effect of stress location, the stressed syllable could be either in penultimate (TaMAra) or antepenultimate (MArica) position. The stressed syllables were also accented. The six words were inserted in carrier Subject-Verb-Object (SVO) sentences.

Table 1. *Example of sentences by boundary type.*

Boundary type	Sentences
IP	*Le lettere da Malaga]$_{AP}$ e da Panama]$_{IP}$ per quanto ne so, stanno nel cassetto* "The letters from Malaga and from Panama, as far as I know, are in the drawer"
ip	*Le lettere da Malaga]$_{AP}$ e da Panama]$_{ip}$ stanno nel cassetto*
AP	*Le lettere da Panama]$_{AP}$ e da Malaga]$_{ip}$ stanno nel cassetto*
syll	*Le lettere da MaRIna]$_{AP}$ e da Marica]$_{ip}$ stanno nel cassetto* "The letters from Marina and from Marica are in the drawer"

The target syllable appeared in different prosodic position within the sentences, depending on the vicinity to the right boundary of four prosodic constituents (IP, ip, AP and syllable). While the IP-boundary was triggered by the insertion of a parenthetical clause [11], the long subject constituent was expected to be uttered as a single ip [12]. Moreover, since the AP edge seems to coincide with the end of the prosodic word [8], the syllable ("syll") condition only included the unstressed target syllables, which were in AP-internal position. That is, they were located in initial position within the word (da MaRIna; da MaRIsa, "*from Marina/Marisa"*). Sentence modality (Q vs. S) was also varied. Examples of target sentences are shown in Table 1.

Simultaneous acoustic and articulatory data were collected by means of Electromagnetic Articulography (AG500) at the ZAS laboratory (Berlin). As for acoustics, the duration of /m/ and the following /a/ and of the stressed vowel were manually labeled in PRAAT [13]. The articulation of the labial consonant was investigated by calculating lip aperture, i.e. the Euclidean distance between upper (UL) and lower lip (LL). For this purpose, articulatory movement tracking of two transducers placed at UL and LL were used. Kinematic data were labeled and measured by means of the MView software developed by Mark Tiede. Three points were defined: the onset of the closing movement from /a/ to /m/, the time point of the movement extremum and the end of the opening movement.

Three dependent variables were derived. In particular, for the closing movements, we measured: (1) closing gesture duration (i.e., time from onset of the closing movement to the lip closure); (2) time-to-peak velocity (i.e., time from onset of closing movement to velocity peak of the closing gesture); and (3) displacement (i.e., Euclidean distance between onset of the closing gesture and the offset).

One male, native speaker of Neapolitan Italian, was asked to read the sentences 3 times. No instructions were given as for the prosodic phrasing or accentuation of the sentences. Stimuli were randomly presented on paper sheets.

The statistical analyses included a series of mixed models, in which each acoustic and articulatory variable was analyzed as a function of stress location (penultimate vs. antepenultimate), sentence type (Q/S) and boundary type (IP/ip/AP/syll). Contrasts between successive levels of boundary type (IP vs. ip; ip vs. AP; AP vs. syll) were calculated. A maximal random effects structure with intercepts and slopes for Words was considered [14]. The inclusion of the random terms as well as of the interactions among fixed factors was warranted by likelihood ratio tests. The cutoff for significance is $|t| > 2$ [15].

3. Results

3.1.1. Acoustic Results

The duration of the onset consonant and that of the following vowel in word-final syllables are shown in Fig. 1. The consonant duration was on average 43 ms. The statistical analysis showed no difference with respect to boundary type, sentence modality and stress location. However, the vowel following the target consonant was significantly shorter in AP (65 ms) than in ip (80 ms) in Q [β = -0.014; t = -3.3; SE= 0.004]. In Q, only the contrast between IP (74 ms) and ip (62 ms) was significant [β = -0.011; t = -2.2; SE= 0.005]. In both modalities, no difference was found between the lower levels of constituency (AP vs. syll). As for the effect of sentence modality, final vowels in IP and ip conditions were shorter in

[1] Target syllables are underlined, stress position is indicated by capitals.

S than in Q but the amount (6 ms) is close to duration measurement error.

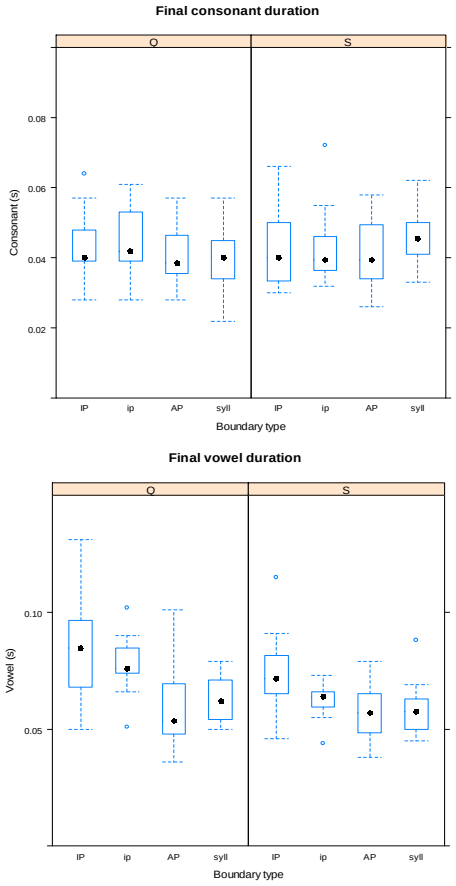

Figure 1: *Boxplots for onset consonant (top) and vowel (bottom) duration in the word final syllable against boundary type and split across sentence type. Data are collapsed across stress location.*

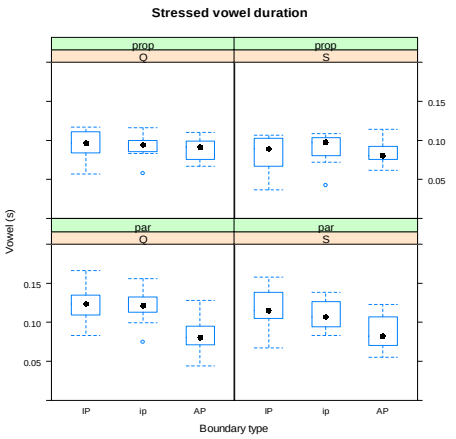

Figure 2: *Boxplots for stressed vowel duration against boundary type. Data are split across sentence type and stress location (prop= proparoxytons; par = paroxytons).*

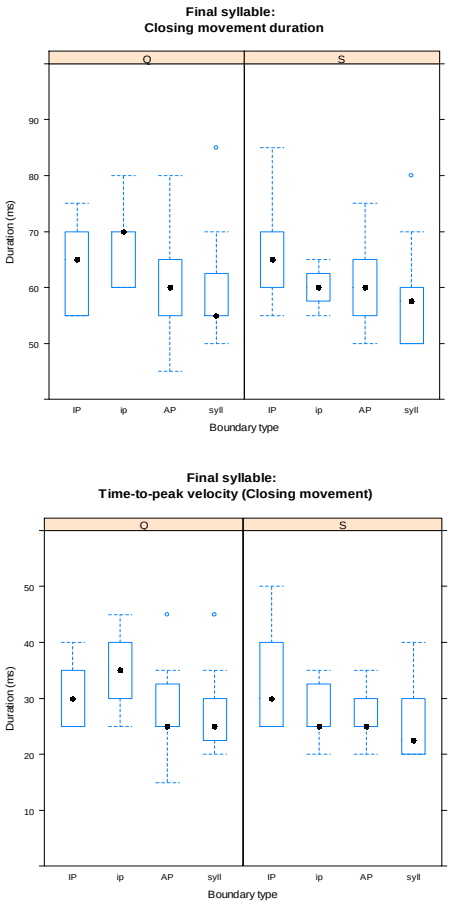
In antepenultimate position, the stressed vowel duration was on average 90 ms (in Q) and 86 ms (in S). However, no significant difference was found across sentence modality and boundary type. In penultimate position, there was no difference in stressed vowel duration between IP and ip. The duration was shorter in AP than in ip [β = -0.02; t = -2.9; SE= 0.006] in both Q and S. The duration of the stressed vowel is shown in Fig. 2.

3.1.2. Articulatory Results

The closing movement of the onset consonant in word-final syllables was affected by prosodic boundary type (Fig. 3). The closing movement duration in Q was significantly shorter in AP than in ip [β = -8.4; t = -2.7; SE= 3]. Neither the contrast between IP vs. ip nor that between AP vs. syll was significant. In S, there was no significant effect of the successive contrasts. The effect of boundary type on time-to-peak velocity also varied with sentence type. In fact, while no significant contrast was found in S, a significant contrast between ip and AP was found in Q [β = 9.9; t = 2.2; SE= 4.4]. Displacement was smaller in AP than in ip [β = -3.5; t = -6.2; SE= 0.5] in both Q and S. The contrast between AP and syll was significant in both sentence modalities [β = -2.6; t = -5.2; SE= 0.4]. However, there was no difference between IP and ip. No effect of stress location was found on the three articulatory parameters. The closing movement duration, time-to-peak velocity and displacement of the onset consonant in the stressed syllables were not affected by boundary type and sentence modality.



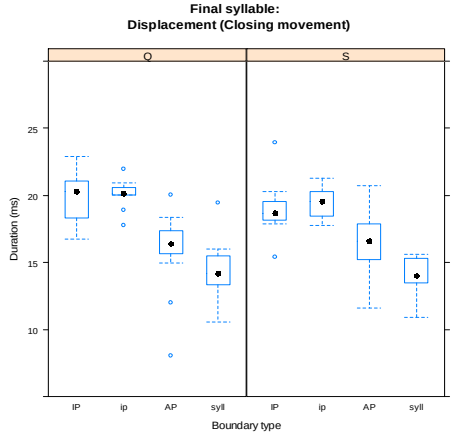


Figure 3: *Boxplots for the duration (top), time-to-peak velocity (middle) and displacement (bottom) of the closing movement of the onset consonant in the final syllable. Data are split across sentence type.*

4. Discussion

While the acoustic results did not show a significant lengthening of the onset consonant in the word final syllable, a clear preboundary lengthening was found for the word final vowel. This result is in line with the *Structure-based* view, which predicts that preboundary lengthening affects only specific linguistic elements. Similarly as English, in Italian the final syllable rime appears to be the sub-syllabic unit on which lengthening applies. The acoustic duration of the stressed vowel was longer before a major (ip/IP) than a minor (AP/syll) prosodic boundary (cf. [1] for similar results in English). This was true only when the stressed syllable was one syllable away from the boundary (in penultimate syllables). This means that preboundary lengthening cannot be determined solely by structural factors. If prominence (accent/stress) would have played a role in determining the domain of final lengthening (as predicted by the *Word Rime hypothesis*), an effect of boundary type should have been found on the stressed vowel independent of its position within the word. On the contrary, durational effects of boundaries are visible only on the segments closer to the edges of the phrase.

This could be in line with the Content View, for which the domain of lengthening depends on the activation of a gesture of fixed duration. It might be possible that, given the simple syllabic structure of the word final syllables (CV), the lengthening gesture could overlap with earlier portions of the word (the penultimate syllables) which would show in turn acoustic lengthening. However, because of its fixed duration, the gesture could not overlap with even earlier portions of the word (the antepenultimate syllables).

A straightforward interpretation of the results is though limited by the partial mismatch between the acoustic and kinematic data. The kinematic results showed a lengthening pattern for the closing movement of the preboundary labial consonant, as well as for time-to-peak velocity and displacement for the same segment, which is in line with the π-gesture hypothesis. This suggests that differently from acoustic lengthening, articulatory constriction movements for the onset consonant of final syllables are affected by prosodic constituency [3]. Since articulatory constrictions usually begin before the acoustic beginning of consonants, variations in the articulatory movements (e.g., closing movement duration) might be acoustically reflected in the lengthening of the preceding vowel rather than on the lengthening of the onset consonant of the word-final syllable.

Moreover, acoustically, preboundary lengthening may extend to penultimate syllables, whereas the articulatory lengthening appears to be limited to final syllables. In fact, the articulatory parameters for the onset consonants within the stressed syllables were unaffected by prosodic constituency. This suggests that the temporal scope of final lengthening is larger in the acoustic than in the articulatory domain. Taken together, the acoustic and articulatory data seem to support a Hybrid view of preboundary lengthening [1], which proposes that the scope of lengthening is determined by structural, phonological and phonetic properties of the phrase-final word. However, more data are needed to better understand the articulatory-acoustic mapping.

As for the number of prosodic levels in Italian, the acoustic and articulatory data showed mixed evidence of two or three levels of phrasing, depending on the parameter examined. In line with the standard view of prosodic hierarchy, this suggests the existence of only two/three categorically distinct levels of prosodic constituency. However, it has been proposed that Italian speakers can distinguish three or even four [8, 9] different categories. A possible explanation for such a discrepancy is that prosodic boundaries are produced in a gradient rather than a categorical manner [16]. As a consequence, values for segmental duration would gradually increase from the lowest to the highest level of the prosodic hierarchy instead of clustering around a limited number of values (one for each prosodic constituent).

Finally, the effects of boundary type on segmental duration differed across sentence modality, indicating that different cues other than the parameters examined (e.g., F0) may be at work to signal prosodic constituency in questions and statements.

5. Conclusion

As predicted by the π-gesture hypothesis, labial closing movements of preboundary consonants show a hierarchical effect of prosodic boundary type despite not being immediately adjacent to the juncture (being one segment away). The effect is both temporal (lengthening of the gesture) and spatial (larger amplitude), though the temporal effect is stronger. On the other hand, the effect does not extend to the closing movements of the stressed syllable, neither for penultimate nor for antepenultimate stress. More data is needed to determine if the findings can be generalized to other speakers and consonantal types and whether the effect is caused by lengthening of the preceding vowel.

Abstract

We investigate the realization and discrimination of lexical stress contrasts in pitch-unaccented words in phrase-medial position in Spanish, a context in which intonational pitch accents are frequently absent. Results from production and perception experiments show that in this context durational and intensity cues to stress are produced by speakers and used by listeners above chance level. However, due to substantial amounts of phonetic overlap between stress categories in production, and of numerous errors in the identification of stress categories in perception, we suggest that, in the absence of intonational cues, Spanish speakers engaged in online language use must rely on contextual information in order to distinguish stress contrasts.

Index Terms: lexical stress, stress cues, phonological neutralization, Spanish.

1. Introduction

In Spanish, the correlates of lexical stress appear to be subtler than in other languages with lexically contrastive stress that have been investigated in this respect, such as English or Dutch, and also closely related languages such as Portuguese and Catalan. Spanish lacks systematic reduction of vowels in unstressed syllables [1], and durational differences between stressed and unstressed syllables in this language are relatively small compared to Portuguese [2, 3]. This results in lexical differences in stress placement often being difficult to perceive for learners of Spanish as a second language [4, 5].

The most robust cues to determine the position of lexical stress in a Spanish word are present when it carries an intonational pitch accent, in which case the pitch accent is associated to the lexically-stressed syllable, lending it phonetic prominence. When the word does not carry an intonational pitch accent, on the other hand, the perception of lexical stress may be jeopardized. Given the important role of pitch accents in disambiguating stress contrasts, the question arises whether lexical stress distinctions are maintained under such conditions, as has been reported for other stress languages such as Dutch and English [6, 7, among others]. To address this issue, [8] conducted a study where Spanish speakers were asked to produce parenthetical reporting clauses, which systematically exhibit a low flat pitch contour judged to lack pitch accents. Under this condition, minimal pairs involving paroxytone and oxytone verb forms (e.g. *determino* vs. *determinó*, stressed syllables in bold) were found to be distinguished in production by consistent differences in vowel duration, and less reliably by intensity.

Reporting clauses such as the ones used by [8] are rather rare in conversational Spanish. On the other hand, a very frequent context where words do not appear to carry pitch accents in Spanish is in phrase-medial position within broad-focus long intonational phrases (IPs). This is illustrated by the following examples, which are typically realized as single intonational phrases ending in rising continuation intonation:

a) [***Siem**pre que **mi**ro la **ho**ra*]$_{IP}$, …
'Every time I look up the time, …'

b) [***Siem**pre que mi**ró** la **ho**ra*]$_{IP}$, …
'Every time she looked up the time, …'

Our observations from the Nijmegen Corpus of Casual Spanish (NCCSP) [9] suggest that in such contexts stress contrasts might be lost, without duration and intensity cues compensating for the absence of a pitch accent. Audio examples of unaccented words in phrase-medial position extracted from the NCCSp can be accessed online at [10]. These examples contain the words ***de**jo* 'I leave' and *de**jó*** 'she left', which contrast only in the position of lexical stress.

In the present study, we investigate to what extent the lack of pitch accents in phrase-medial position in Spanish leads to a neutralization of stress contrasts. In the following sections, we present a production experiment and a perception experiment aimed at answering this question.

2. Experiment I: Production

In Experiment I, we investigate the extent to which Spanish speakers maintain lexical stress contrasts in words lacking a pitch accent in phrase-medial position. We elicit unaccented verbal forms contrasting in the position of stress (e.g. ***ta**po* vs. *ta**pó***) located in phrase-medial position, and examine their phonetic realization in terms of f0, duration, intensity, formant values, and two forms of consonantal lenition using regression modeling and a cross-validation procedure. We use verbal forms from the first conjugation (with infinitives ending in –ar) as targets words, because they provide a systematic contrast in stress placement (oxytones for 3rd p. sg, past tense, vs. paroxytones for, 1st p. sg, present tense).

2.1 Method

Nine native speakers of European Spanish (4 female, 5 male) were recorded in a quiet room with an Audix HT5 head-worn microphone connected to a Sound Devices MM-1 pre-amp, which was in turn connected to a Marantz PMD660 digital recorder. The signal was digitized at 44.1 kHz, 16-bit quantization. Subjects were seated in front of a computer screen and presented with strings of words consisting of a subject pronoun, a verbal tense (present or past), an interrogative pronoun, a target verb in the infinitive form, and

a noun phrase serving as a verbal object. The participants' task was to first examine the elements on the screen, and then produce a fluent wh-question. For instance, for the stimulus *PASADO/él*: *¿Cómo/tocar/tu estrella?* 'PAST/he: How/touch/your star?, the expected response was *¿Cómo tocó tu estrella?* 'How did she touch your star?'. Wh-questions were chosen as carrier sentences because they are typically produced as one intonational phrase, both in spontaneous and laboratory speech. This method elicited a large number of phrase-medial verbal forms belonging to three minimal pairs: ***to**co* 'I touch' vs. *to**có*** 'she touched'; ***ta**po* 'I cover' vs. *ta**pó*** 'she covered'; ***cor**to* 'I cut' vs. *cor**tó*** 'she cut'.

The experimental materials included 60 target sentences (3 verbs * 2 tenses * 10 repetitions) and 60 distractors containing different subject pronouns and verbal tenses. From the 540 elicited tokens (60 target sentences * 9 speakers), we analyzed 456 that were produced as fluent broad-focus intonational phrases. The remaining utterances, exhibiting disfluencies, and less frequently, other phrasing and accentual patterns, were discarded. The majority of the analyzed utterances (74%) were produced with an initial rising accent (L*+>H* in SpToBI notation) on the question word (e.g. *cómo*) and a valley on the stressed syllable of the object (*estrella*) followed by a final rise (L* H%), with falling f0 throughout the phrase-medial verb (*toco* or *tocó*). The second most common intonational contour (24%) consisted of a low accent on the question word (L*), and a rise-fall on the object noun (L+H* L%), with flat f0 throughout the phrase-medial verb.

Acoustic analyses were performed as follows: as a first step, the two syllables of the target verb forms were segmented following standard criteria, with stop consonants starting and vowels ending at the stretches of silence attributable to oral stop closures. The following acoustic measurements were then taken with Praat, and registered as differentials between the first and the second syllable: (a) f0 at the midpoint of the vowel, in Hz; (b) syllable duration, in ms; (c) peak intensity within the syllable, in dB (d); first and second formant values (F1, F2) at the midpoint of the vowel, in Hz. According to several recent studies, Spanish /p t k/ consonants are often voiced and spirantized (realized as approximants, without a complete stop closure) in intervocalic position. These lenition phenomena may be conditioned by prosodic factors such as lexical stress or pitch accent [11, 12, 13]. For this reason, we also annotated (e) the presence of uninterrupted periodicity throughout the closure of each of the two stops in each utterance, and (f) whether vowel formants could be observed throughout the consonantal closure. In cases of spirantization, that is, without clear stop closures, segmentation of the syllables in the target words could not be performed, and the differentials mentioned above were left undefined.

2.2 Results

We first fitted a series of mixed-effects regression models with the f0, duration, F1, and F2 differentials between the first and second syllable of the target verbs as responses, stress pattern (paroxytone, oxytone) as the main predictor, verb type (*cortar*, *tapar, tocar*), and contour type as covariates, and speaker as a random factor. Positive differentials indicate that the first syllable has higher values than the second, while negative differentials indicate the opposite. If lexical stress in phrase-medial unaccented words is distinguished by speakers, some or all of these acoustic differentials should differ between the two stress patterns, with higher differentials for paroxytone words (i.e. with more phonetically prominent first syllables).

Consistent with our impressions that the phrase-medial target words did not carry a pitch accent, no f0 difference was found between the two stress patterns (p = .46). A small difference was observed for F1, with paroxytones having a slightly more open first vowel than oxytones (β = 21.51, t = 4.1, p < .0001), but no difference was observed for F2. Greater differences were observed for duration and intensity. In line with the possibility that a stress distinction is maintained in the absence of pitch accents, paroxytones tended to exhibit longer and more intense first vowels than oxytones (duration: β = 22.3, t = 12.4, p < .0001; intensity: β = 1.77, t = 7.85, p < .0001). Despite these statistical differences, however, we observed a considerable amount of overlap between the two stress patterns, in particular for the intensity differential. This can be appreciated in Figures 1 and 2, which show verb-normalized duration and intensity differentials as a function of stress pattern.

As mentioned above, we also examined consonant voicing and spirantization as possible cues to stress. Around a third (33%) of the consonants in the first syllable of the target word were fully voiced when the syllable was lexically stressed. This percentage was considerably higher (46.4%) in unstressed syllables. As for the consonant onset of the second syllable, it was voiced in 33% of tokens when this syllable was stressed vs. 53.7% when unstressed. Both differences were statistically significant in mixed-effects logistic regression models with consonant voicing as the response, stress pattern as the main predictor, verb type as a covariate, and speaker as a random factor (1st syllable: β = 0.74, z = 3.12, p < .005; 2nd syllable: β =-0.75, z = -3.24, p < .005).

Regarding spirantization, we observed that, in general, it was more frequent in the second consonant (n = 43; 9.4% of the data) than in the first one (n = 10; 2.1%). However, it was only in the first consonant that spirantization seemed to be affected by lexical stress, as suggested by a slight statistical trend in a regression model with spirantization as response, stress pattern as predictor, verb as a covariate, and speaker as a random factor (β = -1.41, z = -1.77, p = .07). In the second consonant, where spirantization was more frequent, no statistical difference was observed (8.3% in stressed syllables vs. 9.5% in unstressed syllables; p = .63).

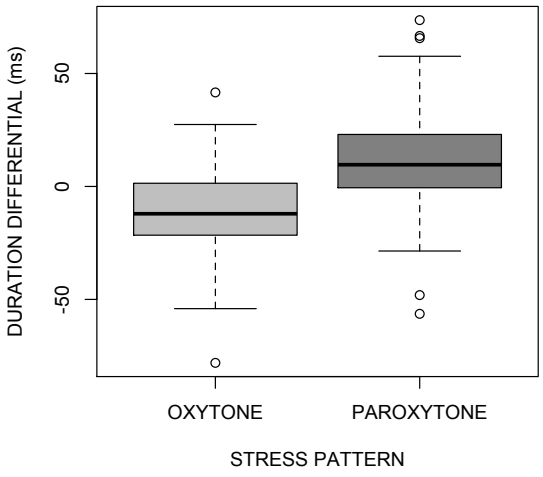

Fig. 1. *Verb-normalized duration differential between first and second syllables in our target words as a function of stress pattern.*

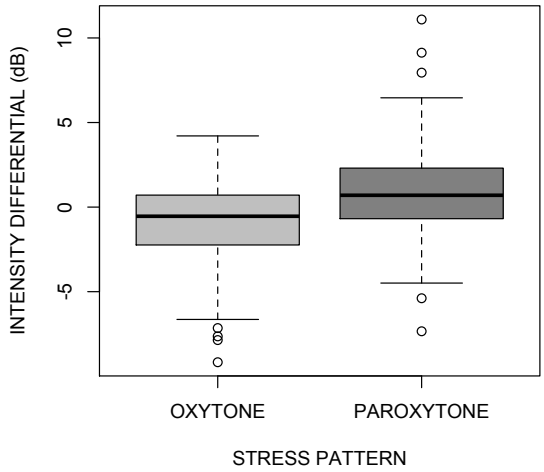

Fig. 2. *Verb-normalized peak intensity differential between first and second syllables as a function of stress pattern.*

To assess the strength of the different identified cues to stress position, we subjected our data to a leave-one-out cross-validation procedure. We simulated predicting stress patterns for unknown data in the following way: for each token in the dataset, we predicted its stress pattern with logistic regression models trained on the rest of the dataset. These models included different combinations of relevant features identified above (i.e. F1, intensity, and duration differentials, and consonantal voicing), plus speaker and verb type.

Table 1 shows percentages of correct classification obtained with five different models. Duration offered the best cue to the stress contrast, achieving 73.8% of correct classification, almost as much as a model containing all features (75.8%). Intensity provided a moderate gain over chance level (62.4%), whereas consonantal voicing and F1 only allowed for results slightly above chance level (55.2% and 51.8%).

We conclude from this analysis that duration and intensity, in this order, provide the best cues to lexical stress in Spanish unaccented words in phrase-medial position. It is also worth noting, however, that almost a quarter of the dataset could not be classified correctly even when all relevant cues where used. This suggests that in such cases there may be little acoustic information that listeners could use to distinguish stress contrasts. We address this issue in the following section.

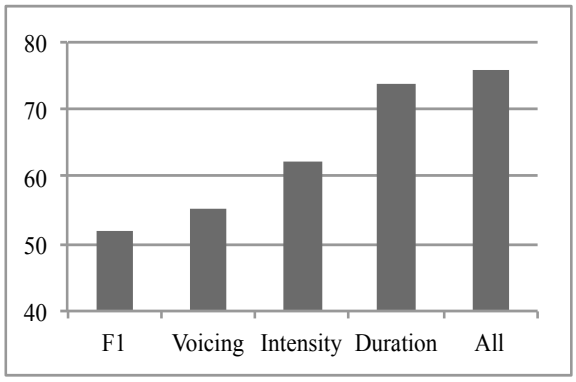

Fig. 3. *Percentages of correct stress pattern classification in Exp. I obtained with different acoustic features in a cross-validation procedure (see text for details).*

3. Experiment II: Perception

In Experiment II, we investigate the extent to which native Spanish listeners can distinguish different stress patterns in phrase-medial unaccented words. We also investigate what phonetic cues are used by listeners to discriminate between stress patterns.

3.1 Method

A random subset of 100 utterances was selected from the 456 utterances analyzed in Experiment I, and used as stimuli in Experiment II. We decided to use only a subset of 100 stimuli in order to avoid fatigue in the participants, which could lead to unreliable results. The experiment consisted of a two-alternative forced-choice task, in which listeners had to classify auditory stimuli in one of two groups according to the tense and person of the verb in the utterance, which, as explained in the previous sections, are distinguished only by the stress pattern of the verbal form (oxytone: 3rd p. sg., past vs. paroxytone: 1st p. sg, present).

Thirteen listeners, all of them native speakers of European Spanish, participated in the experiment. They wore closed headphones and sat in front of a desktop computer in a quiet office. In each trial, two written options appeared on the screen upon presentation of an auditory stimulus: *ÉL/PASADO* 'he/past', in the left part of the screen, and *YO/PRESENTE* 'I/present', in the right part of the screen. The message in the left part of the screen was congruent with an oxytone verb (e.g. ta**pó**), whereas the message in the right part of the screen was congruent with a paroxytone verb (e.g. **ta**po). Participants were asked to press the left or right-arrow key on a computer keyboard according to which message on the screen was congruent with each heard utterance.

3.2 Results

Participants correctly classified the stress pattern of the presented target verbs in 62.9% of the cases. Responses were correct significantly above chance level according to a mixed-effects logistic regression model with stress pattern as dependent variable, the participant's response as the only fixed predictor, and participant as a random factor ($\beta = 1.08$, $z = 9.2$, $p < .0001$). Note, however, that the automatic classification carried out in Experiment I outperformed participants in Experiment II by a considerable margin (75.8 % vs. 62.9%).

An analysis by participants revealed that all of them were able to identify the stress pattern of the verb in the stimuli slightly or moderately above chance level, with percentages of correct classification ranging from 55% to 70%. In an analysis by items ($n = 100$), we found that many of them tended to be correctly classified significantly above chance level (47 above 70%; 27 above 85%), but we also observed a considerable number of items below chance level (16 below 50%; 6 below 30%). Taken together, these results indicate that the stress pattern in the target words could be identified above chance level in most cases, but also that identification errors were common in the data.

We then investigated which cues participants followed when responding to the stimuli in the experiment. We subjected the data to a leave-one-out cross-validation procedure similar to the one employed in Experiment I. This time, we fitted logistic regression models with the participant's response (not the correct answer) as dependent variable, and different combinations of relevant acoustic cues as predictors (i.e. F1, intensity, and duration differentials, consonantal voicing), plus information about participant and verb type.

Figure 4 shows percentages of correct classification of participants' responses obtained with five different models. The model including all acoustic cues achieved 65.5% of correct classification. Interestingly, when only one cue was used, intensity offered the best performance, achieving 59.7% of correct classification. Duration followed closely, with 59.2%. Although in the production data from Experiment I duration clearly offered a better cue to the stress contrast than intensity, these perception data suggest that listeners use both intensity and duration cues in a similar degree when discriminating stress patterns. Regarding F1 and voicing, we found that, as in Experiment I, theses cues played a lesser role than intensity and duration, with percentages of 52.9% and 55.1% respectively.

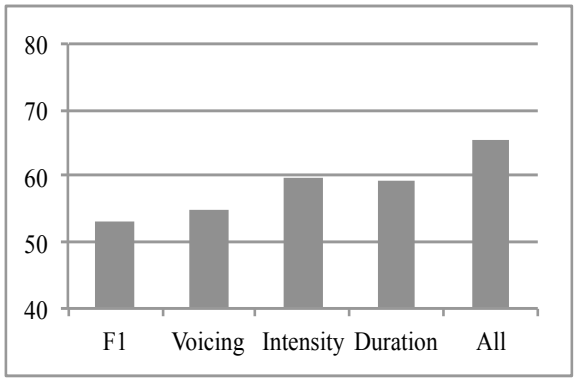

Fig. 4. *Percentages of correct classification of subjects' responses in Experiment II obtained with different acoustic features in a cross-validation procedure (see text for details).*

4. Discussion and conclusion

The previous two sections have presented two experiments aimed at investigating the production and perception of lexical stress contrasts in unaccented words in Spanish. More particularly, we have examined the case of unaccented words in phrase-medial position, a very, and possibly the most, frequent context of deaccenting in Spanish.

Our experiments have shown that, both in production and perception, a contrast in the position of lexical stress is maintained in spite of the lack of prominence-lending pitch cues. In our production experiment, lexically stressed syllables tended to be longer and more intense than their unstressed counterparts. Duration cues allowed for the correct classification of almost three quarters of the data in a cross-validation procedure simulating the discrimination of new unseen data, and they provided a considerably better cue than intensity cues. In perception, we found that all speakers could distinguish the position of lexical stress above chance level, and that, interestingly, their perception of the position of lexical stress was guided as much by intensity cues as by duration cues. Other phonetic cues, such as F1 and the presence of lenitory voicing in consonants also appeared to play a role in distinguishing lexical stress contrasts, but, both in production and perception, in a lesser degree than duration and intensity. Our results for phrase-medial unaccented words are therefore in line with those reported in [8] for parenthetical reporting clauses.

Despite the identified phonetic differences in Experiment I, and the listeners' performance above chance level in Experiment II, it should be noted nevertheless that we observed a considerable amount of phonetic overlap between stress patterns. In production, roughly a quarter of the data could not be classified correctly by a model containing several relevant features such as duration, intensity, voicing and F1; and, in the perception experiment, listeners made identification errors in a two-alternative forced-choice task in 37.1% of the trials. If we take into account that our speech materials were produced in a laboratory setting, and that the perception experiment explicitly required participants to choose between two alternative choices, we may wonder to what extent native Spanish speakers use stress-related phonetic contrasts such as the one examined in this study during online language use. In everyday conversation, it is likely that contextual information is necessary for discriminating between stress patterns, since phonetic cues to stress do not appear to be very robust even in highly controlled data such as ours.

The lack of across-the-board robust cues to stress in Spanish may be related to the low information load that the position of lexical stress has in this language. Except in verb forms, the location of stress in Spanish words is largely predictable: although lexical stress may fall in principle on any of the last three syllables of the word in theory (e.g. ***lám****para* 'lamp', *mam****pa****ra* 'screen', *Pana****má)***, there is an overwhelming tendency for consonant-final words to be stressed on the final syllable, and for vowel-final words to be stressed on the penultimate syllable, with more than 95% of all words in the Spanish lexicon following this rule. Regarding verbs, for which several kinds of minimal pairs exist, ambiguities are likely to be rare in discourse, since these minimal pairs involve verb forms in different tenses (e.g. present vs. past) and with different subjects (e.g. 1st sg. vs. 3rd p. sg.). Robustly conveying information on lexical stress pattern is therefore of little communicative value in Spanish, which may explain the significant amount of phonetic overlap between stress patterns observed in our data.

On the other hand, the fact remains that Spanish words are specified for the position of stress. Even if there are general rules of stress assignment, exceptions must be learned by children during language acquisition. In this regard, the considerable amount of phonetic neutralization that we find in phrase-medial position is not likely to pose a serious challenge to learners with continued exposure to the language, since the position of stress is often conveyed more robustly in other prosodic contexts thanks to the presence of intonational pitch cues [8]. In this sense, the location of lexical stress is not very different from other features that create contrasts between words, and that are sensitive to contextual and realizational factors. For instance, the fact that Spanish /ptk/ consonants are frequently voiced and spirantized in intervocalic position [11, 12, 13], giving rise to occasional ambiguities, does not prevent the /ptk/-/bdg/ opposition from being fully functional in the language. Nevertheless, the fact that Spanish stress contrasts are often lost under specific, but common, conditions, such as the context examined in this study, should be taken into account in descriptions of the prosody of this language.

The effects of stress/accent on VOT depend on language (English, Spanish), consonant (/d/, /t/) and linguistic experience (monolinguals, bilinguals)

Abstract

This study examines Voice Onset Times of coronal stops in utterance-initial position in two languages. Crucially, the effects of lexical stress (stressed, unstressed syllable) on VOT are analyzed. The study investigates aspirated stops (English /t/), short-lag voiceless stops (English /d/, Spanish /t/) and prevoiced stops (Spanish /d/). Three groups of speakers provide data: English monolinguals, Spanish monolinguals, and proficient Spanish-English bilinguals. The study finds that lexical stress lengthens aspiration (English /t/) and prevoicing (Spanish /d/) but it does not alter significantly short-lag stops (Spanish /t/, English /d/). Monolinguals and bilinguals differ slightly in their phonetic behavior. Implications for gestural coordination as well as for feature theory are discussed.
Index Terms: VOT, stress, Spanish, English, bilingualism

1. Introduction

The present study is concerned with the effects of lexical stress on Voice Onset Times (VOT) of /d/ and /t/ in two languages, Spanish and English. The study examines the productions of monolingual and bilingual speakers and assesses the potential impact of linguistic experience on lexical stress effects for Spanish and English /d/ and /t/.

While both Spanish and English possess a contrast between *fortis* (/p t k/) and *lenis* stops (/b d g/), the phonetic implementation of the contrast differs for the two languages. English presents a contrast between a set of aspirated, voiceless stops (/p t k/) and a set of unaspirated, voiceless stops (/b d g/). The Spanish contrast is that between a set of unaspirated, voiceless stops (/p t k/) and a set of voiced stops (/b d g/) [1]. (Note that this description applies to utterance-initial position because Spanish /b d g/ are regularly spirantized in other positions). According to one view, the phonological opposition in English depends on the feature [spread glottis], which is specified for the *fortis* stops but not for the *lenis* ones; on the other hand, the Spanish contrast depends on [voice], which is specified for the *lenis* stops but not for the *fortis* ones [2].

A large body of research has demonstrated that prosodic structure affects fine-phonetic detail in segments. Experimental studies have shown that consonants in prominent syllables (stressed, accented) are hyperarticulated relative to those in non-prominent syllables (unstressed, unaccented) in a number of languages ([3–7, among others]). Hyperarticulation is captured by articulatory and acoustic measurements. One of the acoustic correlates that manifest hyperarticulation is VOT. In a seminal study, [7] found that VOTs in English aspirated stops (/p t k/) were longer when these consonants were found at the onset of lexically stressed syllables than when they were found at the onset of unstressed syllables. This effect was corroborated, for this language, in [3] and, for phrase-accented syllables in connected speech, in [5]. In sum, for consonants with long-lag VOT, such as English /p t k/, the effects of lexical stress are straightforward, and they seem to be of an additive nature—stress lengthens the aspiration period of aspirated consonants.

Stress effects also have been investigated for consonants with short-lag VOTs, although the results are less straightforward than those for aspirated consonants [8–10]. For instance, [7] reported a trend for English /b d g/ according to which these consonants showed a *shorter* VOT when stressed than when unstressed. On the other hand, [5]'s findings are not in line with those in [7] regarding English /b d g/. In [5]'s study, VOT is lengthened when the consonant bears prominence, and that applies to both /p t k/ (English aspirated stops) as well as to /b d g/ (English short-lag, unaspirated stops). The results of a study of Dutch *fortis* (/t/) and *lenis* (/d/) stops are also informative in this regard [4]. Dutch presents a *fortis-lenis* contrast of the "Spanish type", rather than the "English type"; that is, Dutch /t/ is a voiceless, unaspirated stop—a stop with a short-lag VOT. [4] explores the effects of lexical stress and phrasal accent separately. In this study, VOT length of Dutch /t/ is longest when unstressed and unaccented and shortest when stressed and accented. Thus, the effects of stress on this consonant are subtractive (in terms of VOT), rather than additive, and the effects of lexical stress and phrasal accent are cumulative.

No study seems to have straightforwardly addressed the effects of lexical stress on negative VOT or prevoiced stops [8, 9, cf.]. [4] analyzed the duration of voicing during closure in Dutch /d/. In the data in this study, /d/ always appeared in intervocalic, rather than utterance-initial, position. Although this measurement might differ from lead VOT (since voicing during closure in intervocalic /d/ could be due partially to carryover laryngeal coarticulation), the findings in [4] with respect to /d/ are perhaps relevant—lexical stress was found to affect voicing length. In particular, prominent syllables displayed longer voicing periods during closure than unstressed syllables. The fact remains that, to our knowledge, the effects of stress on prevoiced stops remains to be investigated in depth.

The present study analyzes lexical stress effects on long-lag stops (English /t/), short-lag stops (English /d/, Spanish /t/) and prevoiced stops (Spanish /d/). Thus, we explore a language with a [spread glottis] contrast (English), one with a [voice] contrast (Spanish), and, importantly, we study speakers possessing both features and thus all three stop types (Spanish-English bilinguals). The goal of the present study is to gain a broader understanding of stress effects on different VOT categories in order to begin to grasp the impact of prosody on segments more generally.

2. Methods

In order to collect the production data, we used a delayed shadowing task, widely used in the literature on second-language speech learning (e.g., [11]). In this task, speakers listen to and then repeat out loud target phrases.

2.1. Materials

2.1.1. Target phrases

The materials were a list of words beginning with /d/ or /t/. Half of these words were stressed on the word-initial syllable, and the other half were stressed on the second syllable. Therefore, stops could appear in a stressed syllable or unstressed syllable. There were 40 words total, 20 per language. The words were balanced for Consonant (/d/, /t/) and Stress (stressed, unstressed). There were five word items per design cell: 2 (languages) $\times$ 2 (consonants) $\times$ 2 (stress configurations) = 8 design cells $\times$ 5 items = 40 words. The target words were interspersed among many fillers or distractors (n = 36).

2.1.2. Auditory stimuli

The 40 words were printed out on two lists as a function of language—20 English and 20 Spanish words. Three male native speakers of each language (six 'talkers' in total) were asked to read their corresponding word list out loud. Each 'talker' received a different randomization of the list. Words were produced in utterance-initial position in the carrier sentences '__ is the word' and '__ es la palabra.' In this way, three auditory models were recorded for each word item, one per 'talker.' This amounted to 120 (20 items $\times$ 2 languages $\times$ 3 auditory models or 'talkers') different auditory stimuli to be used in the delayed shadowing task.

2.2. Speakers

A total of 47 volunteers participated in this experiment. All speakers were female, and they were all between 18 and 23 years of age. There were three groups of speakers: (i) a group of Spanish-English bilinguals (n = 19), (ii) a group of monolingual Spanish speakers (n = 22), and (iii) a group of monolingual English speakers (n = 7). The monolingual Spanish speakers were recruited from among the student body of the Universitat de les Illes Balears on Majorca, Spain. These participants are bilingual in Catalan. (Note that there are no reported differences between Catalan and Spanish stop consonants with respect to their VOT [12].) The monolingual English speakers, as well as the Spanish-English bilinguals, are/were undergraduate students at the University of Arizona in Tucson, Arizona. The English speakers consider English to be their native language, and they were exposed to English exclusively in their family circle while growing up. The bilinguals, Mexican-Americans born and raised in Southern Arizona, were brought up by Spanish-speaking families and were schooled mostly in English. They use both languages daily both in the classroom as well as with their friends and relatives. A bilingual profile questionnaire was used to establish the groups [13]. In this report, data from the three groups are analyzed separately.

The Spanish-English bilinguals were recorded in both of their languages. The English monolinguals were recorded in English. The Spanish monolinguals were recorded in Spanish.

2.3. Procedure

The 47 female speakers were asked to listen to and then repeat out loud the auditory stimuli. The English monolinguals heard and produced only the English materials (60 tokens). The Spanish monolinguals heard and produced only the Spanish materials (60 tokens). The Spanish-English bilinguals, however, were recorded in both of their languages—they listened to and repeated the English as well as the Spanish materials (120 tokens). Each speaker heard a different randomization of the stimuli.

Importantly, the bilinguals heard and produced the English and Spanish materials in a single block, in random order. In other words, the Spanish and English auditory stimuli were randomized in one single production session so that the English items were interspersed amongst the Spanish items. This hypothetically maximizes the degree of interlingual transfer of phonetic characteristics for these bilinguals [14], and it thus explores this population in a situation diametrically opposed to the one researched in [15]. Speakers were asked to listen to the entire utterance first ('__ is the word' or/and '__ es la palabra') and then to repeat the entire sequence aloud. In this way, shadowing of the target consonant was slightly delayed relative to the time in which it was heard.

Recordings were made through a head-mounted dynamic microphone (Shure SM10A), a pre-amp (Sound Devices MM-1) and a digital voice recorder (Marantz PMD660). Digitization was at 44.1 kHz, 16-bit. The Spanish monolinguals were recorded in a quiet laboratory at the Universitat de les Illes Balears. The English monolinguals and the Spanish-English bilinguals were recorded in a sound-attenuated booth at the Applied Phonetics Laboratory of the University of Arizona. Speakers were recorded one at a time.

2.4. Analysis

A total of 4,020 word tokens were collected for the present study. The English speakers provided 420 tokens, the Spanish speakers provided 1,320 tokens, and the Spanish-English bilinguals provided 2,280 tokens, 1,140 in Spanish and 1,140 in English. The study considered two within-speaker factors: (i) Consonant: /d/, /t/; and (ii) Stress: first syllable in word is either stressed or unstressed. For one of the speaker groups (Spanish-English bilinguals) a third within-speaker factor was added—Language spoken: Spanish, English.

The target /d/ and /t/ tokens were measured for VOT [16]. VOT is an acoustic metric that captures, for stops, the time lag between the burst (i.e., the release of the articulators after the stop closure) and the initiation of periodicity (i.e., the onset of modal voicing). VOT is positive if the burst occurs before the onset of periodicity (since burst = 0 ms) and negative if it occurs after it. In this study, bursts and voicing onsets were hand-located by exploring spectrographic and sound wave displays. The onset of voicing was marked at a zero-crossing on a sound wave display. Voicing onset in lag VOTs was marked by taking into account the initiation of $F2$ in order to make sure that we labeled the initiation of modal voicing rather than voicing *per se*.

3. Results

3.1. Spanish speakers

The Spanish materials produced by the Spanish speakers were analyzed through a repeated-measures ANOVA with VOT (ms) as the dependent variable and Consonant (/t/, /d/) and Stress

	/d/	/t/
stressed	-69.2 (3.52)	15.3 (1.04)
unstressed	-50.4 (3.51)	16.3 (1.38)

Table 1: Mean (+ SE) VOT (ms) as a function of Consonant (/t/, /d/) and Stress (stressed, unstressed) in the Spanish data.

	/d/	/t/
stressed	21.9 (3.66)	78.4 (6.72)
unstressed	26.3 (4.81)	71.4 (5.89)

Table 2: Mean (+ SE) VOT (ms) as a function of Consonant (/t/, /d/) and Stress (stressed, unstressed) in the English data.

(stressed, unstressed) as within-subjects factors. Individual speaker ($n = 22$) was the error term. The descriptive statistics of these data are shown in Table 1. The statistical test revealed significant effects of Consonant ($F(1, 21) = 511.7, p < 0.001$) and Stress ($F(1, 21) = 123, p < 0.001$), as well as a two-way significant interaction ($F(1, 21) = 135.7, p < 0.001$). For these Spanish speakers, /d/ has a lead, negative VOT with a mean of -59.8 ms and /t/ has a short-lag, positive VOT with a mean of 15.8 ms.

In order to explore the interaction, the main effects of Stress were investigated for the two stop consonants separately; this was done by means of paired t-tests. The alpha level was adjusted accordingly (0.05/2 = 0.025) On the one hand, /d/ was shown to present longer prevoicing when stressed than when unstressed by a factor of 1.373 ($t(21) = -12.02, p < 0.001$). On the other hand, /t/ was found not to be affected by Stress ($t(21) = -1.85, p > 0.05$).

3.2. English speakers

The English VOT data were explored by means of a repeated-measures ANOVA with Consonant (/t/, /d/) and Stress (stressed, unstressed) as main factors. Subject ($n = 7$) was the Error term. The ANOVA yielded significant Consonant effects ($F(1, 6) = 244.9, p < 0.001$), but no significant effects of Stress ($F(1, 6) = 1.27, p > 0.05$). The model revealed a significant two-way interaction ($F(1, 6) = 19.22, p < 0.01$). Descriptive statistics are provided in Table 2.

The interaction was examined by means of two separate paired t-tests, and the alpha level was adjusted accordingly. The interaction was due to the fact that Stress effects were robust for /t/ ($t(6) = 3.8, p < 0.01$), but not for /d/ ($t(6) = -2.7, p = 0.03$). At most, one could claim that a marginal trend exists for /d/ as well, although in the opposite direction. The effects for /t/ were due to the fact that stressed /t/ displays a longer period of aspiration than unstressed /t/ by a factor of 1.098.

3.3. Spanish-English bilinguals

The bilingual VOT data were submitted to a repeated-measures ANOVA with Language (Spanish, English), Consonant (/t/, /d/) and Lexical Stress (stressed, unstressed) as fixed factors. All these were within-subjects factors since bilinguals were recorded in both languages. Subject ($n = 19$) was the error term. The statistical model yielded significant effects of all three main effects: Language ($F(1, 18) = 249.5, p < 0.001$), Consonant ($F(1, 18) = 152.4, p < 0.001$), and Stress ($F(1, 18) = 7.58, p = 0.01$). More relevant was the fact that the model revealed three significant two-way interactions (Consonant by Language, $F(1, 18) = 5.3, p = 0.03$; Language by Stress, $F(1, 18) = 54.5, p < 0.001$; Consonant by Stress, $F(1, 18) = 16.95, p < 0.001$) and a significant three-way interaction ($F(1, 18) = 31.6, p < 0.001$). In order to explore the interactions, the dataset was divided into subsets.

Figure 1: Effects of lexical stress on VOT in English /t/ and /d/ in the bilingual speakers' productions.

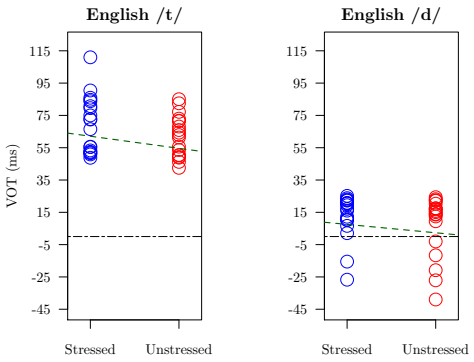

Figure 2: Effects of lexical stress on VOT in Spanish /t/ and /d/ in the bilingual speakers' productions.

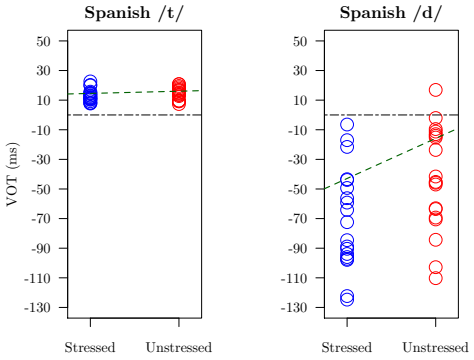

Firstly, the effects of Consonant and Stress were examined for the two languages separately. The first ANOVA investigated the effects of these two fixed, within-subjects factors on VOT for the English data only. These data are plotted in Figure 1. This model yielded significant effects of Consonant ($F(1, 18) = 140, p < 0.001$), as well as Stress ($F(1, 18) = 17.3, p < 0.001$). Importantly, there was no interaction between the two factors ($F(1, 18) < 1$). The effects of Stress were due to the fact that stressed consonants had a longer VOT (a VOT further away from zero) than unstressed consonants by a factor of 1.18. Note that both consonants (/t/, /d/) were similarly affected by the effects of stress in this data subset.

The second follow-up ANOVA explored the effects of Consonant and Stress for the Spanish materials only. (See Figure 2.) In this analysis, Consonant and Stress were within-subjects factors and speaker was the error term. The model revealed significant effects of Consonant ($F(1, 18) = 99.25, p < 0.001$) and Stress ($F(1, 18) = 35.38, p < 0.001$), as well as a significant two-way interaction ($F(1, 18) = 28.42, p < 0.001$). The interaction was due to the fact that /d/ was affected by Stress ($t(18) = -5.73, p < 0.001$) while /t/ was not ($t(18) = -1.6, p > 0.1$). In these data, stressed /d/ had longer prevoicing than unstressed /d/ by a factor of 1.63.

4. Discussion and conclusions

The present study has reported on the results of a production experiment in which the effects of lexical stress on VOT length are examined. VOTs were measured for /d/ and /t/ in both Spanish and English. Three groups of speakers were recorded: Spanish and English monolinguals, and Spanish-English bilinguals. The three groups were investigated separately.

Regarding English /d/ and /t/, the study found that the *fortis*, aspirated stop (/t/) was affected by stress while the *lenis* stop (/d/) was not (or marginally so). The effects of stress on English /t/ were additive—lexical stress lengthened aspiration in this consonant. Therefore, it could be said that stress enhances the acoustic difference between the two members of the /d/-/t/ contrast by affecting one of the two.

The situation for Spanish was different from that for English. In Spanish, it was the *lenis* stop (/d/), rather than the *fortis* one (/t/), the one to be impacted by lexical stress. Spanish /t/ was not modulated by stress. The effects of stress on Spanish /d/ were straightforward—stress lengthens prevoicing in this consonant. Once again, therefore, it could be claimed that stress enhances the acoustic opposition between /d/ and /t/ by displacing one of the two members of the contrast.

The findings of the present study regarding the effects of lexical stress on three VOT categories of two different languages are reminiscent of the literatures on the effects of (i) clear speech and (ii) of speech rate on these sound categories. For instance, [17] found that, in clear speech, aspiration is lengthened in English *fortis* stops and prevoicing is lengthened in Croatian *lenis* stops—short-lag VOT categories are largely unaffected by clear speech.

With respect to speech rate effects, studies typically find that as speech rate decreases (i.e., speech becomes slower) VOTs lengthen, but not for all stop consonants [18, 19]. In parallel to the studies on clear speech (and stress effects), the literature on speech rate has shown that aspiration is lengthened in English *fortis* stops while VOT is not impacted (or only minimally so) in stops characterized by short-lag VOTs [18]. In a fundamental cross-linguistic study, [19] researched the effects of speech rate on Thai, French and English stops. French has a contrast of the "Spanish-type"—*fortis* stops are voiceless, unaspirated and *lenis* stops are prevoiced. Thai has a three-way contrast—it possesses sets of (i) voiceless, aspirated stops, (ii) voiceless, unaspirated stops, and (iii) prevoiced stops. The study found that slow speech lengthened aspiration in English *fortis* stops and French *lenis* stops while short-lag VOT (English *lenis*, French *fortis*) stops were not affected. Regarding the case of Thai, the study found that short-lag VOT categories were not modulated by speech rate while the other two VOT categories were—VOTs were lengthened in the predictable directions.

A review of the literature suggests that the effects of speech rate, clear speech and lexical stress on VOT categories are very similar. What these studies have in common is that they find that, in two-way contrasts, short-lag VOT categories are unaffected while the other category is affected. In three-way contrasts, short-lag VOT categories are also the ones that remain largely unmodified. This could be summarized with the statement that short-lag VOT stop categories act as anchors in situations that lead to contrast enhancement, such as slow and/or clear speech and prosodic prominence.

The "contrast-enhancement" perspective, however, has been challenged by a study that investigated the effects of speech rate on Central Standard Swedish [2]. This language has a two-way contrast. It opposes a set of aspirated, voiceless stops with a set of prevoiced stops—a short-lag VOT category is not found in this language. In Swedish, both stop consonants are affected by slow speech. In sum, the same categories that are affected in French, English and Thai are also affected in Swedish—the only difference is that Swedish does not have an "anchor". The reasoning in [2] is that the Swedish contrast is already acoustically large in faster speech and does not need to be enhanced. [2] propose that speech rate, together with clear speech (and lexical stress), affects VOT categories that *are specified for a phonological feature*. In this view, aspirated stops are specified for [spread glottis], prevoiced stops are specified for [voice] and, importantly, short-lag VOT stops are left unspecified. Contrast enhancement is viewed as an artifact of feature modulation.

An alternative view that does not exploit feature theory is one that depends on articulatory gesture coordination. The VOT metric measures the time lag between two acoustic events that stand for two articulatory gestures, a laryngeal and a supralaryngeal gesture. As such, the VOT metric is a measure of gesture coordination. It is possible that speech rate, clear speech and prosodic prominence do not affect gestural coordination patterns for sounds whose two gestures are robustly synchronized (short-lag VOT stops), but do for those that are loosely synchronized (prevoiced and aspirated stops).

An analysis of the bilingual data found the following: (i) Spanish /d/ is robustly affected by lexical stress while Spanish /t/ is not, and (ii) both English consonants are slightly affected by lexical stress. Therefore, for these bilingual subjects, consonants with lead VOT (Spanish /d/) and long-lag VOT (English /t/) are impacted by lexical stress, although the former more so than the latter. This is the same result that was found for the native English- and Spanish-speaking groups. From the two short-lag VOT consonant (Spanish /t/, English /d/), only English /t/ is affected by lexical stress. While English monolinguals did not display robust stress effects on their English /d/, the bilinguals did.

A possible interpretation of the bilingual findings is suggested by the fact that a subgroup of the Spanish-English bilinguals produced English /d/s with some prevoicing—see Figure 1. This could be a transfer effect from Spanish /d/ for this subgroup. Since negative VOT in prevoiced stops is indeed affected by lexical stress (Spanish /d/, for instance) it is perhaps not surprising that English /d/, as produced by this particular group, is somewhat modulated by stress. Alternatively, English, but not Spanish, *lenis* stops, in general, could be impacted by lexical stress in this population. A strong interpretation of the "featural specification hypothesis" of [2], according to which only consonants with specified features are affected by prosodic modulations, is therefore not possible for the bilingual group. It could be concluded that the Spanish-English bilinguals in this study posess a phonological system consisting of [voice] (Spanish /d/), ∅ (Spanish /d/), and [spread glottis] (English /t/). The nature of the English *lenis* stop would deserve more attention. If [voice] were to be chosen as the featural specification for English /d/, the question arises as to why the phonetic facts for this consonant differ from those for Spanish /d/.

5. Acknowledgments

The authors wish to express their gratitude to the following: Mark Amengual, Melinda Porta, Olivia Obeso, Miquel Llompart, and the 47 volunteers who participated in the study. The authors are also grateful to three anonymous reviewers, and to the SP-7 audience, for constructive criticism.

Is Syllable Stress Information Robust for ASR in Adverse Conditions?

Bogdan Ludusan, Stefan Ziegler, Guillaume Gravier

Abstract

This paper presents a study on the robustness of stress information for automatic speech recognition in the presence of noise. The syllable stress, extracted from the speech signal, was integrated in the recognition process by means of a previously proposed decoding method. Experiments were conducted for several signal-to-noise ratio conditions and the results show that stress information is robust in the presence of medium to low noise. This was found to be true both when syllable boundary information was used for stress detection and when this information was not available. Furthermore, the obtained relative improvement increased with a decrease in signal quality, indicating that the stressed parts of the signal can be considered islands of reliability.

Index Terms: speech recognition, prosody, syllable stress, noise

1. Introduction

Prosodic information has already been used successfully in large vocabulary speech recognition (e.g. [1, 2]). Prosodic information (duration, pauses, F0, etc) was integrated in automatic speech recognition (ASR) systems both at the acoustic and language model level, being posited that prosodic features are robust to noise and unaffected by channel condition [1].

Among the major prosody components, stress seems to present several characteristics which are particularly helpful for speech recognition tasks under different conditions. Studies examining the role of stressed syllables showed that they provide salience in terms of their acoustic attributes, they are less likely to suffer phonological modification or to be misinterpreted and they are detected more consistently than unstressed syllables in *noisy* environments [3].

Indirect evidence supports the relevance of stress information in noisy conditions, not only for humans, as shown by psycholinguistics studies [4] but also for machines [5]. A human perception in noise study [4] examined the intelligibility of speech at very low signal-to-noise ratios (SNR), by either masking or unmasking the stressed syllables. It showed that the SNR required to identify the consonants of the unstressed syllables increased when the stressed syllables were masked and it decreased when the stressed syllables were unmasked. The author concluded that the listener relies on prosody to achieve robust speech understanding and that the information in the stressed syllables helps predict the neighbouring unstressed syllables. Further evidence can be found in an ASR study investigating the effects of phonetic information reduction on recognition performance [5]. When phone identity was substituted with manner feature, performance dropped in both clean and noisy conditions, but no significant difference was observed when phone identity only inside unstressed syllables was replaced by manner information. This suggests that the information carried by the stressed syllables has a higher importance for speech recognition in noisy environments than the one present in non-stressed syllables.

Based on the fact that humans exploit stress information not only under normal acoustic conditions, but also in the presence of noise, and that this information is salient for them, we are interested in investigating whether adding stress information to ASR in adverse conditions would be useful. One would expect it, as stressed syllables display higher energy than non-stressed syllable and in noisy environments they would exhibit a higher SNR than the neighbouring syllables, thus helping to their recognition.

Stress information has been used before in several speech recognition systems [6, 7, 8, 9, 10]. The systems employed different methods to add this new information to the recognition process: at the lexicon level [7, 8], as a separate model in the decoding process [6, 9], or to guide paths during search [10]. Most of these studies reported statistically significant improvements when including stress, but the role of stress was examined exclusively under normal acoustic conditions. To our knowledge, there is only one study in the literature which reported results for speech under adverse conditions [10]. In that study, experiments both on normal and strong accented speech were performed and the same level of improvement was obtained for the two types of speech, when stress information was used. A close analysis of the system showed that the integration of stress information improved speech recognition due to its interaction with the pruning process, by helping prune away some of the wrong hypotheses.

The current paper builds upon a previous mentioned study [10] and aims at the following two aspects: to enlarge the investigation of stress robustness for ASR in adverse condition to a new case (additive noise) and to explore the behaviour of the system when there is no syllable boundary information available for the computation of the stress score. Because we wanted to examine only the effect of stress on the recognition performance, the same system was used in the clean and noisy condition, with no speech enhancing pre-processing. Further details on the recognition system employed and on the stress detection procedure can be found in section 2. For the recognition experiments presented in section 3, we used white and pink noise at various SNRs and we tested two conditions based on whether syllable boundary information was available for stress detection or not. We have chosen to use coloured noise in this study as a starting point in our research, an initial test, but we envisage our future work to include more complex types of noise.

2. System Presentation

The system used in this paper is composed of two components: a stress detection procedure and a speech recognizer. The first component computes syllable-level stress scores which are sub-

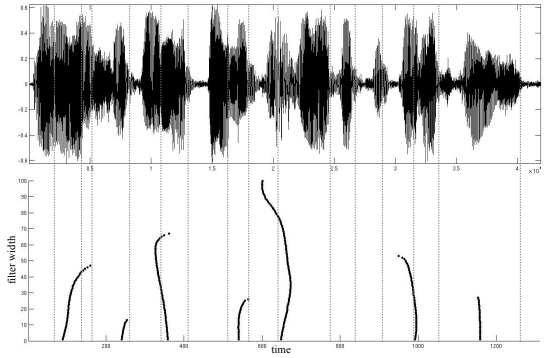

Figure 1: Speech waveform and corresponding rhythmogram.

sequently integrated in the search process of the ASR system.

2.1. Stress Detection

For the computation of the stress score, an unsupervised method based on the auditory primal sketch (APS) [11] was used. The APS is a model of rhythm perception which seeks to identify strong acoustic events present in speech, in a similar way to edge detection in vision theory [12]. In order to accomplish this, the speech signal is filtered with a bank of Gaussian filters with different filter widths. The peaks of the obtained functions are stacked onto each other, with the peaks of the minimum filter width at the bottom. The stacking of the maxima forms contiguous lines which we call "events" (as exemplified in Figure 3). Thus, a hierarchical representation of speech, called a rhythmogram, is obtained. The rhythmogram contains the time on the abscissa and the event height on the ordinate and can be condensed into a two-line vector, containing the time instants of the events on the first line and their corresponding values on the second line.

The procedure used for obtaining the rhythmogram, as well as the values of the parameters needed for its computation, are the one proposed in a previous study [13]. It consists of the following steps:

1. resample at 500 Hz,
2. perform full wave rectification,
3. take the cubic root, to model the ears' loudness function,
4. apply one hundred logarithmically-distanced Gaussian filters,
5. stack the maxima of the obtained function in a 2-D representation, with time on the x-axis and filter width on the y-axis.

Once the rhythmogram is computed, information about syllable boundaries is needed in order to obtain a syllable-level stress score. Then, a search within each syllable is performed and the value of the highest event is taken as the stress score. For the experiments conducted in section 3.2 we had this information available, while the experiments presented in section 3.3 made use of an approximation. Further details will be given in the respective sections.

Figure 1 illustrates the waveform of a sentence from the corpus used in the experiments along with its corresponding rhythmogram. Each point of the rhytmogram is associated to a time instant (t) and a filter width (i) and it represents a peak at time t in the function obtained with the ith filter. For this particular example we can observe that for the minimum filter width (bottom of lower panel) the function had 7 maxima, for the 40th filter 4 maxima, while applying the filter with the highest width returned a function with one maximum (top part of lower panel). By plotting these points in space, we obtain the contiguous lines observed in the figure (the events). In order to compute the stress score we determine to which syllable each event belongs, based on the start time of the event, obtained with the lowest filter width. The stress score will be equal to the number of points which form the event, in this case a stress score of 0 is obtained for the first syllable, a stress score of 47 for the second one, etc.

2.2. Speech Recognition System

For all the experiments we used a two-pass recognition system [10]. The recognizer, produced a word graph after the first pass, graph which will be rescored using more complex acoustic models in the second pass. It uses in the first pass word-internal triphone acoustic models with 4,019 distinct states and 32 Gaussians per state and word trigrams as language model. The rescoring pass has 4-grams as language model and cross-word triphone models with 6,000 states and 32 Gaussians each.

In order to integrate the stress information in the recognition system, the Viterbi search was modified as shown in Equation 1.

$$Q(j,t) = \max_i Q(i,t-1) + log(a_{ij}) + log(b_j(y_t)) + \\ + str(t) \cdot R \quad (1)$$

The first three terms are also present in the classical Viterbi decoding: $Q(j,t)$, the score of the path up to state j at time t, $log(a_{ij})$, the transition probability between states i and j, and $log(b_j(y_t))$, the observation probability of y_t when in state j. The last term is a product between $str(t)$, the stress score of the syllable at time t (taking values between 0 and 1), and R, a weighting factor which represents the contribution of the stress information to the decoding process. The value of R was determined by optimizing the recognition performance on the development set.

Thus, by adding the new term in the search equation, the decoding procedure reinforces all the phonemes belonging to the stressed syllables with a value proportional to the syllable stress score. This implementation choice was made based on the fact that stressed syllables are more stable and are distinguished better [3] and, by giving them a higher weight in the search process, improvements can be obtained [10].

3. Experiments

Speech recognition experiments were conducted on a corpus of broadcast news to which coloured noise, at different SNRs, was added. We investigated the role of syllable boundary information for the computation of the stress score as well as the effect of optimizing the stress weighting factor for each noise level. For each of the experiments, the recognition performance was evaluated by considering the reduction brought in terms of word error rate.

3.1. Materials

The materials used for the experiments presented here are the files of the ESTER 2 evaluation campaign corpus [14]. The corpus consists of mainly broadcast news recordings from French radio stations, although it also contains some more spontaneous radio shows as well as recordings from French-speaking African radio stations which exhibit strong accents.

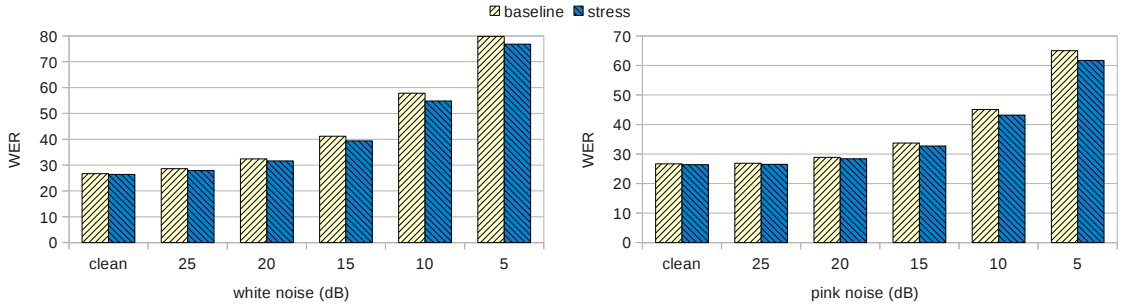

Figure 2: The WER obtained for various SNRs of additive white noise (left panel) or additive pink noise (right panel).

The entire training set, approximately 180 hours of data, was used for the estimation of the acoustic models. Its corresponding transcriptions, along with articles from newspapers, were employed in the computation of the language model. The rest of the corpus forms the development set, used for tuning the system parameters, and the test set, on which the performance of the system was evaluated. These subsets contain circa 6 and 7 hours of recordings, respectively.

For the experiments, two types of additive noise were added to the speech files: white noise and pink noise, ranging from 25 to 5 dB SNR. The white noise was generated using the MATLAB function *wgn*, while the pink noise was obtained by filtering the previously generated white noise [15]. For each SNR, the gain of the filter was determined in order to obtain the desired SNR after the filtering operation. The noise was added only to the files belonging to the development and evaluation sets, the acoustic models having been previously trained with the original training set files.

3.2. Experiment 1

As mentioned in section 2.2, in the first experiment we had knowledge of syllable boundaries for computing the syllable stress score. The boundaries were determined by force aligning the data at the phoneme level and then applying French syllabification rules [16]. Although the quality of the syllabification was not as good as when manual syllables would have been used, this was the best available option for computing a syllable-level stress score. The search for the parameter R in Equation 1 was performed only on the clean data and the obtained value was used in all experiments, regardless of the SNR. The stress score was determined at each step from the noisy data.

The recognition results for various levels of noise are presented in Figure 2: for white noise (WN) in the left panel and for pink noise (PN) in the right panel, with the reported measure being the word error rate (WER). The results obtained with the baseline system are represented by the lighter coloured columns, while those of the recognizer employing stress knowledge are represented by the darker coloured columns. The clean condition is illustrated in both panels for an easier comparison. It can be observed that the importance of stress information in the recognition process increases with the decrease in SNR.

$$WER_{rel} = \frac{WER_{stress} - WER_{base}}{WER_{base}} \quad (2)$$

Next, we used the relative WER (see Equation 2) to compare the performance at different SNRs of the speech signal. As can be seen in Figure 2, the results of the system using stress information were always better than those of the baseline. Thus, we show in Table 2 the values of $abs(WER_{rel})$, which represent the relative improvement (in %), at each SNR, with respect to the baseline. A Wilcoxon signed rank test was used to determine the statistical significance of the results. All the differences were found to be *significant* at the $p < 0.001$ level, except for PN25 ($p < 0.01$).

Noise	Clean	25 dB	20 dB	15 dB	10 dB	5 dB
WN	1.1	2.5	2.5	4.4	5.2	3.8
PN		1.5	1.7	3.0	4.2	5.1

Table 1: *Relative improvement (in %) when syllable boundaries are known.*

The same tendency is observed for both types of noise: the relative improvement increases with the decrease in signal quality. This suggests that the information in the stressed parts tends to have a higher weight on the recognition process as conditions deteriorate. Also, because we were using a value for R determined on clean data it also proves the robustness of the information added. The results obtained in this experiment can be considered as an upper bound for the improvement brought by adding stress information, as it uses almost ideal syllable boundary information.

3.3. Experiment 2

In the second experiment no syllable boundary information was used. Instead we define a time interval around each rhythmogram event which will act as a "pseudo-syllable", i.e. the whole region will be considered as one entity and it will be assigned a stress score equal to the height of its corresponding rhythmogram event. The gaps between the obtained regions will be assigned a zero stress score and, thus, they will have no effect on the decoding process. Similarly to the first experiment, the value of R was determined on the clean development set, while the stress score was obtained from the noisy data.

The "pseudo-syllable" approach is illustrated in Figure 3. The curly braces under each event correspond to the size of the region considered, while the intervals delimited by dashed lines and labeled PS_n represent the final entities. Their size might be lower than the chosen region size, due to events being too close to each other, or too close to the beginning or the end of an utterance. In order to choose the size of the region we took a look at the average size of the dev set syllables having non-zero stress scores. The value obtained, 197 ms, can be compared to the 141 ms average length of syllables having stress scores equal to zero. By rounding the 197 ms to the closest odd number of frames (the central frame and an equal number of frames on

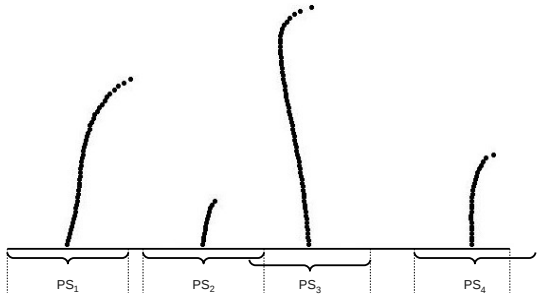

Figure 3: The approach used for hypothesizing syllables, when syllable boundaries are unknown.

each side) we get regions 19 frames wide. This value was used in the present experiment.

Table 2 shows the results given by the recognizer when the previously explained approach is employed. All differences except for PN25 and WN20, were found to be statistically *significant* (WN25 $p < 0.05$, WN15-WN5 $p < 0.01$, PN20 $p < 0.01$, PN15 $p < 0.05$, PN10-PN5 $p < 0.001$). Although the performance increase obtained is not as important as in in the case when syllable boundaries were known, a similar trend in the results can be observed.

Noise	Clean	25 dB	20 dB	15 dB	10 dB	5 dB
WN	0.8	0.7	0.3	1.2	1.4	1.0
PN		0	0.7	0.6	1.1	1.9

Table 2: *Relative improvement (in %) when syllable boundaries are unknown.*

3.4. Experiment 3

As a final test, we examined the effect of parameter optimization on the recognition performance. The experiment was run only on the data containing additive white noise and an optimum value of the R parameter was obtained for each SNR, on the dev set. Both conditions used in the previous two experiments, with or without knowledge of syllable boundary information, were considered and the results obtained are presented in Table 3.

Condition	25 dB	20 dB	15 dB	10 dB	5 dB
Exp 1	2.5	2.5	3.2	5.5	5.0
Exp 2	1.1	1.9	3.4	3.3	0.5

Table 3: *Relative improvement (in %) for an optimized value of the R parameter, in the case of white noise.*

Comparing the results in the first row with those illustrated in section 3.2, one can see that they are quite *similar*, the only case where a significant improvement was obtained is for the 5 dB level ($p < 0.001$). Furthermore, the performance advantage obtained in Experiment 1 for 15 dB is statistically significant ($p < 0.01$). This shows that, when the syllable boundaries are known, the values of R obtained in clean conditions give a good performance also for noisy speech. And, by not needing to optimize R for each SNR, we avoid having to estimate the noise level prior to the actual recognition process.

For the conditions described in Experiment 2, the optimization of the parameter R gives instead *significant* improvements for all noise levels (WN25, WN5 $p < 0.05$, WN20-WN10 $p < 0.001$). An interesting results was obtained for the 5 dB WN condition: although the performance was lower in all the experiments conducted, here the difference was the highest. This might be due to the length of the region considered for our syllable approximation. In case of low SNR it would probably more appropriate to consider smaller regions. While this will decrease the effect that stress has on recognition, by reinforcing a smaller area it is more likely that this area will fall inside the boundaries of the actual syllable and it will not introduce any other errors.

4. Conclusions

In this study we investigated the robustness of stress information in the recognition process, when speech is corrupted by additive noise. To our knowledge this is the first study in the literature aimed at investigating this issue. Using white and pink noise in the experiments conducted, we have observed the same behaviour in both cases: for medium to low SNRs, higher relative improvements are obtained with the increase in the noise level, when stress knowledge is integrated into the recognizer. These results support the view that stressed syllables represent the reliable regions of the speech signal and that the information they carry is important for speech recognition. Besides agreeing with the role given to stress by psycholinguistic studies [3, 4] as well as to the indirect evidence coming from other ASR studies [5] the results of this investigation also encourage the use of such information in speech recognition.

Stress information is robust in the presence of additive noise, especially when syllable boundaries are known for the computation of the stress score. This finding is supported by the small difference observed when the R parameter was optimized for each noise level, compared to the case when the value for R obtained on the clean data was used in the experiments. While improvements are obtained also when a syllable approximation is used instead of the actual syllables, they are significantly lower and depend more on the value of the R parameter, for different noise levels. This might suggest that the approximation used is not suitable for calculating the stress score and that a new approach should be sought. A possible alternative would be to hypothesize syllable boundaries based on the transcription obtained after the first pass of the recognizer. Unfortunately this approach would then limit the use of stress information to the second step only and it was shown in [10] that a big part of the improvement brought by stress information was due to its use in the first pass.

In this work we examined the role of stress information only in the case of coloured noise, but, in the future, we plan to extend the study to also include speech in the presence of competing talkers. Further lines of research to follow include the search for a better syllable approximation or the use of stress only in the rescoring step, as syllable information can be extracted from the word graph produced by the first pass. Also, we used a 19-frame representation in the present work, but a search for the optimum size of the region to be considered might give better results.

Prosodic Differences between Taiwanese L2 and North American L1 speakers—Under-differentiation of Lexical Stress

Chiu-yu Tseng & Chao-yu Su

Phonetics Lab, Institute of Linguistics, Academia Sinica, Taipei, Taiwan
cytling@sinica.edu.tw

Abstract

Assuming that categorical differentiation is major acoustic characteristics of English lexical stress through binary instead of more complex 3-way distinction, we investigated lexical stress in broad and narrow focus positions and found how binary distinction is achieved by the concomitancy of secondary stress defined by its position and distance in relation to primary stress. Similar results are found in broad (sentence initial) and narrow focus as well. These results suggest that binary categorical contrast is the optimal choice while differentiation is dependent on robust contrast patterns in the speech signal. Comparison between Taiwanese L2 and North American L1 speakers revealed how L2 speakers' realization of the binary opposition is of a lesser degree. The results explain why L2 speech is less differentiable and not as expressive.

Index Terms: English stress, primary, secondary, binary, contrast pattern, differentiation

1. Introduction

Earlier studies of L2 or foreign accents that concentrated mainly on segmental features [1, 2, 3], however, more recent shift to prosodic features has led to the discovery that prosodic deviations have as much an effect on the intelligibility and comprehensibility of L2 speech, and contribute significantly to perceived foreign accent as well. For example, Field [4] showed that shift of lexical stress has a strong effect on the intelligibility of native vs. non-native speech group. Mixdorff et al. [5] further showed how the speech rhythm in L2 Vietnamese (tone and syllable-timed) and Japanese (pitch accent and mora-timed) Australian English differed from L1 speakers; both Vietnamese and Japanese speakers produce longer and more equal syllable durations than Australian English speakers. However, we see instead the more even syllable duration of L2 speech not as a rate issue but as lack of the required long/short contrast for categorical stress differentiation. Our hypothesis is that patterns of robust contrast in the speech signal are directly correlated to linguistic categorical contrasts, while lack of or under-differentiation is a major feature of L2 speech.

In the case of English lexical stress, while it is necessary for L2 speakers to learn where the stressed syllable of a word is, it is as important for them also to learn how to maintain the contrast patterns between stressed/unstressed syllables. In other words, even when the correct syllable is stressed, insufficient contrast degree would still result in less differentiable perception and impair intelligibility. Based on the rationale of contrast robustness, we studied the contrast patterns of English lexical stress of all three acoustic correlates the F0, duration and amplitude between English stressed/unstressed syllables produced by L1 American vs. L2 Taiwan Mandarin (TM) speakers and found that in L1 English the most significant contrast is in F0 (pitch contrast), not duration (rhythmic contrast). And as expected, contrast by lesser degree is found in both F0 and amplitude in TM L2 English. TM L2 speakers were able to maintain similar rhythmic contrast as L1speakers do but still sounds flatter and foreign due to lack of pitch contrast [6]. Our results of TM L2 speakers differ considerably from Vietnamese and Japanese L2 speakers in [5], thus reduces possible generalization of how syllable-timed L1 may affect L2 English rhythm in general.

In a subsequent study of stress contrast, we further discovered that the 3-way primary/secondary/tertiary stress contrasts as English lexical stress is defined were not found in both L1 and L2 speech [7]. Instead, significant difference is only found in a 2-way contrast between stressed/unstressed syllables in both speaker groups, and again TM L2 speech exhibited less degree of contrasts. In addition, we found no significant contrast between secondary and tertiary stress across L1 and L2 speech and further discovered that 6 of the 20 tested words differ in where the secondary stress should be in three dictionaries consulted. Nevertheless, our results do suggest that 2-way contrast seem most optimal. This has lead us to further hypothesize that (1) in forming the optimal 2-way contrast the role of secondary stress is a concomitant one; its varied realization a surface phenomenon and should predictable. (2) The same rationale of maintaining the optimal 2-way contrast can also be applied to other prosodic categories such as broad sentential focus and narrow focus induced by context or syntactic structure. Prosodic contrasts of larger sized units are even coarser ones to facilitate long distance prediction, providing contextual and pragmatic information that distinguishes speech from text most significantly.

In the following study, we will analyze English secondary stress under the assumption that its concomitancy is dependent on two factors: (1) its linear order (before or after) the primary stress and its distance from it as well. Namely, if a secondary stress appears immediately BEFORE the primary one it is likely to be assimilated to the target primary stress. However, if it appears AFTER the primary stress then it is likely to be assimilated to the following tertiary stress and be reduced to a lower level in order to create the robust contrast patterns. (2) However, if there is more distance between the primary and secondary stress, such as BEFORE but intercepted by a tertiary stress, then the secondary stress stands more chance to be more differentiable from either the primary or the tertiary counterparts.

In the following analysis, we will compare English secondary stress in different positions in a word, in sentence/broad focus position and in narrow focus position in relation to categorical stress differentiation.

2. Method

2.1. Speech Materials

A subset of the AESOP-ILAS (Asian English Speech cOrpus Project—Institute of Linguistics Academia Sinica) corpus was

used for the present study. AESOP is a multinational collaboration whose aim is to build up English speech corpora across Asia that would represent the varieties of English spoken in that region while ILAS is part of the consortium that specifically collects L2 English of Mandarin L1 speakers in Taiwan. The materials used here are 20 frequently used words from 2-, 3- and 4-syllables categorized according to syllabicity and stress type: (1) 2-syllable initial stress 2, (2) 3-syllable initial stress, (3) 3-syllable medial stress, (4) 3-syllable final stress, (5) 4-syllable initial stress, (6)4-syllable medial 1 stress, (7) 4-syllable medial 2 stress, (8) 4-syllable final stress, (9) left-headed compounds (e.g orange juice), (10) right-headed compounds (e.g. afternoon). The chosen words are money, morning, white wine, hospital, apartment, department, tomorrow, video, overnight, January, supermarket, elevator, available, Japanese, afternoon, misunderstand, information, experience, California and Vietnamese. These words are then embedded in two conditions: (1) in a fixed sentence-medial broad-focus position two words removed from any phrase boundary, i.e., "I said OVERNIGHT five times." for the purpose of baseline comparison as well as broad focus. (2) As elicited narrow focus to create phrasal and sentential prominence in broad and narrow focus positions. For example, *Context: Will 3-day delivery be fast enough?* Reply: "No. We need OVERNIGHT delivery" where the provided context requires the answer to disambiguate. As illustrated, the same target word in the previous broad focus position would now re-appear as narrow focus. At the same time, the sentence-initial word "we" may receive sentential prominence, thus providing both narrow focus and sentential prominence in the same sentence.

Speech data were recorded by trained proctors in quiet rooms directly into a laptop computer, using a recording platform developed specifically for AESOP. Experimental sentences and context were preloaded and appeared individually on a computer screen. Participants wore head-mounted Sennheiser PC155 microphones positioned 2 cm away from their mouths; they were instructed to speak naturally at a normal rate and volume. The speech data of a total of 25 speakers were analyzed: 11 L1 North American English speakers (5 male and 6 female), 16 Taiwan L2 speakers (8 male and 8 female)

2.2. Data Analysis

Prosodic contrast is presented by F0, duration and intensity using Z-score normalization by each sentence first. In order to extract F0 due to lexical stress without intonation effect for subsequent analysis, a straight line with minimal distance (RMSE) to original F0 contour is derived to represent intonation and subtracted, the residual is regarded as F0 without intonation effect. In turn, duration extraction is also refined to remove the effect of inherent segmental duration and boundary lengthening using a multi-layered normalization method shown below[8], in which *factor1* represents information at the segmental level, *factor2* represents respective syllable position within the word (to remove word-final boundary lengthening effects), and ε_i represents all other unpredictable values. Extracted values μ_i thus represent duration values which have been normalized for inherent segmental duration and boundary effect:

$$x_i = \mu_i + factor_1 + factor_2 + ... + \varepsilon_i$$

3. Results and Discussion

3.1. Contrast patterns--primary vs. secondary stress

This study examines prosodic contrast of secondary stress by linear order (before or after) to the primary stress and its distance from primary stress to test (1) if a secondary stress is assimilated to the target primary stress when it immediately precedes the primary stress; if a secondary stress immediately follows the primary stress it is reduced to tertiary stress in order to create more robust contrast patterns. (2) If there is more distance between the primary and secondary stress due to intermediate tertiary stress, then the secondary stress is more differentiable from either the primary or the tertiary counterparts. Furthermore, this study tests if these characteristics could help distinguish L1 and L2 English.

3.1.1. F0 without intonation effect—pitch contrast

Figure2 shows F0 of secondary stress without intonation effect by L1/L2, linear order (preceding or following) regarding the primary stress and its distance from the primary stress. When the primary stress precedes the secondary stress, no significant difference between L1 and L2 English is found. However, the most distinct difference between L1 and L2 English is found when the secondary stress is immediately BEFORE the primary stress (1-syllable distance). The F0 of primary stress in L1 English is higher than secondary stress while L2 English lacks the same contrast pattern and highly varied. When secondary stress appears BEFORE primary stress (2-syllable distance), both L1 and L2 English show how secondary stress "stands out" and becomes more differentiable from the primary stress.

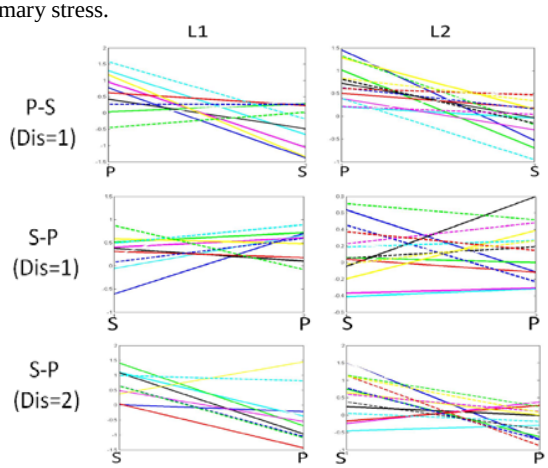

Figure 2: *F0 of secondary stress without intonation effect by L1/L2, linear order (before or after) the primary stress and its distance from primary stress. Each color line denotes F0 patterns of one speaker.*

The above results suggest that the F0 realization of secondary stress without intonation effect is context-dependent, concomitant but predictable. When secondary stress precedes the primary one, the F0 distinction does not always exist; the two categories are often under-differentiated. However, in reversed positions when secondary stress follows the primary one, it is lowered significantly, thus creating a sharper pitch contrast as shown in upper left panel. It is therefore no surprise why secondary stress is annotated differently in

different dictionaries. It is therefore also true that it is more difficult for L2 speakers to master.

3.1.2. Duration without segmental duration—rhythm contrast

Figure3 shows normalized duration of secondary stress by L1/L2, linear order (before or after) the primary stress and its distance from primary stress. The most distinct difference between L1 and L2 English is found when secondary stress appears immediately BEFORE primary stresses. By this context, the primary stress is distinctly longer than secondary stress while L2 English is again highly varied. For L1 English, primary stress is always longer than secondary stress thus the positions of primary stresses could be indicated by systematic rhythm/beat variation while L2 English exhibited no similar rhythm patterns.

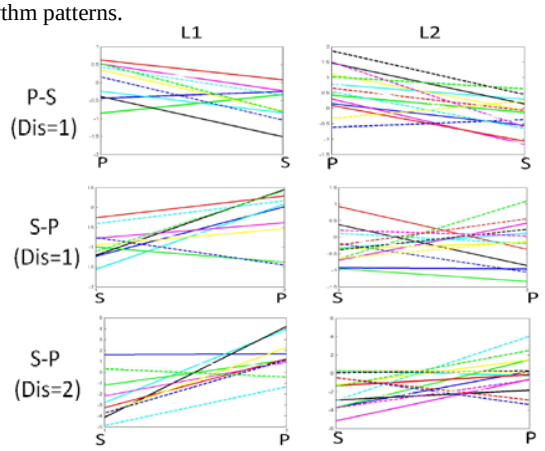

Figure 3: *Normalized Duration of secondary stress by L1/L2 and primary/secondary stress context which is represented by order and distance between primary and secondary stress. Each color line denotes F0 patterns of one speaker.*

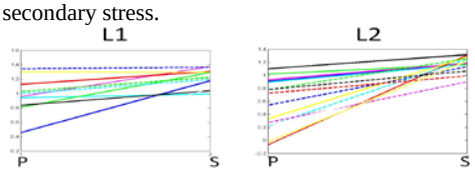
The above results suggest the most robust feature to distinguish L1 and L2 English is normalized duration. For L1 English, primary stressed syllables are always longer than secondary stresses, creating systematic rhythmic patterns that imply distinctly the position of primary stresses in a word. However, L2 English lacks the same rhythmic contrast even some duration difference is exhibited. In other words, no categorical rhythm differentiation can be found in L2 English.

3.1.3. Intensity—loudness contrast

Figure4 shows intensity of secondary stress by L1/L2, linear order (before or after) to the primary stress and its distance from primary stress. For both L1 and L2 English, no significant difference is found between primary stress and secondary stress.



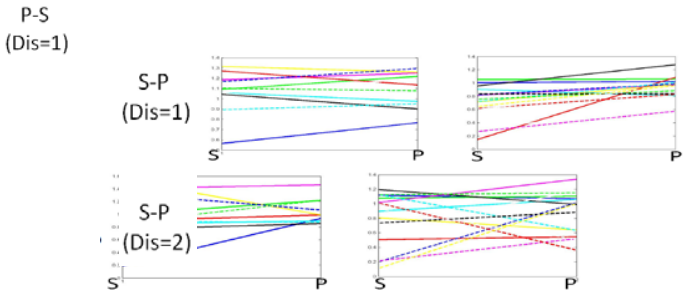


Figure 4: *Normalized Duration of secondary stress by L1/L2, linear order (before or after) the primary stress and its distance from primary stress. Each color line denotes F0 patterns of one speaker.*

3.2. Contrast patterns--narrow focus vs. sentential prominence

This study examines prosodic contrast of broad focus (sentential prominence) by linear order (before or after) to the narrow focus and its distance from narrow focus to test if (1) a sentence-initial broad focus is assimilated to the narrow focus when it is immediately BEFORE the narrow focus; or if the broad focus is reduced to a lower level in order to create more robust contrast patterns when it is AFTER the narrow focus. (2) However, if the same rationale can be applied to distance as well. Furthermore, this study tests if these characteristics could also help distinguish L1 and L2 English.

3.2.1. F0 without intonation effect—pitch contrast

Figure5 shows F0 of broad focus without intonation effect by L1/L2, linear order (before or after) to the narrow focus and its distance from narrow focus. When narrow focus precedes prominent word, the narrow focus is higher than broad focus for both L1 and L2 English. When broad focus precedes narrow focus, the contrast between narrow focus/broad focus is not clear for both L1 and L2 except for distance=8. It denotes broad focus “stand out” and is more differentiable from narrow focus when there is more distance between them. In addition, the contrast degree of L1 English is slightly higher than L2 English.

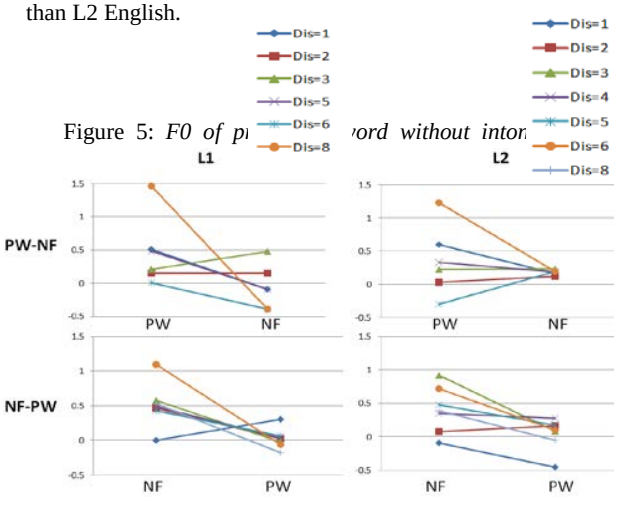

Figure 5: *F0 of pi ord without intor effect by L1/L2, linear order (before or after) the narrow focus and its distance from narrow focus PW, NF and Dis represent narrow focus, prominent word and distance by words.*

The above results show how the contrast patterns of broad/narrow focus distinction is similar to patterns found between primary and secondary stress, as shown in 3.1. Broad focus is dependent on position and distance from narrow focus. The concomitant and more subtle differentiation again proves to be difficult for L2 speakers. L2 speech sounds flatter in melody.

3.2.2. Duration—Tempo contrast

Figure6 shows duration patterns of broad focus by L1/L2, linear order (before or after) to the narrow focus and its distance from narrow focus. For narrow focus before or after broad focus, L1 English shows significant difference with L2 English, namely, a distinct contrast between narrow focus and broad focus. Narrow focus is always slower than broad focus thus the position of narrow focus could be indicated by systematic change of tempo. For L2 English, the tempo pattern between broad and narrow focus is more monotonous and exhibits no systematic tempo variations as found in L1.

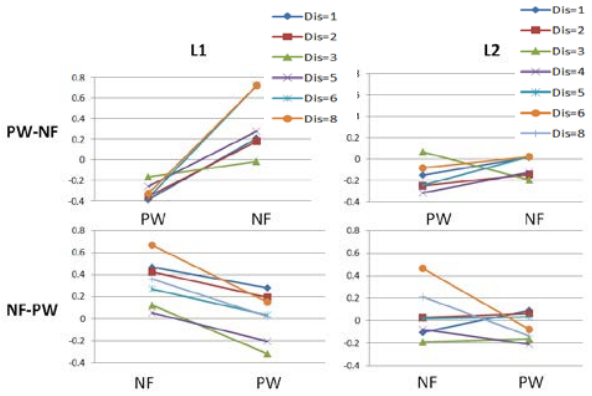

Figure 6: *Tempo of prominent word by L1/L2, linear order (before or after) the narrow focus and its distance from narrow focus. PW, NF and Dis represent narrow focus, prominent word and distance by words.*

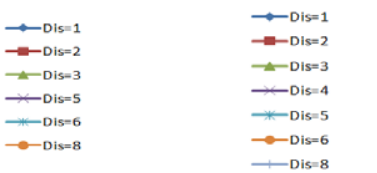
The results above showed that the most significant difference of broad and narrow focus between L1 and L2 English is tempo patterns. While L1 speakers maintain distinct differentiating patterns as shown in left panels in Figure 6, L2 speakers could not realize the same tempo contrast patterns. As a result, L2 speech sounds more monotonous.

3.2.3. Intensity

Figure7 shows intensity patterns of broad focus by L1/L2, linear order (before or after) to the narrow focus and its distance from narrow focus. Difference between L1 and L2 English is found when narrow focus precedes broad focus. By this context, a lager degree of contrast in L1 English is found than L2 English.



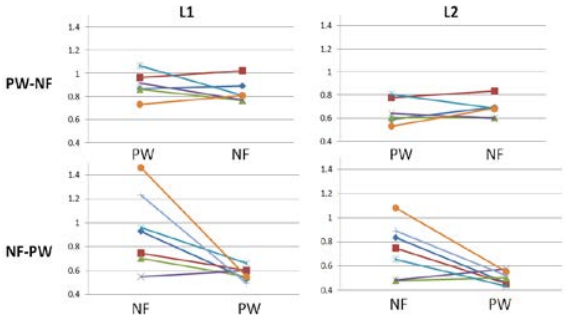


Figure 7: *Intensity of prominent word by L1/L2, linear order (before or after) the narrow focus and its distance from narrow focus. PW, NF and Dis represent narrow focus, prominent word and distance by words.*

The results above showed that the strong/weak contrast of broad/narrow focus is only differentiable for L1 when distance factor is bigger. L2 speech is less differentiable as expected.

4. General Discussion and Conclusion

Following our previous studies that showed the major acoustic characteristics of English lexical stress is F0 (pitch) contrast [6, 7], we further found in the present study that the major acoustic characteristic of primary vs. secondary stress is duration (rhythm) contrast, as shown in L1 speech. Though the same rationale is also found in the differentiation of broad vs. narrow focus, the patterns are additional contrast patterns on top of word level distinctions. The added results collectively suggest that binary contrast is the optimal choice of differentiating patterns, thus providing evidence of binary opposition, a crucial phonological concept, in the physical sense. Furthermore, these relative opposition patterns appeared to be quite difficult for L2 speakers to produce, suggesting on how perceptual sensitivity of such relative contrast patterns may be language dependent, and why L2 speech is less differentiable in production and flatter sounding in perception. Hence, under-differentiation of the necessary contrasts is a major feature of Taiwanese L2 English. We believe category related differentiation that require robust but sometime concomitant contrasts have not been properly addressed in language teaching in general and could be implemented to CALL technologies.

Crowdsourcing regional variation in speaking rate through the iOS app 'Dialäkt Äpp'

Adrian Leemann[1], Marie-José Kolly[1], Volker Dellwo[1]

[1]Phonetics Laboratory, Department of General Linguistics, University of Zurich
{adrian.leemann, marie-jose.kolly}@pholab.uzh.ch, volker.dellwo@uzh.ch

Abstract

It is a common stereotype in Switzerland that speakers from Bern speak slowly and speakers from Zurich speak quickly. Are these differences in perception at all mirrored in production? We present a new method of crowdsourcing speaking rate through a free of charge iOS application. Astonishingly, results indicate that the temporal structure of a few words alone – as spoken by a few hundred speakers – are sufficient to tell apart the two dialects in speaking rate. In line with previous literature, females articulate more slowly than males. Further potential fields of application of the introduced method are discussed.

Index Terms: Speaking rate, crowdsourcing, dialectology, Swiss German, iOS application

1. Introduction

Swiss German dialects are spoken by roughly 4.5 million people [1] and enjoy high prestige in Swiss society [2, 3, 4]. Speakers of Swiss German (SwG) are well aware of regional variation and many dialects are stereotyped: Zurich Swiss German (ZH SwG), for example, is perceived as fast. Bern Swiss German (BE SwG), which enjoys the status of being Switzerland's most popular regional variety [5], is perceived as very slow [6, 7, 8]. Whether these differences in perception are reflected in production has been examined in passing by [9, 10]. Based on a corpus of spontaneous speech for ten speakers per dialect, [9, 10] reported that ZH SwG speakers articulate nearly one syllable more per second than BE SwG speakers (5.8 syll./sec. vs. 5.0 syll./sec – excluding pauses), thereby corroborating the previously mentioned stereotypes. Possible reasons for these differences in speaking rate were given in [10], who showed that BE SwG speakers produced distinctly longer mean durations of vowels and, in particular, exhibited more distinct phrase-final lengthening.

The studies mentioned present one major weakness: while clearly highlighting trends in regional variation in speaking rate, these tendencies have yet to be validated on a large set of speakers and on controlled material. We aim to alleviate this issue: based on crowdsourced data from an iOS application, we provide a more precise estimate of regional variation in speaking rate on the basis of nearly 250 speakers who articulated a controlled set of words. The term 'crowdsourcing' refers to "the practice of obtaining needed services, ideas, or content by soliciting contributions from a large group of people and especially from the online community rather than from traditional employees or suppliers" [11].

The use of crowdsourcing applications for studying linguistic phenomena has, until recently, received relatively little attention. This is somewhat surprising given that iPhone microphones, for example, feature wide frequency ranges of 50Hz-20kHz that enable high-quality audio recordings [12]. Previous research showed that a first generation iPhone from 2007 provides very useful for speech analysis and allows for reliable acoustic measurements – particularly for F1 and F2 [13]. Currently, a number of smartphone applications are in use or in development for crowdsourcing linguistic data. [14, 15] developed Android applications as a means to collect speech for the training of acoustic models. [16, 17] are applications currently in development for the purpose of documenting endangered languages, putting language documentation in the hands of the speakers. The mentioned apps are primarily used for acoustic modeling, dictionary building, text collection, translation, as well as dialect mapping. We present a novel method for crowdsourcing data to conduct research on prosodic features of dialects.

2. Data and methods

2.1. iOS application: 'Dialäkt Äpp'

'Dialäkt Äpp' [18] capitalizes on the Swiss' public interest in dialectology. It provides functionality that allows users (1) to localize their own Swiss German dialect by indicating – i.e. listening to pre-canned recordings and then tapping on the screen – their dialectal pronunciation of 16 tokens, i.e. words, and (2) to articulate and anonymously record these 16 tokens in their dialect. Data used in the current study stem from this second function.

The user interface (UI) prompts the users to indicate their dialect (possible localities are those used in [19]), age, and gender (Figure 1, left panel) before they proceed to the recording instructions screen (Figure 1, right panel), see Figure 1.

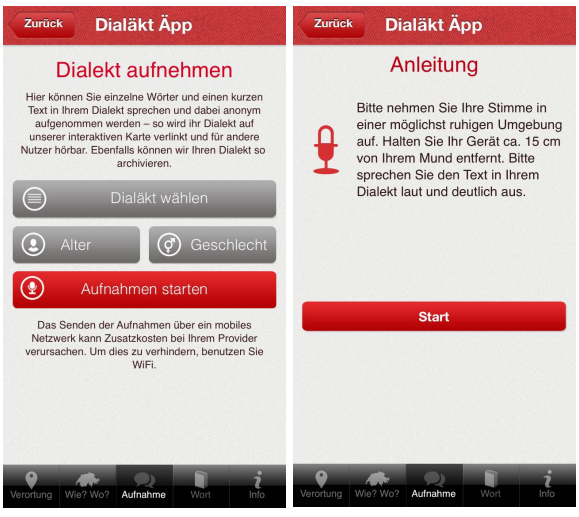

Figure 1: *UI for dialect, age, and gender selection (left panel) and recording instructions (right panel).*

The right panel in Figure 1 reads: "Please record your voice in as quiet an environment as possible. Keep an approximate distance of about 15 cm between your device and your lips. Please articulate the text loudly and clearly in your own dialectal pronunciation". Next, the user articulates and records the token shown on the screen (see Figure 2, left panel). The 16 tokens in this recording function are the same as those used for the localization function. Once the recordings are finished they are anonymously uploaded on our servers where each audio file is given a unique ID. Following the upload, users can navigate to an interactive map of Switzerland where they can listen to their own recordings and those of other users (Figure 2, right panel, green and purple pins).

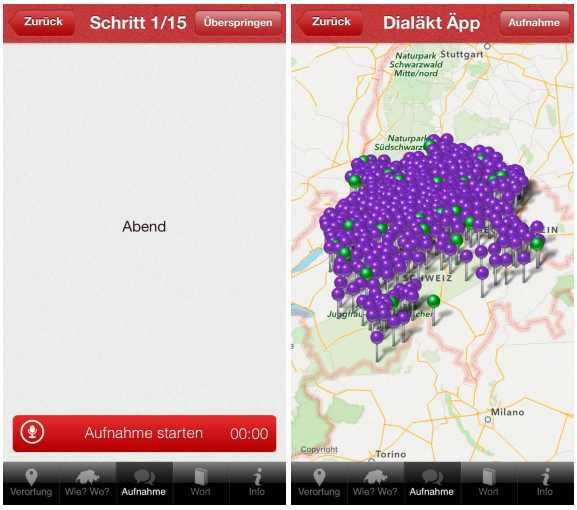

Figure 2: *UI for token recording (left panel) and audio playback map of one's own and other users' recordings (right panel).*

In Switzerland, 'Dialäkt Äpp' was the number one downloaded free app for iPhones after its release on March 22, 2013 [20]. It received major media attention and, so far, has >58,000 downloads. More than 2300 users from all over German-speaking Switzerland have uploaded voice recordings.

2.2. Subjects

Users who declared BE SwG (i.e. Bern city) and ZH SwG (i.e. Zurich city) as their local dialect served as subjects. In total there were 115 unique BE SwG speakers and 205 unique ZH SwG speakers. Not all speakers read all of the presented words, which is why the number of observations varies from token to token (cf. 2.3). On average speakers were 32-years-old, ranging between 4 years of age and 75 years of age, with 60% males and 40% females.

2.3. Material

We selected six out of a total of 16 'Dialäkt Äpp' tokens (cf. 2.1) for analysis of speaking rate. Selection criteria were that each token consisted of two syllables, given that we measured the temporal distance between adjacent vowel onsets (cf. 2.4). Half of our selected words further featured phonologically Middle High German long vowels or diphthongs while the other half featured underlying short vowels. The selected words with underlying long vowels were *Abend* 'evening', *Augen* 'eyes', and *fragen* 'to ask'; those with underlying short vowels *Donnerstag* 'Thursday', *heben* 'to lift', and *trinken* 'to drink'. Typically, these words are articulated as follows:

Long vowels/diphthongs:
Abend: BE SwG: [ˈɑːb̥ə], ZH SwG: [ˈɒːb̥ig̥]
Augen: BE SwG: [ˈɔug̥ə], ZH SwG: [ˈæug̥ə]
fragen: BE SwG: [ˈfrɑːg̥ə], ZH SwG: [ˈfrœːg̥ə]

Short vowels:
Donnerstag: BE SwG: [ˈd̥ɔnʃt̥i], ZH SwG: [ˈd̥unʃt̥ig]
heben: BE SwG: [ˈlʏp͡fə], ZH SwG: [ˈlup͡fə]
trinken: BE SwG: [ˈtrɪŋk͡xə], ZH SwG: [ˈtriŋk͡xə]

Table 1 presents the total number of observations, i.e. speakers, with figures on gender.

	ZH SwG	BE SwG
Abend 'evening'	n=188 (114m, 74f)	n=100 (58m, 42f)
fragen 'to ask'	n=193 (118m, 75f)	n=103 (64m, 39f)
Augen 'eyes'	n=186 (113m, 73f)	n=96 (60m, 36f)
Donnerstag 'Thursday'	n=186 (114m, 72f)	n=100 (63m, 37f)
heben 'to lift'	n=194 (118m, 76f)	n=104 (64m, 40f)
trinken 'to drink'	n=199 (120m, 79f)	n=105 (66m, 39f)

Table 1: *Summary of the number of total observations, i.e. speakers.*

The majority of recordings were usable, i.e. demonstrated little background noise interference nor were the speakers goofing off. Instances of unfavorable audio quality or otherwise unusable material were disregarded from the analyses (percentage of discarded tokens: approximately 20%).

2.4. Procedure

There are various approaches to measuring speaking rate. Most commonly one measures a linguistic unit per second (words, syllables, segments, consonantal intervals, vocalic intervals; cf. [21]). Since our corpus contains words that exhibit cross-dialectal differences in syllable structure (e.g. *Abend*: BE SwG V.CV [ˈɑːb̥ə] vs. ZH SwG V.CVC [ˈɒːb̥ig̥] or *Donnerstag*: BE SwG CVC.CCV [ˈd̥ɔnʃt̥i], vs. ZH SwG CVC.CCVC [ˈd̥unʃt̥ig]), we refrained from applying conventional speaking rate measures such as number of syllables per second, and instead measured the temporal duration between the two vowel onsets. In theory, this is motivated by [22]'s findings that vowel onsets represent perceptually prominent centers of a syllable. We call this measure of vowel-onset-to-vowel-onset duration *durVonVon*. Figure 3 schematically shows the measurement technique applied in the present study

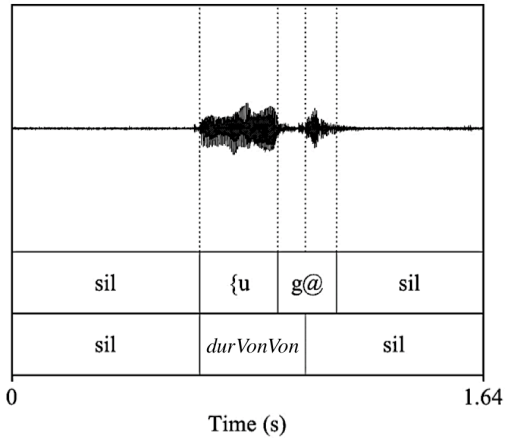

Figure 3: *Schematic of vowel-onset-to-vowel-onset measurement (2nd tier).*

Figure 3 shows the oscillogram of a ZH SwG speaker articulating the token *Augen* as [ˈæugə] (cf. 1st tier). The 2nd tier shows the boundaries placed at the vowel onsets. 'sil' indicates silence. Altogether there were 2920 measurement points (1460 intervals). Temporal duration between these two vowel onsets was measured in Praat [23].

3. Results

3.1. Statistical analyses

All data were analyzed using R [24] and the R packages *lme4* [25] and *languageR* [26, 27]. If not indicated otherwise, we analyzed data using linear mixed effect models (LMEs). Normality was checked by visual inspection of quantile plots. *Dialect*, *gender*, and *vowel type* were treated as fixed effects, *token* and *age* as random effects. Effects were tested by model comparison between a full model, in which the factor in question is entered as either a fixed or a random effect, and a reduced model without this effect. p-Values were obtained by comparing the results from the two models using ANOVAs. For the assessment of the relative goodness of fit, we report *AIC* (Akaike Information Criterion) values that decrease with goodness of fit. Only p-values that are considered significant at the α= 0.05 level are reported.

3.2. Overall regional differences

Figure 4 shows the boxplots representing the two dialects' *durVonVon* data.

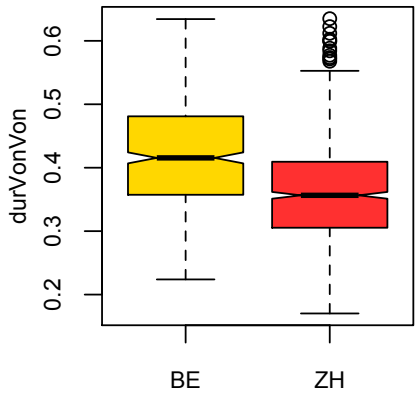

Figure 4: *Boxplots of the dialects' durVonVon.*

The yellow boxplot indicates the values for BE SwG, the red boxplot those of ZH SwG. Visually, the two boxes' notches do not overlap, which can be taken as strong evidence that their medians differ. The comparison between the full and reduced models showed a significant difference for dialect, with the full model exhibiting an increased goodness of fit (BE SwG M=.42, SD=.08; ZH SwG M=.36, SD=.08; p<.0001; *AIC*=-3806). There was thus a significant difference in *durVonVon* between the two dialects. BE SwG speakers showed longer *durVonVon* intervals than ZH SwG speakers.

3.3. Cross-gender differences by dialect

Figure 5 shows the distribution of *durVonVon* across *dialect* and *gender*.

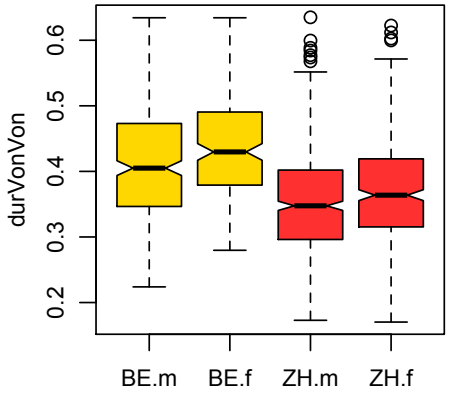

Figure 5: *Boxplots of durVonVon across dialect and gender.*

The differences between the genders were significant in both dialects (Bonferroni adjusted for *gender*, α=0.025; both p<.0001; BE SwG: *AIC*=-1244, ZH SwG: *AIC*=-2598). The boxplots in Figure 5 indicate that for both BE SwG and ZH SwG, females demonstrated significantly longer vowel-onset-to-vowel-onset durations. There was no significant interaction of *dialect*gender* (p=.20; *AIC*=-3799).

4. Discussion

Based on a controlled set of words spoken by a large number of speakers, the current study found that BE and ZH SwG strongly differ in terms of speaking rate. For the sake of

illustration, let us extrapolate these results to a more realistic scenario. Say a BE SwG and a ZH SwG speaker read Aesop's fable "The North Wind and the Sun". In Zurich German, the fable consists of 129 syllables, i.e. approximately 128 vowel-onset-to-vowel-onset intervals (cf. [28]). Based on raw findings of the current study – disregarding contextual factors such as phrase-final lengthening – the BE SwG speaker would need 54 seconds to read the text while the ZH SwG speaker would only take 46 seconds.

This finding is intriguing in a number of ways. [10] notes that BE SwG speakers speak more slowly particularly because they exhibit more distinct phrase-final lengthening. Results of the current study show, however, that the two dialects strongly vary from one another in speaking rate irrespective of such contextual factors. Our findings are unique in just this sense: the temporal information contained in a few words alone is already sufficient to tell apart the two dialects (cf. Figure 4) – regardless of contextual factors such as phrase-final lengthening. In future studies it would be interesting to test whether vowel length differences are the major influential factor. Moreover, it will be interesting to examine if we find these between-dialect differences in each of the 6 tokens individually.

Concerning gender differences in speaking rate. The result that female speakers articulate more slowly than males is in line with previous studies on cross-gender differences in speaking rate on British English dialects [29] and on American English dialects [30, 31]. It is further in line with [32] who shows that in German, durations of female vowels are systematically longer than durations of male vowels.

Several questions remain unanswered at present. Is it conceivable that listeners can tell apart the two dialects based solely on time domain information in perception experiments? To answer this question one would require tokens that are identical in segmental, syllabic, and prosodic structure, which (deliberately) does not apply to the tokens used in 'Dialäkt Äpp'. One could, however, use 'Dialäkt Äpp' tokens that are identical in syllabic structure and delexicalize them (e.g. *sasasa*-delexicalization, where every consonantal interval is replaced with a pre-recorded [s] and every vocalic interval with a pre-recorded [a] (cf. [33]).

Speaking rate represents only one of countless areas of application in speech prosody where crowdsourcing is useful. In the present region-wide 'Dialäkt Äpp' corpus, more than 2300 speakers have uploaded voice recordings, and in most cases speakers recorded all 16 words. This amounts to approximately 36,000 voice recordings. In future studies we will further examine fundamental frequency distributions, temporal, stress and intonational patterns, and generate vowel plots. These phenomena can be explored in multiple dimensions, enabling us to test for effects of speaker, age, gender, locality or region. Crowdsourcing applications for American English, German regional varieties, and British English are currently being developed, inspired by the 'Dialäkt Äpp' framework. The acoustic data crowdsourced through the 'Dialäkt Äpp' is further used to train an automatic speech recognition system. This system will be part of a follow-up smartphone application [34] that will perform dialect localization based on spoken language input.

5. Conclusion

Based on crowdsourced utterances from a large number of speakers, results of the current study corroborate previous impressionistic and empirical observations that ZH SwG is fast and BE SwG slowly spoken [6, 7, 8, 9, 10]. Results of the current study revealed that regional differences in speaking rate are prevalent on the basis of a few words alone. We further showed that female speakers articulate more slowly than male speakers, which is in line with other research findings.

6. Acknowledgments

We thank Daniel Wanitsch for server-side technical assistance and audio data extraction and Ingrid Hove for database maintenance. We are indebted to 65 backers who made 'Dialäkt Äpp' possible through crowdfunding. Thank you!

Abstract

This study explores the temporal coordination between gesture and speech by addressing two main questions: (1) Are speakers sensitive to the misalignment between gesture prominence and prosodic prominence? (2) Is this sensitivity modulated by the semantic information conveyed by gesture and speech modalities in production? Experiment 1 tested question (1) and Experiment 2 tested question (2). Results from Experiment 1 revealed that the combinations in which prominences were misaligned were less acceptable than combinations with aligned prominences, and that the metrical pattern of the target word had an effect on the speakers' sensitivity: unsynchronized trochees (with the gesture prominence at the post-tonic syllable) were frequently accepted, while unsynchronized iambs (with the gesture prominence at the pre-tonic syllable) were rejected. Results from Experiment 2 revealed that when the pointing gesture adds information to speech, i.e. it is supplementary to speech, the prominences are frequently misaligned (with gesture occurring after the speech), as if two different speech acts were produced. These findings suggest that the semantic content of gesture-speech combinations might influence the speakers' sensitivity of the misalignment between prosodic and gesture prominences.

Index Terms: gesture-speech synchronization, audiovisual prosody, multimodal prominence

1. Introduction

There is ample evidence in the literature that humans coordinate gesture movements with speech, suggesting that both modalities are in fact part of an integrated system [1-3]. This coordination is evidenced from both semantic and temporal points of view. What speakers express with their hands is semantically related with what they express with their speech (what could be called 'semantic coordination'). Also, gesture and speech timings are coordinated, since the most prominent part of the gesture co-occurs with the most prominent part of speech ('temporal coordination') [3].

1.1. Temporal and semantic coordination

Studies investigating the temporal coordination of gesture and speech have found convincing evidence that gesture and speech co-occur in time in the sense that the point of maximal expression of a gesture (hereafter 'gesture prominence') coincides with the moment of maximal prosodic prominence in speech [4]. In order to define gestural prominence, most studies use either the stroke of the gesture (the interval involving the greatest physical effort in the gesture) or the apex of the gesture (the point in time in which the gesture reaches its maximal extension). As for the prominent feature of speech, a growing body of research has found that the speech landmark with which the gesture prominence aligns is the lexical stress [5, 6] and even the pitch peak within the stressed syllable when it is uttered in a contrastive focus situation [7, 8].

However, it has also been proposed that the temporal synchronization between gesture and speech may depend on their semantic coordination: when the meanings expressed by the co-speech gesture and by the accompanying lexical affiliate are complementary, the onset of the gesture stroke is closely aligned with its lexical affiliate; but when the two modalities express supplementary semantic features, stroke onset and lexical affiliate are not so closely aligned [9]. But more evidence is needed to corroborate this hypothesis.

1.2. Perception of temporal asynchrony

But how important is this tight temporal coordination? As interlocutors, do we expect the gesture apex to co-occur with the lexical stress? Do we perceive misalignments in their temporal coordination?

Most of the studies examining the perception of audio-visual asynchrony have focused on the human ability to perceive unsynchronized audiovisual events in articulatory gestures of a person producing syllables or a list of words. They found that adults can detect an audiovisual asynchrony of around 200 ms when the visual attributes of an audiovisual event precede the auditory attributes, and around 100 ms when the auditory attributes precede the visual attributes [10]. However, the articulatory synchronization patterns tested in these experiments did not answer the question of whether the temporal coordination of prominences found for co-speech gestures is relevant in perception.

Few studies have examined the effects of the gesture-prosodic misalignment in the perception of the lexical stress [11-13]. Results seem contradictory, some finding a clear influence [12, 13] and some not [11]. From these, only in [11] the authors analyzed pointing gestures and they did not find a clear influence and the authors suggest that their results might be influenced by some methodological problems with the procedure. Thus, the influence of the timing of the gesture prominence with respect to the speech prominence needs to be further analyzed.

1.3. Aim of the study

The aim of the present study was two-fold: first, to investigate speakers' ability to perceive a temporal asynchrony between gesture and speech prominences (Experiment 1); second, to investigate whether this perceptual ability is related to how

speakers align gesture and speech when the semantic information expressed by gesture supplements what is expressed in speech (Experiment 2).

2. Experiment 1

2.1. Methods

2.1.1. Participants

Twenty-two adult Catalan-speakers took part in an online acceptability judgment task. They were unaware of the purpose of the study and participated voluntarily.

2.1.2. Materials

An online survey was prepared using the SurveyGizmo application. Participants watched a series of video clips each showing a woman producing a disyllabic word accompanied by a deictic pointing gesture. The woman appeared sideways in the right part of the screen and pointed to the left part of the screen. In order to prevent participants from looking at her lip movements, the woman covered her mouth with the hand not used for pointing (see Figure 1, left panel).

Sixteen disyllabic words were used, half of them iambs (with stress on the second syllable) and the other half trochees (with stress on the first syllable). They were all common words, such as "miRALL" ('mirror'), "ioGURT" ('yogurt'), "AIgua" ('water'), or "COtxe" ('car').[1] Words were pronounced in an exaggerated manner so that syllable duration values were longer and pitch range values were higher than in spontaneous speech (see Figure 1, right panel).

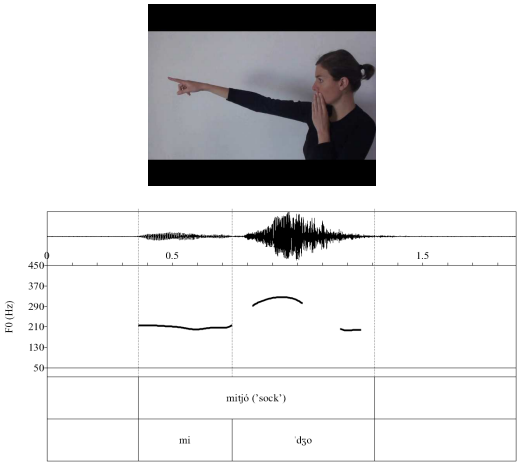

Figure 1: *Top panel, visual stimulus presented in the survey: a video clip showing a woman pointing while saying a word (frame showing the apex of the gesture). Bottom panel, waveform and pitch contour of the word produced while pointing, with the F0 peak coinciding with the gesture apex.*

Of the total number of video clips that participants observed (N = 32), half were synchronized (gesture apex coinciding with lexical stress) and half were unsynchronized (gesture apex not coinciding with lexical stress). Using Adobe Premiere Pro, all clips were constructed with the same pointing gesture and then the various audio inputs were juxtaposed on it, either synchronized or not. To create the synchronized stimuli, we combined the audio track of the different target words with the video track of the pointing movement so that the apex of the gesture movement coincided with the pitch peak of the target word (see the frame in Figure 1). To create the unsynchronized stimuli, we combined the audio track of each target word with the video track of the pointing movement in such a fashion that the apex of the gesture movement occurred in the middle of the unaccented syllable. Synchronized and unsynchronized stimuli were randomly mixed during the survey.

2.1.3. Procedure

Participants were asked to rate the acceptability of the video clips containing either synchronized or unsynchronized gesture-speech combinations on a 5-point Likert scale (1 = totally unnatural; 2 = quite unnatural; 3 = slightly unnatural; 4 = quite natural; 5 = totally natural).

Before the survey, participants were asked to imagine that the person in the videos was pointing at an object while naming it because she wanted to show them where the object was. Also, they were told that they had to base their acceptability judgments on the degree of coordination between gesture and speech that they perceived. The duration of the experiment was approximately 6 minutes.

2.2. Results

The total number of ratings obtained were 736 (23 participants x 32 clips), but 20 clips were found to have been left unrated by one or the other participant, so the total number of ratings analyzed was 716 (179 ratings for each of the four stimulus types, i.e. synchronized trochee, synchronized iamb, unsynchronized trochee, and unsynchronized iamb). An ANOVA analysis was carried out with acceptability rate as the dependent variable and stimulus type as the independent variable (four levels: synchronized trochee, synchronized iamb, unsynchronized trochee, unsynchronized iamb). The statistical analysis revealed that stimulus type significantly affected the acceptability rate ($F(3,715)=73.778$) = $p< .001$). Bonferroni post-hoc comparisons showed that, as expected, ratings for synchronized and unsynchronized trochees were significantly different ($p < .01$), and ratings for synchronized and unsynchronized iambs were also significantly different ($p < .001$), while synchronized trochees and synchronized iambs were rated similarly ($p> .05$). Surprisingly, ratings for unsynchronized trochees were also significantly different from ratings for unsynchronized iambs ($p< .001$). As Figure 2 shows, the mean acceptability rating for synchronized stimuli was very close to '4 = quite natural' (M = 3.79, *SD* = 0.983 for trochees; M = 3.89, *SD* = 0.963 for iambs). Unsynchronized iambs were rated very close to '2 = quite unnatural' (M = 2.36, *SD* = 1.331). However, participants judged unsynchronized trochees between '3 = slightly unnatural' and '4 = quite natural' (M = 3.39, *SD* = 1.050), thus more acceptable than unsynchronized iambs.

The results from Experiment 1 indicate that speakers detect the asynchrony between gesture and speech prominence, but it is more acceptable to them when the gesture apex occurs during an unaccented syllable in word-final (and also phrase-final in our stimuli) position (trochees) than during an unaccented syllable in word-initial position (iambs). Experiment 2 aimed at investigating the reason why misaligned trochees are more accepted than misaligned iambs.

[1]Capital letters indicate the accented syllable.

We hypothesized that when the pointing gesture conveys supplementary information to speech, speakers may misalign both modalities such that the gesture prominence can occur in post-tonic position but not in a pre-tonic one.

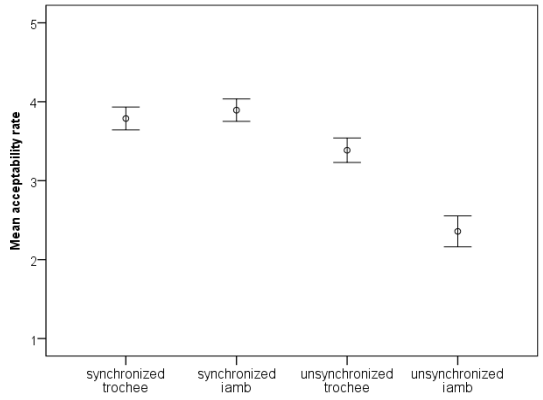

Figure 2: *Error bars of the mean acceptability rating as a function of stimulus type in Experiment 1.*

3. Experiment 2

In the second experiment we explored whether when the gesture is supplementary to speech speakers produce misaligned trochees (with gesture apexes in post-tonic position, i.e., phrase-final positions) but not misaligned iambs (with the apex in pre-tonic position).

3.1. Methods

3.1.1. Participants

Six Catalan-speakers participated in a pointing task. They were unaware of the purpose of the study and participated voluntarily.

3.1.2. Materials

In this pointing task, participants were asked to teach the experimenter the name of eight strange objects that were lined up in a row on a table (see Figure 3). The names of these objects were disyllabic nonsense words, half trochees (CVcv) and the other half iambs (cvCV), but all consisting of combinations of the same vowels and consonants, e.g. 'DUbi', 'duBÍ', 'BIdu' 'biDÚ'. Nonsense words were used to give meaning to the act of teaching and they were similar to make the game more challenging for the participants. Crucially, the participants had to name the object in the context of the sentence "*Agafa el* [target name]" ('Pick up the [target name]') and they were instructed not to produce any other kind of speech. Since the experimenter did not know which name referred to which object, participants were offered the possibility of using gestural strategies to indicate which object they were referring to.

3.1.3. Procedure

During the task, participants were recorded using a Panasonic HD AVCCAM recording at 25 frames per second. The sound was recorded through a small microphone that was placed somewhere on their clothing and as close as possible to their mouth.

Figure 3: *Setting of Experiment 2.*

At the beginning of the experiment, participants were given a legend in which the objects were labeled with their names. Participants were instructed to keep it hidden on their lap during the experiment and were then told that they were going to play a game in which they had to teach the experimenter the name of each object. In this teaching phase, the participant indicated the name of an object and its location to the interlocutor, then the interlocutor picked up that object, held it for a couple of seconds, and then put it back on the table. The participant then moved on to the next object. The task continued until the participant thought that the interlocutor would now be able to remember all the objects' names and locations. At that point the task ended and the interlocutor attempted to name all the objects.

3.1.4. Coding

All gesture-speech combinations that appeared in the video recordings were annotated using ELAN software in terms of the temporal features of both speech and pointing gestures. For speech, we annotated the temporal limits of the target name within the sentence, the metrical pattern of the name (either trochaic or iambic), and the temporal limits of the accented syllable within it. For pointing gestures, we annotated the preparation, stroke, and retraction phases of the gesture, and the location of the gesture apex [3].

3.2. Results and discussion

To examine whether participants produced unsynchronized trochees but not unsynchronized iambs, we calculated the location of the apex with respect to the end of the accented syllable as a function of the two metrical patterns. In total, 147 instances of items were analyzed, 73 with trochaic words and 74 with iambic words. Figure 4 and 5 illustrate the position of all the gesture apexes with respect to the accented syllable in trochaic and iambic words, separated by participant. In both figures, the solid horizontal line indicates the end of the accented syllable and the dotted line indicates the beginning of the accented syllable. Thus, circles occurring below the dotted line are cases in which the gesture apex occurs in the pre-tonic position and circles occurring above the solid horizontal line are cases in which the gesture apex occurs in the post-tonic (phrase-final) position.

Despite the high variability within and across participants, some patterns can be observed: (1) apexes occurring during the pre-tonic material are extremely scarce (3 cases in trochees and 4 cases in iambs, i.e. 4% and 5.4% respectively), and crucially all of them contain a pause between the pointing gesture and the upcoming speech; (2) in around one third of all instances, gesture apexes occur within the accented syllable (19 cases in trochees and 27 cases in iambs, i.e. 26.1% and 36.6% respectively); and (3) more than half of the participants produced the gesture apexes in phrase-final position,

irrespective of the metrical pattern (51 cases in trochees and 43 cases in iambs, i.e. 69.9% and 58% respectively).

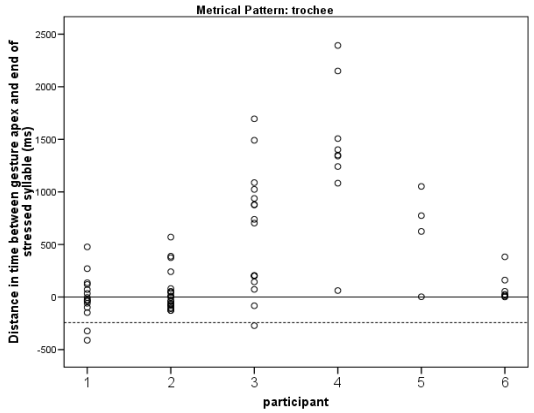

Figure 4: *Dispersion graph of the distance between gesture apex and end of the stressed syllable (in milliseconds) in trochaic words as a function of each participant.*

Chi-square tests indicated that the proportion of gesture apex occurring at a pre-tonic, tonic, or post-tonic position did not change across the two metrical patterns ($\chi^2(2) = 2.597$, $p > .05$). They also showed that the proportion of apexes at a pre-tonic position differed significantly from the proportion of apexes at tonic ($\chi^2(1) = 27.769$, $p < .001$) and post-tonic positions ($\chi^2(1) = 74.941$, $p < .001$), and a significant difference was also seen when comparing the proportion of apexes occurring at the tonic and post-tonic positions ($\chi^2(1) = 17.273$, $p < .001$).

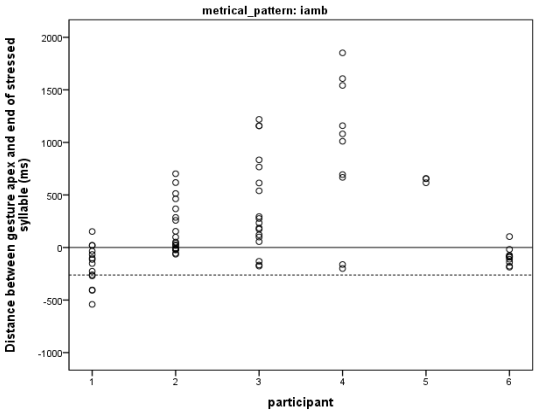

Figure 5: *Dispersion graph of the distance between gesture apex and end of the stressed syllable (in milliseconds) in iambic words as a function of each participant.*

We observed three strategies regarding the use of gesture and speech. The most frequent strategy was to utter a sentence and follow it by a pointing gesture, e.g. "Take the" [speech] + "object's name" [speech] + *it is this one* [gesture]. The second most frequent strategy was to utter unsynchronized pointing plus speech combinations, e.g. "Take the" [speech] + "object's name/ *it is this one* [gesture-speech combination]. And finally, there were few instances where the gesture apexes occurred during pre-tonic material, and these were produced with a pause between the pointing and the following word, e.g. "Take" [speech] + *this one* [gesture] + "which is called object's name" [speech]". These results show that pointing gestures can be produced before or after the target words, i.e. they are positioned at the edges of prosodic phrase boundaries, provided that they are perceived as separate speech acts carrying different semantic information.

4. Discussion

The purpose of this study was to investigate whether speakers detect temporal asynchrony between gesture and speech prominences (Experiment 1) and whether this perceptual ability is related to how they actually align gesture and speech in natural interactions (Experiment 2).

The results of Experiment 1 indicated that speakers do indeed detect asynchrony between gesture and speech prominences. However, surprisingly, unsynchronized trochees were perceived as more natural than unsynchronized iambs. More research is needed to investigate whether this effect is also found in trisyllabic words in which the misalignment of prominences can lead to an apex occurring at the pre-tonic or at the post-tonic position. This unexpected finding was further explored through a production experiment which elicited pointing gestures with the goal of teaching the name of the object and at the same time indicating its location. Our hypothesis was that speakers would rate unsynchronized trochees as fairly natural because in natural interactions speakers frequently align gesture prominences with phrase-final positions, especially when the semantic information conveyed by gesture is supplementary to the one conveyed in speech. Results of the production experiment (Experiment 2) confirmed this hypothesis: speakers produced practically no apexes during the pre-tonic material while apexes aligned during the post-tonic material were fairly frequent.

In our production study participants signaled the object they were referring to through a pointing gesture that frequently occurred after the object naming. It seems that speakers were actually saying "Pick up the object" using speech strategies + "that is there" using a pointing strategy. Thus, the gesture supplemented the meaning of speech and this affected the temporal coordination of the two modalities. This is not the first study showing evidence for the interrelation between semantic and temporal synchrony [9]. In [9] the authors found that gesture and speech timings were better aligned in complementary gesture-speech combinations than in supplementary gesture-speech combinations.

In sum, our results suggest that speakers perceive the alignment of gestural prominences by taking into account the temporal coordination of these gestures to prosodic heads (i.e. stressed syllables) or prosodic edges (i.e. phrase boundaries), and also by taking into account the semantic coordination of those gestures. Although further research is needed, this study has attempted to contribute to gain a better understanding of the temporal coordination between gesture and speech.

5. Acknowledgments

We thank Alfonso Igualada, Rafèu Sichel, and Santiago González for help with running the studies, and also the participants in the experiments. This research has been funded by grants FFI2012-31995, PSI-2011-25376, 2009SGR-701, and by the RECERCAIXA 2012 grant "Els precursors del llenguatge: una guia TIC per a pares i educadors".

Prominence and Coreference – On the Perceptual Relevance of F0 Movement, Duration and Intensity

Abstract

We conducted a web-based experiment on German testing the perception of an element's prosodic prominence in relation to its status as a potential coreferent of an antecedent. Data were elicited by asking subjects to judge the probability of a coreference relation between a context noun (antecedent) and a target word (anaphor), whose lexically stressed syllable was manipulated as to the parameters F0 movement, duration and intensity. Results suggest a direct but inverse relationship between prominence and coreference judgements indicating that the likelihood of a coreference interpretation decreases with increasing prosodic prominence. F0 movement turned out to be the dominant cue for prominence – as the main trigger for the perception of pitch accents – with rises being perceived as more prominent than falls. In turn, lack of tonal movement probably led to perceived deaccentuation and thus favoured the evaluation of a target word as being coreferential with an antecedent. Duration was found to be a significant factor as well, while intensity did not prove to be relevant for the task given. Thus, the present study with its revised methodology adds new aspects to the debate of which parameters are crucial for prominence perception, directly linking it to the investigation of information structure.

Index Terms: prosody, coreference, prominence, perception, pitch accent, givenness

1. Introduction

A central aspect in the analysis of an utterance's information structure is the information status of its elements, defining whether an element can be regarded as Given, Accessible or New (e.g. [1]). In many accounts, Givenness is equated with coreference, i.e. referential identity (e.g. [2]) (although it can be shown that a lexical level of description is also relevant for a comprehensive account of information status; see [3]). In (1a), e.g., *a lasagne* introduces a New referent, while in (1b), *the tasteless stuff* is Given, since it stands in a coreference relation to the previously mentioned *lasagne*:

(1) a. Yesterday, a friend of mine prepared a laSAgne for me.
b. I found it hard to enJOY the tasteless stuff. [4:16]

Prosodically, New referents are mostly marked by pitch accents in West Germanic languages (in the example, nuclear accents are indicated by capital letters, as in *lasagne* in (1a)), whereas coreferential anaphors are often deaccented (as *the tasteless stuff* in (1b)) or at least marked by a clearly attenuated, i.e. less prominent, prosody. Thus, there seems to be a more or less direct link between the information status of an element and the prominence of its prosodic marking. We will base our study on this general assumption.

There has been a long-standing debate on which acoustic parameters are most relevant for the perception of post-lexical prominence, in particular change in fundamental frequency (F0) (perceptual level: pitch movement), longer duration (perceptual level: increased length), or higher intensity (perceptual level: increased loudness). Another relevant parameter is vowel quality, differentiating between full and reduced vowels. Previous perception studies presented quite different results, assigning the greatest importance for prominence judgements either to F0 variation (e.g. [5], [6]), duration (e.g. [7]), intensity (e.g. [8]), or to a combination of duration and intensity (a factor called 'total amplitude' by [9]). Furthermore, there is conflicting evidence for the question of whether rising or falling pitch accents are preceived as more prominent (cf. [4] and [10]). See also [11] for an overview of acoustic and perceptual correlates of prosodic prominence.

There are a number of recent empirical (perception or production) studies on prosody and information status in German but they either do not differentiate between various levels of Givenness (conflating coreference, semantic-pragmatic accessibility and lexical repetition, e.g. [12]) or they do not relate an element's information status directly to its degree or level of prosodic prominence ([13], but see [4]). In the experiment we report on in the present paper we explicitly ask subjects to judge the probability of a coreference relation between an antecedent and a potential anaphor, the latter being manipulated as to its degree of prosodic prominence. This elicitation technique allows us to analyze the relation between coreference and perceived prominence, expressed in the following hypotheses:

Hypothesis 1: Acoustic/prosodic prominence correlates with perceived (non-)coreference – here: the more prominence-lending parameters (e.g. longer duration, higher intensity) are present, the less likely is a referent to be perceived as coreferential with an antecedent.

Hypothesis 2: Prosodic parameters vary in their relevance for the perception of prominence/non-coreference: F0 movement > duration > intensity.

2. Method

2.1. Test material

Three female proper names were chosen as target words: *Tamara*, *Pamela* and *Simone*. All of them are trisyllabic in German, with lexical stress on the second syllable. The stressed syllables contain the bilabial nasal /m/ in the onset and one of the long vowels /a:/, /e:/, /o:/ in the syllable rhyme. We created three test sentences. These contain a time specification (weekday), the subject pronoun *ich* ('I'), one of the three proper names as an accusative object, and a predicate

composed of the auxiliary verb *haben* ('have') and a past participle of one of the transitive irregular verbs *getroffen* ('met'), *gesprochen* ('talked') or *gesehen* ('seen'):

(2) Montag habe ich Tamara getroffen.
'On Monday I met Tamara.'

(3) Dienstag habe ich Pamela gesprochen.
'On Tuesday I talked to Pamela.'

(4) Freitag habe ich Simone gesehen.
'On Friday I saw Simone.'

The sentences were spoken by a female native German speaker and were recorded with an Edirol R-44 in a sound attenuated booth. The prosody of the recorded sentences was controlled for. In particular, three prosodic parameters of the stressed syllables in the target words were manipulated, namely F0 movement, duration and intensity.

F0 was varied to create rising, falling and level contours. For the rising condition, the stressed syllable starts at 190 Hz and rises to 240 Hz at the end of the syllable. For the falling condition, the F0 starts at 240 Hz at target syllable onset and falls down to 190 Hz at syllable offset. In the level condition, we assigned a value of 190 Hz throughout the whole target word. Figure 1 shows a *Praat* [14] screenshot for test sentence (2) with a rising pitch (solid line), a falling pitch (dotted line) and no pitch movement (dashed line) on the stressed syllable *ma* in the target word *Tamara*:

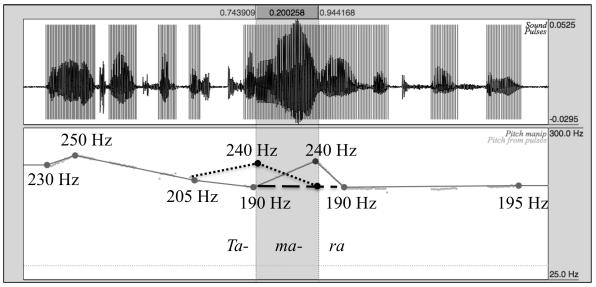

Figure 1: *Screenshot of the sentence* Montag habe ich Tamara getroffen ('On Monday I met Tamara') *in the Praat manipulation window. The stressed syllable of Tamara is shaded; it contains an F0 rise (solid line; first condition) an F0 fall (dotted line; second condition) or no F0 movement (dashed line; third condition).*

As to duration, two values were used: long syllables with 200 ms and short syllables with 150 ms. Similarly, we created two intensity levels: loud syllables with a maximum of 57 dB and soft syllables with a maximum of 47 dB. While F0 and duration were manipulated in *Praat*, we used the audio editor *Audacity* [15] to adjust the intensity of the target syllables. All combinations of the acoustic parameters were implemented in each sentence, resulting in 12 manipulated versions of each target sentence. Thus, 36 manipulated sentences for the perception experiment were generated in total. An overview of the manipulations is provided in Table 1.

The prosodic context for the target syllables was held constant throughout. That is, the weekday always carried a H* pitch accent (following [16]), with an F0 rise from 230 Hz to 250 Hz. It was crucial to create at least one pitch accent in the sentence which turns into the nuclear accent in cases of largely attenuated prominence of the target word. In this condition, the sentences would have lacked a pitch accent altogether without the early accent in the phrase, which would have sounded highly unnatural. Furthermore, the pitch height of the personal pronoun (*ich* 'I') immediately preceding the target word constantly had a value of 205 Hz, and the intonation phrase always ended at 195 Hz (cf. Figure 1).

Table 1: *Overview of manipulated prosodic parameters on target words.*

	Stressed syllable of target word	
F0 movement ('Tone')	rise	190Hz – 240Hz
	fall	240Hz – 190Hz
	none	190Hz – 190Hz
Duration	long	200 ms
	short	150 ms
Intensity	loud	57 dB
	soft	47 dB

Duration and intensity values for the rest of the target sentence were also controlled. In particular, the first and third syllable of the target word invariably had a duration of 150 ms and 130 ms, respectively, while both syllables were set to a maximum intensity of 50 dB.

2.2. Procedure

We conducted an online perception experiment via an open URL, using the professional software package *SoSci Survey* [17]. All 36 manipulated sentences were pseudo-randomized and matched with a respective context question. We created 12 different context questions for each target sentence, in order to diversify the task for the subjects. All questions followed the same structure; an example is given in (5):

(5) Hast du deine Cousine getroffen / gesprochen / gesehen?
'Have you met / talked to / seen your cousin?'

Twelve concrete, female nouns (as accusative objects) were used, which served as potential antecedents for the proper names in the target sentences: *Cousine* 'cousin', *Schwester* 'sister', *Nachbarin* 'neighbour', *Klassenkammeradin* 'classmate', *Tennispartnerin* 'tennis partner', *Arbeitskollegin* 'co-worker', *Mitbewohnerin* 'roommate', *Kommilitonin* 'fellow student', *Schulfreundin* 'schoolmate', *Teamkollegin* 'teammate', *Bekannte* 'acquaintance' and *Trainerin* 'trainer'.

The context questions were presented only visually, while the manipulated test sentences were presented auditorily. The participants controlled when to start a stimulus and were free to listen to it as many times as they chose. Afterwards, the subjects had to answer a question by rating the probability of a (non-)coreference relation between the proper name in the target sentence and the noun in the context question. An example of the questions is shown in (6):

(6) Für wie wahrscheinlich halten Sie es, dass es sich bei der Cousine um Tamara handelt?

'How likely do you think it is that the cousin is Tamara?'

Judgements were given via a horizontal scroll bar whose poles were labelled *sehr wahrscheinlich* 'very likely' (left side) and *sehr unwahrscheinlich* 'very unlikely' (right side). Figure 2 gives an example of the setup.

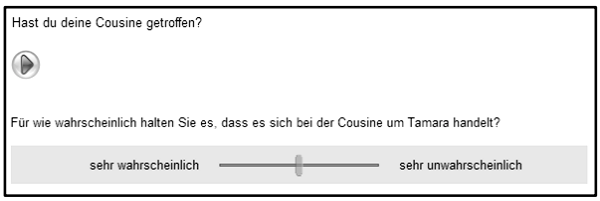

Figure 2: *Screenshot of the response submission setup in the online questionnaire, including a context question* ('Have you met your cousin?')*, the button for playing the target sentence, and the rating task* ('How likely do you think it is that the cousin is Tamara?') *with the scroll bar.*

The pole 'very likely' (= low values on the scale) corresponds to the judgement of coreference between the context noun (e.g. *Cousine*) and the proper name (e.g. *Tamara*). That is, the target word is perceived as Given information. In contrast, the pole 'very unlikely' (= high values on the scale) corresponds to the perception of a non-coreference relation between the context noun and the proper name. This means that the target word displays New information.

The experimental setup also included an instruction and a short practice section prior to the main experiment. The subjects were asked to conduct the experiment in a quiet environment and to wear headphones when listening to the stimuli. The entire procedure took approximately 10 to 15 minutes per subject.

2.3. Subjects and analysis

We collected judgements of 40 native speakers of German (32 female, 8 male), aged between 19 and 62 years. The mean age was 27 years. They grew up in nine different German Federal States. The subjects were no experts in the analysis of spoken language and did not report any hearing impairment.

The elicited judgements were encoded on an interval scale, illustrated as a horizontal continuous line in the experimental condition, ranging from 1% at the left pole ('very likely') to 100% at the right pole ('very unlikely'). For the statistical analysis, we used these percentage values as the dependent variable in a linear mixed model, with TONE (i.e. F0 movement), DURATION, INTENSITY and TEST WORD as fixed effects, and SUBJECT as a random effect.

3. Results and discussion

First of all, the subjects covered the whole range of the scale when judging the probability of corefence relations. This suggests that the stimuli were reasonably balanced for the type of task presented. Nevertheless, there is a slight bias towards the left pole of the scale (coreference judgements), maybe because a syntactically unmarked answer to a polar question (i.e. lacking an explicit 'yes' or 'no') tends to be interpreted as a confirmation.

Results reveal a significant main effect for TONE ($p<0.001$) in the coreference judgements. Figure 3 shows that the highest values were assigned to the target words if they carried a rising F0 movement, and that a falling contour still triggered clearly higher values than no F0 movement. That is, non-coreference (Newness) judgements correlate with tonal movement, and more so with rises (presumably more prominent; mean = 66.62%) than with falls (presumably less prominent; mean = 51.51%) whereas coreference (Givenness) judgements correlate with – the least prominent – lack of tonal movement (mean = 24.05%).

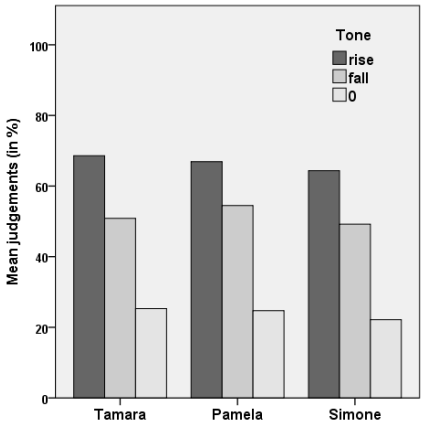

Figure 3: *Bar plot of mean judgements on (non-)coreference-probability scale with respect to the factor TONE; '0' stands for lack of tonal movement; all subjects pooled.*

The factor DURATION shows a significant main effect as well ($p<0.01$), with longer syllables favouring the subjects' impression that a coreference relation between context noun and proper name is unlikely (means = 49.63% for long syllables, 45.16% for short syllables; see Figure 4). Thus again, an increase in prosodic prominence leads to a decrease in coreference judgements.

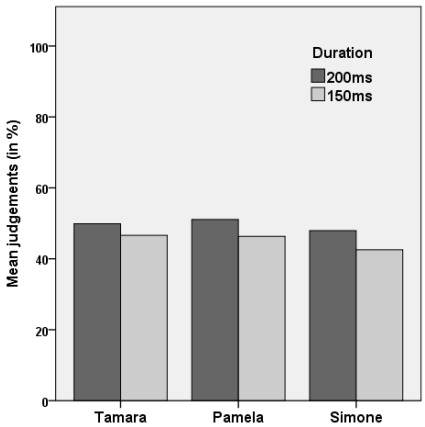

Figure 4: *Bar plot of mean judgements on (non-)coreference-probability scale with respect to the factor DURATION; all subjects pooled.*

No significant effect on coreference evaluations has been found for the parameter INTENSITY (p=0.131), although the judgements for two test words display the expected tendency, namely higher values (indicating lower probability of coreference) for test words carrying a louder stressed syllable (see Figure 5). In fact, the manipulation method for intensity may have been particularly prone to result in an unnatural outcome of this parameter (e.g. no adequate variation of spectral tilt) which may explain the somewhat inconsistent judgements.

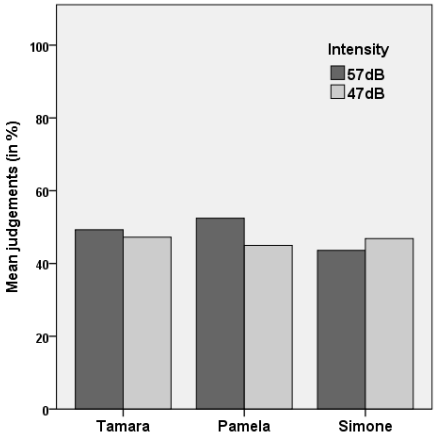

Figure 5: *Bar plot of mean judgements on (non-)coreference-probability scale with respect to the factor INTENSITY; all subjects pooled.*

The factor TEST WORD does not show a significantly distinct distribution over all three parameters either (p=0.085). Thus, the quality of the stressed vowel in the target word did not have an influence on the task.

Finally, no significant interactions were found between the fixed factors investigated. This result came as a surprise since an incremental effect of the prominence-lending parameters with respect to the (non-)coreference judgements would have been expected. That is, e.g., a target word with a rising F0 movement was not found to be interpreted as 'less coreferential' with an antecedent if it was *accompanied* by increased duration and intensity.

This notwithstanding, both hypotheses could generally be confirmed. As to Hypothesis 1, there are clear indications for an inverse but straightforward relation between perceived prosodic prominence and listeners' judgements of coreference. For example, if a target word such as *Tamara* in *Montag habe ich Tamara getroffen* ('On Monday I met Tamara') is realized in a prosodically attenuated manner, e.g. by lack of tonal movement or relatively short and soft syllables (in particular the lexically stressed syllable), the likelihood is high to interpret *Tamara* as the same referent as the cousin in the context sentence *Hast du deine Cousine getroffen?* ('Have you met your cousin?'). In contrast, a rising tone as well as increased duration on the lexically stressed syllable (*Tamara*) enhances the likelihood of the word to be interpreted as New information, which thus cannot be coreferential. However, as mentioned above, an additive effect of the parameters could not be found.

As to Hypothesis 2, the factor *tonal movement* is clearly dominant, while duration – which shows a significant effect as well – and intensity are much weaker cues (contrary to the claims proposed e.g. by [7] or [8]). This primacy of F0 variation is an old assertion already made by Fry [5], who based his findings on perception experiments in English, and Bolinger [6], who closely linked prominence with pitch accents (at least for West Germanic languages). Although pitch accents are combinations of F0 movement and increased duration and intensity, an F0 change in the vicinity of a stressed syllable is the defining characteristic of a pitch accent.

Moreover, the present experiment adds to the findings of more recent studies on West Germanic languages by suggesting that the shape or *type* of pitch accent does not only play a crucial role for the evaluation of Given or New information but also for the perception of prosodic prominence – with low and falling accents being perceived as less prominent than high and rising accents ([4], [13], [18]). In particular, there is evidence that the most important factor is the question of whether the *onglide* to the accented syllable is rising or falling ([19]).

4. Conclusions

The present study relates the interpretation of information status to the perception of prosodic prominence, assuming a basic link between them. Methodologically, it proved to be possible to use a gradient probability measure based on distinctions at various levels of prosodic parameters to evaluate the intrinsically categorical distinction between coreference (i.e. referential identity) and lack of coreference.

Results suggest that tonal movement is the central cue to perceived prominence, since it is characteristic of a pitch accent. Nevertheless, it is generally agreed on today that non-tonal cues such as duration, intensity and vowel quality are highly relevant for indicating the presence of *rhythmic* prominences (e.g. [20]) as well, which, however, may not contribute to the marking of information status in the same way as pitch accents do.

Abstract

This study investigates the acoustic correlates of word stress in Estonian. It forms part of a broader international collaboration the aim of which is to develop a universal language-independent model for evaluating lexical stress regardless of the phonological structure of a given language. To this aim the characteristics of word stress in a range of languages are studied using unified methodology. For the present study, four acoustic measures were analysed as a function of speaking style and stress: vowel duration, F0 mean, F0 standard deviation, and spectral emphasis. The results show that the strongest correlate of style and stress in Estonian is vowel duration, but stress has a strong interaction with the Estonian three-way quantity system.

Index Terms: word stress, quantity, speaking style, Estonian

1. Introduction

The present study forms part of the Word Stress Project (http://wordstress.ling.gu.se/index2.html), which addresses the acoustic description of word stress correlates and the perception of these correlates as cues to relative syllable prominence. At present 7 languages are included: Brazilian Portuguese, British English, Estonian, French, German, Italian and Swedish. The results of the project will ultimately be used to formulate a typology of word stress suggesting methods that could be applied to the study of any language.

All languages included in the project are studied using the same methodology, whereby the acoustic correlates of stress are described as a function of stress level (primary, secondary and unstressed) and speaking style (spontaneous, phrase reading and word list reading). The acoustic correlates measured for each syllable of a word are the mean F0, standard deviation of the F0, vowel duration, and spectral emphasis. So far, results have been obtained for Swedish [1], [2], Brazilian Portuguese [3], [4], and German [5]. In this paper similar methodology will be applied to Estonian – an unrelated Finno-Ugric language which is known for its three quantity degrees.

In Estonian, the main word stress is usually fixed on the first syllable. It can be elsewhere only in foreign and loan words, interjections and names. As pointed out by Lehiste, the role of stress in Estonian is primarily identificational rather than contrastive [6]. The position of stresses, and thus the division of the word into feet, follows the trochaic rhythm structure. Disyllabic or trisyllabic words typically consist of a single foot (a primary stressed syllable is followed by one or two unstressed syllables). A tetrasyllabic word is generally made up of two disyllabic metric feet. Secondary stresses normally fall on successive odd-numbered syllables (e.g. *magamata* [ˈmɑ.kɑ.ˌmɑt:.tɑ] 'sleepless', *lõpetatigi* [ˈlʏp.pe.ˌtɑt.ti.ki] 'was finished'). In longer words the stress pattern is not fully predictable, although it is often determined by the morphology.

All primary stressed syllables in Estonian are in one of the three quantity degrees: short (Q1), long (Q2) and overlong (Q3). This distinction operates only over a disyllabic trochaic foot, and the decisive factor in determining the degree of quantity is the duration ratio between the first (stressed) and second (unstressed) syllable, regardless of the stressed syllable structure [7]. An additional cue to the quantity distinction is the pitch contour which in Q1 and Q2 is a step down between the two first syllables, but in Q3 is realised as an early fall in the first syllable.

Word stress in Estonian has been subject to thorough phonological investigations [8]–[10] whereas very little is known about its phonetic characteristics. Earlier studies addressing acoustic correlates of Estonian stress are limited to a small-scale investigation into the influence of stress on nasal flow, amplitude and duration [11], where duration was shown to be the parameter on which stress had most consistent influence. The temporal patterns of stressed and unstressed syllables have also been studied in relation to the quantity system. A study of penta- and hexasyllabic words [12] showed that the secondary stressed feet were systematically shorter than the stressed feet while the stressed-to-unstressed syllable ratio was retained to a certain extent. Additionally, there is some acoustic evidence which shows that the degree of stress in Estonian has an influence on vowel quality [13], [14].

The aims of the present study are two-fold: firstly, to test the suitability of the methodology of the Word Stress Project on Estonian, which is a typologically different language from the others included in the project so far, and secondly, to gain new knowledge about the little-studied acoustic correlates of word stress in Estonian. As the main stress in Estonian is fixed it could be hypothesised that stress correlates are fewer and not as strong as in languages with a morphologically unbound stress like, for instance, English. We predict vowel duration to be the most important correlate.

2. Materials and method

Identical methodology as used by the other studies carried out in the framework of the international Word Stress Project (e.g. [1], [3], [5]) was applied. The starting point of the materials was the University of Tartu Phonetic Corpus of Spontaneous Speech (http://www.keel.ut.ee/foneetikakorpus). Spontaneous recordings of 16 native speakers of Estonian – 10 females and 6 males – were chosen from the corpus on the basis of the speaker's age and dialectal background. All speakers were between 22 and 34 years old, and represented the Standard North Estonian variety. At the time of the recording they were either students or graduates of the University of Tartu. From each (approximately 30 min long) recording 15–20 utterances were selected per speaker, and from each utterance one or two target words were chosen. The two criteria for selecting the

words were the position of the word in the utterance (prenuclear i.e. not preceded or followed by an IP-boundary) and the number of syllables (at least two or preferably more syllables long). The words therefore display various syllable structures and phonological quantities. Two lists were prepared with these utterances and target words where each phrase and word appeared three times in random order. The two lists were read by the same 16 speakers.

The final data set comprises 276 target words in three different speaking styles: spontaneous speech, phrase reading and word list reading. Most commonly, in our data, a target word is trisyllabic.

The recordings were analysed in Praat [15]. The analysis focussed on the vowels of the target words which were manually labelled. Combined labels were given for stress and quantity. Stress was marked with numbers 3 (primary), 2 (secondary), and 1 (unstressed), and depending on the quantity of each foot the relevant number was used once (Q1), twice (Q2) or three times (Q3), as for instance: 3+1+1 in case of a Q1 foot (e.g. *midagi* [ˈmi.tɑ.ki] 'something'), 33+11+11 in case of a Q2 foot (e.g. *rongile* [ˈroŋ.ki.le] 'train AllSg'), and 333+111+111 in case of a Q3 foot (e.g. *eelmine* [ˈee:l.mi.ne] 'previous'). In tetrasyllabic and longer words where successive feet carry secondary stress the labelling was following: 3+1+2+1 for two Q1 feet (e.g. *esimene* [ˈe.si.ˌme.ne] 'first'), 33+11+22+11 for two Q2 feet (e.g. *värviliste* [ˈvær.vi.ˌlis.te] 'coloured one GenPl'), and 3+1+222+111 for a combination of a Q1 and Q3 foot (e.g. *mesilasse* [ˈme.si.ˌlɑs:.se] 'beeyard IllSg').

Stress and quantity levels were identified by a trained phonetician. The measures of duration, F0 mean, F0 standard deviation, and spectral emphasis were extracted using a Praat script. For spectral emphasis the formula $SE = L - L_0$ was used, where L is the entire intensity of the segment spectrum and L_0 is its intensity in the low band from 0 to 43 % over the F0 median in Hertz (see [16] for details). The data was analysed statistically in R. The mean values of the measures were calculated for each speaker for the factors Style, Stress and Quantity. Three-way Anova tests were used to evaluate the significance of the factors, and post-hoc tests were carried out with Tukey HSD.

3. Results and discussion

The results will be presented separately for each measure studied. For duration the data from male and female speakers was pooled as there is no reason to presume any gender related differences. For F0 and spectral emphasis the analysis was carried out separately for male and female speakers.

3.1. Vowel duration

It can be seen that vowel duration is significant for all factors: Style $F(2, 399) = 97.4$, $p < 0.001$; Stress $F(2, 399) = 69.4$, $p < 0.001$; Quantity $F(2, 399)$ 36.5, $p < 0.001$, and there is a weak interaction of Style and Stress $F(4, 399) = 2.7$, $p < 0.05$, and a strong interaction of Stress and Quantity $F(4, 399) = 41.8$, $p < 0.001$. Post-hoc testing showed that Style is significant on all levels, duration being the longest in word list reading and the shortest in spontaneous speech. For Stress there are diversely different patterns for different quantity levels: in Q2 and Q3, vowel duration is the longest in primary stressed syllables and the shortest in unstressed syllables; but conversely in Q1 the unstressed syllables are the longest and the primary stressed syllables the shortest.

The strong interaction of Stress and Quantity resulting in diversely different stressed-unstressed duration patterns is in line with previous findings from the studies of Estonian quantity system, e.g. [14]. Additionally it can be seen from Figure 1 that there is a large variation of the stressed syllable durations in Q2 and especially in Q3. This is due to the fact that in the present analysis we only considered the foot level quantity but not the stressed vowels being short or long. As pointed out above, the Estonian three-way quantity operates over a disyllabic foot and the main feature of quantity is the relative temporal pattern of stressed and unstressed syllables. The stressed syllables can be filled by various segmental combinations, including a long or an overlong vowel or a combination of a short or a long vowel followed by a short or long coda consonant. Therefore, a more accurate description of stress patterns in Estonian could be obtained by taking the phonological structure into account.

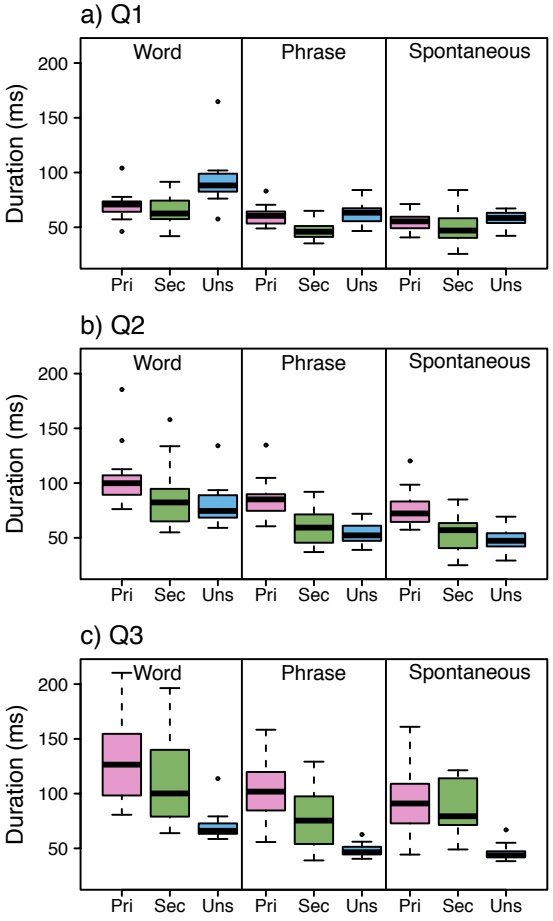

Figure 1: *Duration as a function Style (word list reading, phrase reading, spontaneous) and Stress (primary, secondary, unstressed), grouped by Quantity (Q1, Q2, Q3).*

3.2. F0 mean

For male speakers, the mean pitch is significant for Style $F(2, 151) = 14.9$, $p < 0.001$, and Stress $F(2, 151) = 43.6$, $p < 0.001$. For female speakers, there is only a significant effect of Stress

$F(2, 255) = 17.6$, $p < 0.001$. Post-hoc tests showed that for both male and female speakers, the F0 mean is higher in the primary stressed syllables, but there is no difference between secondary and unstressed vowels. For male speakers, the F0 mean is higher in read speech than in spontaneous speech, but there is no significant difference between the word list reading and phrase reading.

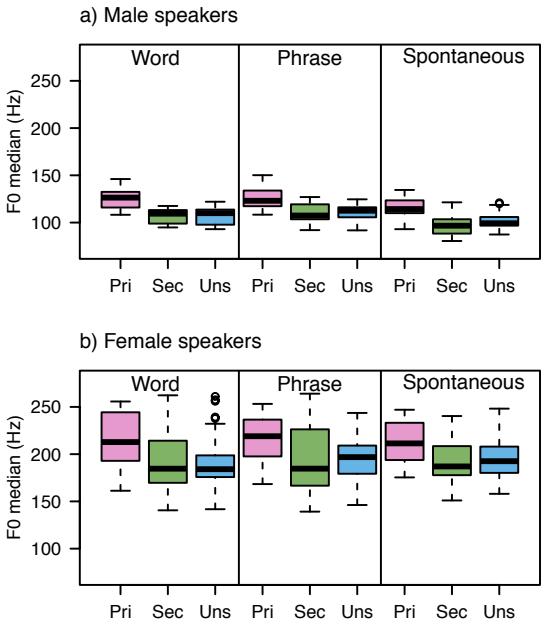

Figure 2: *F0 median as a function Style (word list reading, phrase reading, spontaneous) and Stress (primary, secondary, unstressed).*

Unexpectedly, there was no effect of Quantity on the F0 mean, although it is known from previous studies that there is more pitch movement in Q3 primary stressed syllables.

On the side we noticed a considerable amount of creaky voice in non-initial syllables that were left out of the present analysis. Creakiness usually occurs in Estonian in less prominent parts of speech and can be associated with the lack of prominence. Therefore, some measure of creakiness should be included in the stress model.

3.3. F0 variation

The F0 variation within vowels has different patterns for male and female speakers. For male speakers, there is a significant effect of Stress $F(2, 146) = 12.9$, $p < 0.001$ and a weak interaction of Stress and Quantity $F(4, 146) = 2.4$, $p < 0.05$. Post-hoc testing showed that the F0 variation is greater in primary stressed and unstressed syllables than in secondary stressed syllables. The interaction of Stress and Quantity indicates that the variation of F0 is somewhat different in primary stressed vowels of Q1 vs. Q3 ($p < 0.05$), but in secondary and unstressed syllables the quantity has no effect.

For female speakers, there is a significant effect of Stress $F(2, 249) = 7.4$, $p < 0.001$, and a weak interaction of Style and Stress $F(4, 249) = 2.7$, $p < 0.05$. Post-hoc testing showed that unlike for male speakers the variation of F0 is greater in unstressed vowels, and there is no significant difference between primary and secondary stressed vowels. The post-hoc testing of the interaction of Style and Stress did not reveal any meaningful patterns.

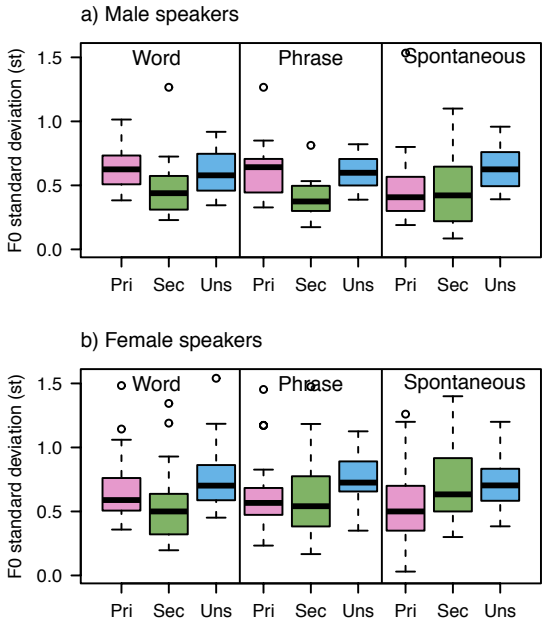

Figure 3: *F0 standard deviation as a function Style (word list reading, phrase reading, spontaneous) and Stress (primary, secondary, unstressed).*

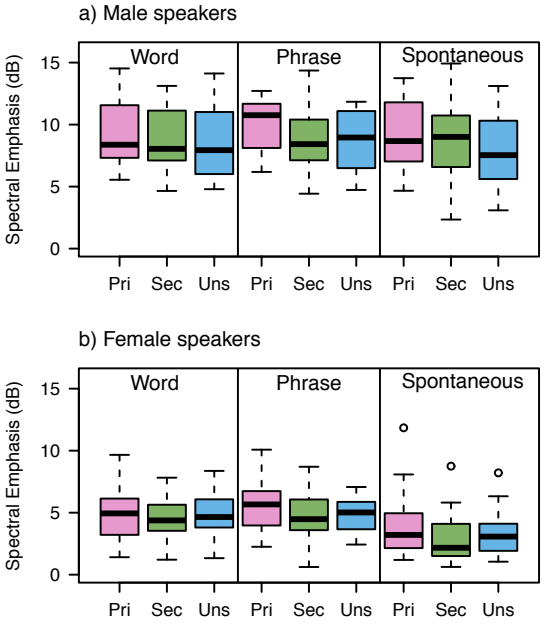

Figure 4: *Spectral emphasis as a function Style (word list reading, phrase reading, spontaneous) and Stress (primary, secondary, unstressed).*

An interaction between Stress and Quantity was expected and could have been even stronger, because it is known that the F0 in Q1 and Q2 stressed syllables is flat, whereas there is an F0 fall within the Q3 stressed syllable [14]. Also, it is

possible that a larger F0 variation in unstressed syllables is linked to the fact that a more marked F0 movement takes place in Q1 and Q2. A greater variation in unstressed syllables was also shown for German [5].

3.4. Spectral emphasis

Spectral emphasis is the weakest measure for Style and Stress in Estonian. Again there is a difference between the genders. None of the tested factors are significant for the male speakers, while the data of the female speakers only shows a significant effect of Style $F(2, 253) = 19.7$, $p < 0.001$. A post-hoc test showed that the spectral emphasis is greater in read as compared to spontaneous speech. Additionally, for female speakers, the effect of Stress closely fails to reach the significance level $F(2, 253) = 2.9$, $p = 0.0595$, the spectral emphasis being somewhat higher in primary stressed vowels than in secondary and unstressed syllables.

4. Conclusions

The application of the methodology of the Word Stress Project yielded new results about the acoustic correlates of Estonian word stress. Four measures were studied: duration, F0 mean, F0 standard deviation, and spectral emphasis.

As predicted, vowel duration turned out to be the most important stress correlate. It was shown to be the strongest for Style and Stress with there being a strong interaction with Quantity. In Q2 and Q3 the stressed vowels were longer than the unstressed ones, but in Q1 the unstressed syllables were the longest. The secondary stressed vowels were always shorter than the primary stressed ones.

The pitch in primary stressed vowels was higher than in secondary and unstressed vowels, while the variation of pitch was high in stressed and unstressed vowels and lower in secondary stressed vowels. The F0 variation could be partly quantity-related, but the nature of the data does not enable to draw a solid conclusion. Additionally, F0 mean was associated with speaking style, although this was only apparent for male speakers whose F0 mean was higher in read than in spontaneous speech.

Spectral emphasis turned out to be the weakest measure of stress for Estonian, being only significant for female speakers, distinguishing read from spontaneous speech.

The results seem to support the hypothesis about there being fewer and weaker stress correlates in Estonian. Since Estonian has a fixed word stress and very clear phonological rules determining the stress patterns, it seems logical that it is not as important to mark stress acoustically as it is in many other languages.

In this study neither the duration of the stressed vowel nor the phonological structure of the stressed syllable was taken into account. Thus, in further work on Estonian word stress, not only the foot level quantity but also the segmental structure of the foot should be factored in.

5. Acknowledgements

The authors are very grateful to the speakers who participated in this study. We would also like to thank the participants of the 2nd Word Stress Workshop for feedback and comments. The study was supported by the Estonian Research Council grant IUT2-37, the targeted financing project SF0050023s09, and the National Program for the Estonian Language Technology Project EKT4.

Abstract

The study investigates prominence patterns in Czech-accented English comparing the production of non-native speakers of English at two distinct stages of phonological acquisition (beginners and intermediates) with a native performance. Word stress in Czech is entirely different from English, it has a fixed position, a delimitative function and rather impalpable acoustic manifestations. Alternations in the realization of word stress were analyzed by measuring the ratios or differences of acoustic correlates of prominence: duration, fundamental frequency, sound pressure level and spectral slope. Since word stress is a relational phenomenon, these characteristics were measured in two adjacent syllables one of which was a canonical stress bearer. The results reveal a clear difference between native and non-native treatment of word stress in all parameters examined. In the non-native sample distinct interferences of L1 across the two groups were detected: the subjects displayed different exploitation of duration, spectral slope and sound pressure level (SPL) with relation to their proficiency in L2 English. Out of these, duration ratio proves to be the most significant correlate. Furthermore, our findings indicate a strong effect of prosodic context coinciding with the prominence features, particularly in intonation declination and phrase-final lengthening.

Index Terms: Czech English, word stress, prominence, duration, F0, SPL, spectral slope

1. Introduction

Non-native accents of English have gradually ceased to be frowned upon, firstly due to the vast interconnectedness of today's world requiring the ability to understand a wide range of interlocutors and secondly thanks to the continuous research offering valuable insights into the nature of foreign-accentedness and its impact on human communication. One such groundbreaking study revealed that even heavily accented speech may be objectively intelligible [1], however the authors in the same breath warn of subjectively perceived difficulty to comprehend strongly accented productions which may consequently trigger negative attitudes or result in prejudiced judgments [2], [3]. In the field of second language pedagogy it has been repeatedly argued that appropriate prosodic features may contribute greatly to successful communication, increase intelligibility e.g., [4], [5], [6] and weaken the degree of foreignness [7]. Nevertheless, phonological transfer from the mother tongue places many constraints on the acquisition of the target sound system, especially in the area of rhythm and intonation [8].

The present study aims at mapping the relationship between L1 (Czech) and L2 (English) at different stages of phonological acquisition in the area of prominence patterning. One of the main functions of stress in English is to maintain the natural rhythm in connected speech [9], [10]. Stress misplacement may therefore bring about momentary confusion on the listeners' part as the deviated surface form does not immediately match the expected prominence scheme. Stress is a relational phenomenon and its degree of prominence cannot be determined within monosyllabic isolated words. The juxtaposition of stressed and unstressed syllables makes stressed parts stand out clearly which leads to their smoother identification and processing. The decreased degree or even absence of prominence in unstressed syllables corresponds perceptually to relative shortness, lower pitch, quietness and vowel reduction involving a centralization of peripheral vowel qualities, which is most frequently materialized as *schwa* [11]. The stress systems of English and Czech do not coincide, the former being completely unpredictable for a Czech speaker with the experience of a fixed stress mother tongue and a very limited space for reductions in standard pronunciation.

In general, word stress is not a one-dimensional phenomenon as it manifests itself in different ways in the speech signal. Several reliable acoustic correlates of word stress have been identified: F0, duration, intensity and spectral slope, e.g., [12, 13, 14, 15, 16, 17, 18, 19]. However, the way these parameters are manipulated by the speakers in order to create prominence contrasts can be highly language-specific, see e.g., [20].

In Czech, word stress remains somewhat impalpable and its comprehensive description is yet to be completed. Contrary to English, its position is fixed to the first syllable and its acoustic manifestations do not usually include an increase of F0, intensity or duration. Furthermore, unstressed syllables contain predominantly full vowel qualities. Duration is mainly used for marking phonologically long and short vowels and the stressed syllables can be shorter than the unstressed ones [21]. Also, F0 of stressed syllables is often lower due to a post-stress rise (i.e., L*+H accent) typical of Czech stress-groups [22]. The results concerning intensity and spectral slope are still preliminary and these acoustic attributes are an object of ongoing research.

The issue of prominence in Czech English has enjoyed an increased interest among researchers in both perception and production domains in the past decade. In the former, Czech listeners demonstrate a weakened perceptual sensitivity to English vowel reductions [23] and experience greater difficulties identifying strong beats when individual acoustic attributes indicating syllable prominence are in conflict [24]. As far as production is concerned, Czech-accented English can be generally characterised as lacking clear temporal contrasts, that is to say stressed syllables tend to be shorter and unstressed syllables longer than in native speech, which may, however, in certain contexts give rise to positive L1 transfer [25]. The strong inclination of Czech speakers to equalize the duration of vowels with a different degree of prominence seems to be a straightforward fact, although at a closer inspection, various strategies for signalling prominence have been detected. These largely depend on a number of factors, such as phonological structure of words, their textual frequency and resemblance to Czech counterparts [26]. Turning to weak vowels, the measurement of their spectral slope yielded quite reliable results in discriminating Czech and

British speakers of English [27]. Prominence investigation was also opted for in the assessment of strength of foreign accentedness under adverse listening conditions [28].

The current study follows and further develops the previously mentioned research in two respects. First, it compares the ratios or differences of acoustic parameters in stressed and adjacent unstressed vowels instead of comparing the values of duration, F0, intensity and spectral slope in grand means. We believe that this method better reflects the relational character of the explored phenomenon and is consistent with the idea of the speakers' effort to create local contrasts between prominent and non-prominent elements. Second, Czech respondents were subdivided into two groups according to the achieved language competence (beginners A1/A2 × intermediates B2/C1), which allows us to monitor the development of interlanguage at two distinct stages of phonological acquisition. Native speakers' prominence patterns served as an important reference point. Since a single corpus on Czech-accented speech involving various language levels is not available to the best of our knowledge, we drew the data from two different corpora with a high degree of compatibility [29], [30]. Although we may hypothesize that the more proficient speakers will exploit prominence features in a more native-like manner, we do not know which of the investigated prosodic dimensions will be most amenable to the acquisition process. Thus, the results should be generally informative with respect to prosodic pattern acquisition.

2. Method

2.1. Czech beginners

Czech beginners, 34 pupils of a lower-secondary school in Prague were asked to read aloud a list of 12 words, 8 short sentences and a limerick. The choice of lexicon corresponded to the respondents' language level or was lower. 18 boys and 16 girls at the age of 12 or 13 were recorded individually with a portable professional device Edirol HR-09, sampling frequency of 48 kHz and 16-bit resolution. The subjects reported no or rather limited contact with native English outside the classroom setting. All respondents were perceptually assessed as having a heavy foreign accent.

2.2. Czech intermediate and native British speakers

As for the Czech intermediate and British native speakers, their recordings were taken from the Prague Phonetic Corpus [29]. The subjects were 16 (8 Czech, 8 British) female non-professional speakers ranging in age from 20 to 25 years. They were instructed to read a news bulletin from the BBC in the length of about 500 words. The British subjects were speaking with a Southern Standard British accent, whereas the Czech subjects were selected as having a clear Czech accent, which was afterwards verified by naive listeners in a perception test (see [31]). Nevertheless the speakers were advanced enough to read a relatively complex text without substantial dysfluencies.

The recordings of the Czech intermediate speakers were made in a sound-treated studio with an electret microphone IMG ECM 2000, soundcard SB Audigy 2 ZS, 32-kHz sampling frequency and 16-bit resolution. The English speakers were recorded in the same way as the group of Czech beginners. All the recordings obtained with the Edirol HR-09 were afterwards downsampled to 32 kHz. Word and phone boundaries in both corpora were manually labelled in *Praat* [32] by experienced phoneticians.

2.3. Data selection

For this study, we selected comparable material from both corpora – pairs of vowels in adjacent syllables within a word, where one carries primary stress and the other is unstressed according to the lexical rules [33]. This resulted in two possible patterns – an unstressed vowel following a stressed vowel (S-U pattern, constituting 67.6 % of all pairs) and vice versa (U-S pattern, constituting the remaining 32.4 %).

Tokens containing dysfluencies, external noise or mispronounced elements were discarded. In total, we analyzed 1913 words: 884 uttered by beginners, 493 by intermediates and 536 by native speakers. The following parameters were extracted from or determined for each vowel:

- identity of the vowel (similar vowels clustered into six resulting types: /i/, /e/, /a/, /o/, /u/, /ə/)
- canonical prominence status (stressed, S × unstressed, U)
- position within a prosodic phrase (non-final × final)
- duration (in milliseconds)
- sound pressure level (in dB)
- F0 (in semitones relative to 100 Hz)
- spectral slope quantified with the α measure (difference between spectral energy above and below 1000 Hz, the highest boundary being the Nyquist frequency, that is 16 kHz; expressed in dB)

The last three characteristics were taken in the middle third of each vowel's duration to reduce the effects of consonantal transitions and potential labelling inaccuracies. F0 was not extracted from the beginners' word-list task, since it could be confounded by specific melodies of isolated word reading.

In the analyses, we compared the neighbouring vowels in the selected acoustic parameters. Our variables were:

- duration ratio (U/S)
- F0 difference (S-U)
- SPL difference (S-U)
- α difference (S-U)

The duration variable was expressed as a ratio in order to neutralize the effects of speaking tempo and differences in number of syllables in the examined words. The statistical significance of the results was verified by one- or two-way ANOVAs for independent measures with Tukey HSD post-hoc tests.

3. Results

3.1. Duration

The ratio of duration (unstressed/stressed vowel) in phrase non-final words decreases as the proficiency of the speaker group increases. The BrE speakers exhibit an average ratio of 0.7 (i.e., the unstressed vowel duration constitutes seven tenths of the stressed vowel duration), regardless of the stress pattern type. The CzE speakers differed according to their proficiency level and the investigated stress pattern.

Figure 1 shows how the duration ratio changes in the three speaker groups and in S-U vs. U-S patterns. The interaction of LEVEL*PATTERN is statistically significant (two-way ANOVA: $F(2, 892) = 6.5$, $p = 0.002$). Unlike BrE speakers, the two Czech groups yield different results in their temporal treatment of stress patterns. In U-S, they are more native-like – the difference between the CzE intermediate group and the native speakers is not even significant, whereas in S-U, they treat the temporal ratio quite differently: the beginners prolong the

second, unstressed syllable (the ratio is higher than 1) and the intermediates display roughly the same duration of both.

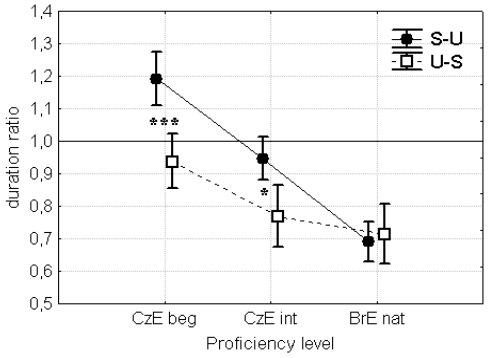

Figure 1: *Average duration ratio of adjacent stressed (S) and unstressed (U) vowels in non-final words of two patterns: S-U and U-S. Whiskers indicate 0.95 conf. intervals. Tukey post-hoc tests: *** → $p < 0.001$, * →$0.01 < p < 0.05$.*

The durations in phrase final words are not easy to interpret, since final lengthening influences the situation in a more arbitrary manner. Nevertheless, our data suggest that phrase-final lengthening may intensify the differences stemming from the stress pattern. This tendency applies to all three groups. In the case of U-S sequence, the effects of both lengthenings combine, resulting in lower ratios than in non-final words. In S-U cases it works in the opposite direction and equalizes the duration values making the ratio around one or higher.

3.2. Sound Pressure Level

In the case of sound pressure level differences, we discovered that Czech speakers of both proficiency levels behave identically – the difference between stressed and unstressed vowels was around 0.7 dB. Conversely, native speakers mark the stressed vowels substantially – the stressed elements have on average 3.3 dB higher sound pressure level than the neighbouring unstressed ones (see Figure 2); one-way ANOVA: $F(2, 1910) = 70.6$, $p < 0.001$.

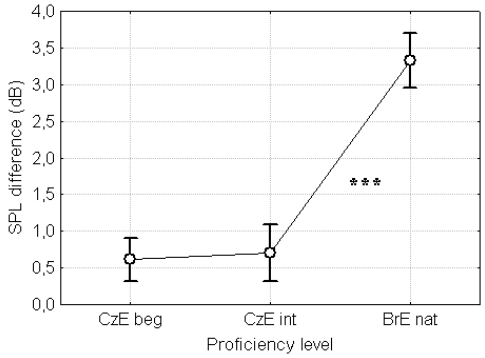

Figure 2: *Average SPL difference between adjacent stressed and unstressed vowels.*

The differences in SPL between words in final and non-final prosodic positions were negligible in all groups. However, when we examined the two stress patterns individually, we discovered a significant difference in the beginners group's final words. In U-S the SPL of the first vowel is 1.5 dB higher, whereas in S-U it is the other way round (the average difference is -1.9 dB). Thus the first syllable of phrase-final words of CzE beginners has always higher SPL regardless of its canonical stress status.

On the other hand, both BrE and CzE intermediate speakers maintain a constant SPL difference between the stressed vowel and its unstressed neighbour, regardless of the position or stress pattern. The former group has an average difference of 3.3 dB and the latter of 0.7 dB.

3.3. F0

Taking into consideration the typical Czech pattern of post-stress pitch rise, it seemed necessary to analyze both S-U and U-S groups separately to avoid its possible influence.

Generally, it is possible to infer from our data that Czech speakers do not use F0 difference to mark the stressed vowel, irrespective of the proficiency level, while the British speakers do, albeit only in the S-U pattern (see Figure 3). The stressed syllable of the native speakers is on average about 1.7 ST higher than the adjacent unstressed one and a Tukey post-hoc test reveals a highly significant difference between S-U and U-S of the British speakers: $p < 0.001$. Both Czech groups in both stress patterns fluctuate around zero and none of the differences between beginners and intermediates is significant.

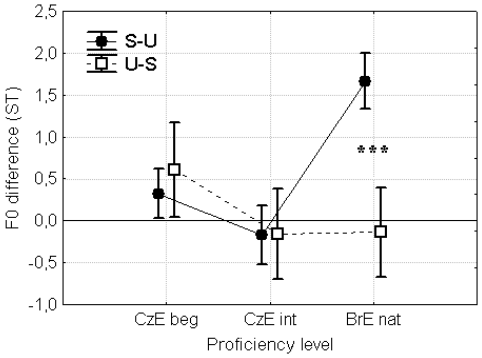

Figure 3: *Average F0 difference between adjacent stressed (S) and unstressed (U) vowels in two orders: S-U and U-S.*

We also investigated prosodically final words on their own as the phrase-final lowering (enhanced declination) could have an effect on the F0 stress pattern. Particularly, it could interact differently with S-U or U-S positions in the same way as in the durational domain.

Due to the exclusion of the word list reading task from F0 measurements, there were not enough U-S final cases in CzE beginners, therefore only CzE intermediates and BrE natives underwent the analysis. Both groups show a similar distinction in their treatment of S-U F0 difference in final words, which coincides with phrase-final declination. In the U-S pattern, the difference is reversed in both groups, i.e., unstressed syllable is higher that the stressed one. In the S-U sequence it is vice versa, the declination and the F0 difference caused by the stress pattern reinforce each other, resulting in higher F0 differences in both groups (Tukey post-hoc: $p \leq 0.01$).

3.4. Spectral slope

The results concerning spectral slope have to be interpreted with caution. As far as we know, all metrics of short-term spectral slope are sensitive to vowel identity (see e.g., [34]), so

the difference in spectral slope between two adjacent vowels can occur due to their different qualities and not due to prominence or vocal effort. Nevertheless, with all vowels pooled, we still found a highly significant dissimilarity between the speaker groups – CzE speakers of both proficiency levels showed α difference around zero, while BrE ranged around 3 dB (one-way ANOVA: $F(2, 1910) = 27.4$; $p < 0.001$). This means that the stressed syllables of the native speakers demonstrate in general a flatter spectral slope than the neighbouring unstressed syllables.

This tendency was confirmed by inspecting vowels with identical qualities – the pairs /i/-/ə/, /e/-/ə/, /a/-/ə/ and /u/-/ə/ (other pairs were not represented sufficiently). The pair /e/-/ə/ with the highest occurrence in our data is shown in Figure 5.

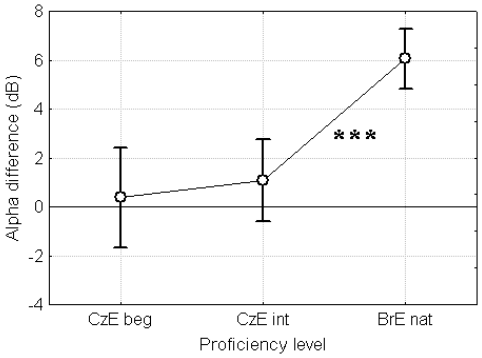

Figure 4: *Average α-measure difference between adjacent stressed /e/ and unstressed /ə/.*

If the vowel quality were the decisive factor, then we would expect no differences across individual groups. However, in this case, the BrE speaker group differs significantly (one-way ANOVA: $F(2, 249) = 16.8$, $p < 0.001$). The same applies to the /u/-/ə/ couple (one-way ANOVA: $F(2, 106) = 7.2$, $p = 0.001$). In the case of /i/-/ə/, the CzE intermediates coincide with the BrE natives, whereas the CzE beginners differ significantly (one-way ANOVA: $F(2, 227) = 8.2$, $p < 0.001$). With /a/-/ə/ the same trend emerges but it was not found significant.

4. Discussion

Addressing our research questions, British native speakers display different behaviour from Czech respondents with regard to all investigated parameters: duration, SPL, F0 and spectral slope of two adjacent vowels. The acoustic characteristics of the BrE native group correspond to the prototypical prominence scheme documented in literature: i.e., the stressed vowels exhibited longer duration, higher SPL, higher F0 and flatter spectral slope than the unstressed ones. On the other hand, Czech speakers fail to create prominence contrasts as systematically and comprehensively as their native counterparts.

Nevertheless, certain variability was detected within the Czech sample. The beginners differ substantially from the intermediates in duration and to a lesser degree in SPL and spectral slope. The character of these findings corroborates the initial hypothesis: more advanced speakers employ the examined features in the direction of native-like realizations.

In the temporal area the results accord with the previous studies exploring Czech English [25], [26], [30]. Moreover, the duration ratio turned out to be the most reliable predictor of the level of L2 phonological acquisition. The ability of Czech speakers to alter the duration of stressed and unstressed vowels seems to improve proportionately to the amount of their linguistic competence in L2. Interestingly, Trofimovich and Baker's data confirmed a similar tendency in English [35], despite differences in their respondents' language background and learning setting (Korean immigrants).

With regard to the SPL, an interesting contrast occurred across the group of CzE speakers. In the phrase-final words the beginners produced the first syllable with a higher SPL consistently regardless of its canonical stress status. This led to a native-like difference in the S-U items and a reversed pattern in the U-S sequences. Since higher SPL does not function as a consistent marker of Czech stress, we may also attribute this outcome to the influence of prosody in the reading task rather than to the mother tongue transfer.

F0 differences showed a notable distinction within the native speaker group. The U-S pattern was treated differently from the S-U, the former exhibiting no change between the two adjacent vowels. This phenomenon could be explained by anticipation: the speakers raise their F0 before the target vowel, so that it manifests itself on the preceding one, too. It has also been shown by [36] that if two subsequent syllables have the same pitch, the second one is perceived as more prominent, because of the expected F0 declination pattern. Examinations of the F0 differences in phrase-final words revealed that phrasal prosody plays a greater role than the F0 stress patterning and tends to override it in both native and CzE intermediate speakers. It would be interesting to see if the F0 measurements in the middle third of the vowels conceal any finer F0 dynamics occurring throughout the whole vowel.

The spectral slope results also suggest that CzE speakers treat the stressed-unstressed contrast differently from the native speakers. The measured contrast is smaller, which implies that Czech speakers articulate both vowels with a similar vocal effort and do not reduce the unstressed elements sufficiently. This finding is in accordance with [27] which found that Czech speakers articulate schwa with a flatter spectral slope than natives.

In conclusion, our results have shed some light on the nature of phonological acquisition of stress by Czech speakers of English. The acquisition process could be viewed as gradual clustering of fragmented acoustic parameters for signalling prominence. While Czech speakers' production illustrates low interconnectedness of the discussed features due to L1 interference, native speakers exploit them in a more cohesive way. Furthermore, SPL, spectral slope and F0 seem to be more compliant with the L1 constraints than duration: the temporal contrast proved to be in stronger relation to learners' L2 experience. How exactly and in which order the remaining aspects develop and interact to create natural prominence patterns poses a question for the future research. In addition, fuller understanding of Czech prominence scheme may help determine the extent of mother tongue transfer.

Abstract

In this paper, we motivate and present a sketch of an extrinsic timing model of speech production. It is a three-stage model, involving 1) phonological planning, where symbolic segmental representations are sequenced and slotted into an appropriate prosodic structure, and where appropriate acoustic cues are selected for each segment in its context, and 2) phonetic planning, where cues are mapped onto sets of articulators, and appropriate values for spatial and temporal parameters of movement are computed, and 3) phonetic implementation, where articulator movements are generated, monitored, and updated. We cite model components from the literature that accomplish many of the required functions.

Index Terms: speech production, extrinsic timing, prosodic structure

1. Introduction

Articulatory Phonology/Task Dynamics (hereafter AP/TD [1,2]) is the model of speech production that currently provides the most comprehensive account of speech timing phenomena. Timing control in this model is intrinsic, that is, surface timing patterns emerge from properties of the system and do not need to be represented, specified, or tracked during an utterance using a system-extrinsic timekeeper. However, several lines of behavioral evidence challenge intrinsic timing as implemented in AP/TD, and support the view that timing control in speech production is extrinsic. In this paper, we first present three types of evidence that support extrinsic timing in speech production, and then discuss a preliminary sketch of an alternative model of speech production that involves symbolic phonological representations and extrinsic timing. We point out model components from the literature that can be used to implement the model.

2. Evidence for extrinsic timing

2.1. Increasing variability with increases in interval duration, as predicted by a "noisy timekeeper" model

Many studies show more variability in interval duration for longer intervals in a variety of motor tasks [3]; for speech production, see e.g. [4]. As explained in [4, p. 422], these findings are expected in extrinsic timing models: "the mechanism that *meters out* intervals of time … is variable, and the amount of variability is directly proportional to the length of the interval of time to be metered out." (This is because time is metered out in smaller units than the total interval, and the variability in each inter-tick interval adds up). The relationship of variability to mean duration follows Weber's law, with an approximately constant coefficient of variation (standard deviation/mean) for a range of intervals in both humans and animals, consistent with an extrinsic timing mechanism [5,6].

2.2. Surface timing constraints and goal specifications suggest extrinsic timing

Within AP/TD, desired surface durations aren't specified as part of the utterance plan, but instead emerge from interacting components within the task dynamical system. For example, gesture durations in phrase-final position reflect the settling-time of their mass-spring system, their gestural activation interval, and an adjustment which lengthens the gestural activation intervals at the boundary [7,8]. In AP/TD, the surface duration emerges from these mechanisms and is not explicitly specified in the original utterance plan. However, [9] suggest that a constraint on surface durations of phonemically short vowels in phrase-final position may be required to preserve the short vs. long phonemic contrast in Northern Finnish. The authors observed that the magnitude of final, accentual, and combined lengthening on phonemically short vowels in word-final syllables was restricted compared to lengthening on phonemically long vowels (17% combined accentual + final lengthening on phonemically short vowels in a word-final syllables vs. 68% on long vowels in the same context). These results are consistent with the view that the surface durations of the phonemically short vowel are restricted in order to avoid endangering the phonemic short vs. long vowel quantity contrast in this language. Although it is possible to *implement* this type of effect in AP/TD, the effect is difficult to *explain* within the theory, since surface durations can't be referred to. Additional support for the representation of surface durations can be found in studies of speech rate effects and durational correlates of prosodic structure and quantity [10-12]; despite considerable variability in the strategies that different speakers use to implement these factors, speakers all achieve a common surface duration pattern of relatively long surface durations e.g. in phrase-final position, at slow speech rates, and for phonemically long vowels. These findings challenge intrinsic timing in AP/TD because they suggest the equivalence of different strategies that result in similar surface duration patterns, and therefore support the specification of surface duration goals.

2.3. Separate control of movement targets vs. onsets challenges intrinsic mass-spring models

In [13], Dave Lee commented "it is frequently not critical when a movement starts—just so long as it does not start too late. For example, an experienced driver who knows the car

and road conditions can start braking safely for an obstacle a bit later than an inexperienced driver…" This type of example suggests that timing variability may be different at target attainment vs. movement onset, difficult to account for in mass-spring models such as AP/TD, but relatively straightforward to account for in extrinsic timing models that allow separate timing specification and prioritization for target attainment vs. other parts of movement [14].

Several studies have confirmed the differential variability in the timing of target attainment compared to the timing of other movement events such as movement onset ([15-18], for non-speech motor activity; [19] for speech). For example, [19] showed differences in of timing variability for onsets vs. target attainment for upper lip protrusion movements during spoken /i_u/ sequences. While AP/TD does provide a mechanism for separately adjusting the timing of the beginning and the end of an activation interval (by applying its prosodic "stretching" mechanism to a proportion of the interval), it doesn't provide a mechanism by which these timings could be differently variable. These findings suggest that target attainment timing is controlled independently of movement onset timing, and that target attainment timing takes higher priority. Similar findings of differential variability at target attainment vs. elsewhere in movement have been observed for spatial characteristics of repeated non-speech movements, where spatial variability is lowest at a movement target and higher elsewhere, e.g. [20]. These findings add further support for the separate control of targets vs. other parts of movement.

3. Key features

The key feature of our proposed model sketch is that it involves extrinsic timing, with a way to assign different priorities to the timing of movement targets vs. other parts of movement such as onsets. Extrinsic timing implies a-temporal representations, and we therefore assume that representations are symbolic, because symbolic representations are a type of a-temporal representation. We favor symbolic representations because they offer a better account of phonological equivalence than alternative a-temporal representations such as spatial paths without timing. Mechanisms of phonetic implementation are required to map these symbolic representations onto their surface phonetic form. We therefore assume a three-stage model, involving 1) phonological planning, and 2) phonetic planning, and 3) phonetic implementation. We assume that timing specification is a part of phonetic planning that is separate from the specification of spectral/spatial information (see [21] for a similar view). Timing information is combined with spatial information to generate movements intended to get to their targets on time. We discuss the planning and implementation stages in more detail below.

4. Phonological planning

We assume that phonological planning involves sequencing symbolic segmental representations and slotting them into a prosodic frame that includes hierarchical constituent and prominence structure [22]. Following [23,24], we hypothesize that prosodic structure is planned with the goal of an even distribution of recognition likelihood by the listener throughout an utterance (called smooth signal redundancy). To this end, predictability information (from language and real-world context) is used to plan prosodic structure so that relatively unpredictable elements are highlighted, either by manipulating relative prosodic prominence, or by manipulating relative prosodic boundary strength (highlighting through edge demarcation). In the planning stage, other task requirements are identified, such as speaking quickly, or in a particular style (e.g. clear speech, periodic speech, etc.), as illustrated in Figure 1. These requirements are assigned relative priorities so that, in the Phonetic Implementation stage, they can be balanced against movement costs to yield optimal movements (see below and Figure 1).

Several aspects of Figure 1 are worthy of comment. First, the effects of predictability on planned phonetic form are assumed to be indirect, where predictability affects plnaned prosodic structure, and prosodic structure in turn affects planned surface phonetics. This view represents our current hypothesis, but we note that it is possible that predictability might have additional direct effects on phonetic form (in addition to those that are mediated by prosodic form). Second, we assume that the effects of non-grammatical factors, like rate and style of speech, on phonetic form have a direct effect on planned surface phonetics. Although these factors have been observed to affect aspects of prosody (e.g. fewer "breaks" at faster rates of speech, cf. [25]), our view is that a speaker would plan the same prosodic structure (i.e. same relative prominence and relative boundary strength structure) for a given utterance at different rates of speech, but that the planned correlates of this structure would be different at different rates because the rate of speech requirement would be balanced against the prosodic structure requirement in determining optimum phonetic characteristics that meet the competing demands. Third, the list of factors mentioned in the "Non-grammatical factors" box is intended to be a preliminary indicator of the many non-grammatical factors that might be at work, and may not be exhaustive.

At the planning stage, each symbolic representation in its context (prosodic, stylistic, etc.) is associated with a set of acoustic cues [26]. For example, in syllable initial position English /t/ might be associated with silence, then a relatively high frequency release burst + aspiration noise, but with a different set of cues in syllable final and ambisyllabic position.

5. Phonetic planning

Phonetic planning involves a) mapping cues onto sets of articulators, and b) assigning values to a set of movement parameters, including timing and spatial parameters (and perhaps accuracy goals).

Selected acoustic cues are mapped onto quantitative acoustic/constriction goals, which are achieved by sets of articulators, or synergies (see [27] for a plausible neural network model of the mapping between acoustics and articulatory goals). We assume that the constriction goals are very similar to the set defined by Saltzman & Munhall [2], and adopted by [27].

We assume that movement parameters include spatial aspects of the constriction target, e.g. lip aperture, tongue tip constriction with the alveolar ridge, etc., a default relative contribution of each articulator in a synergy, as well as a set of timing parameters.

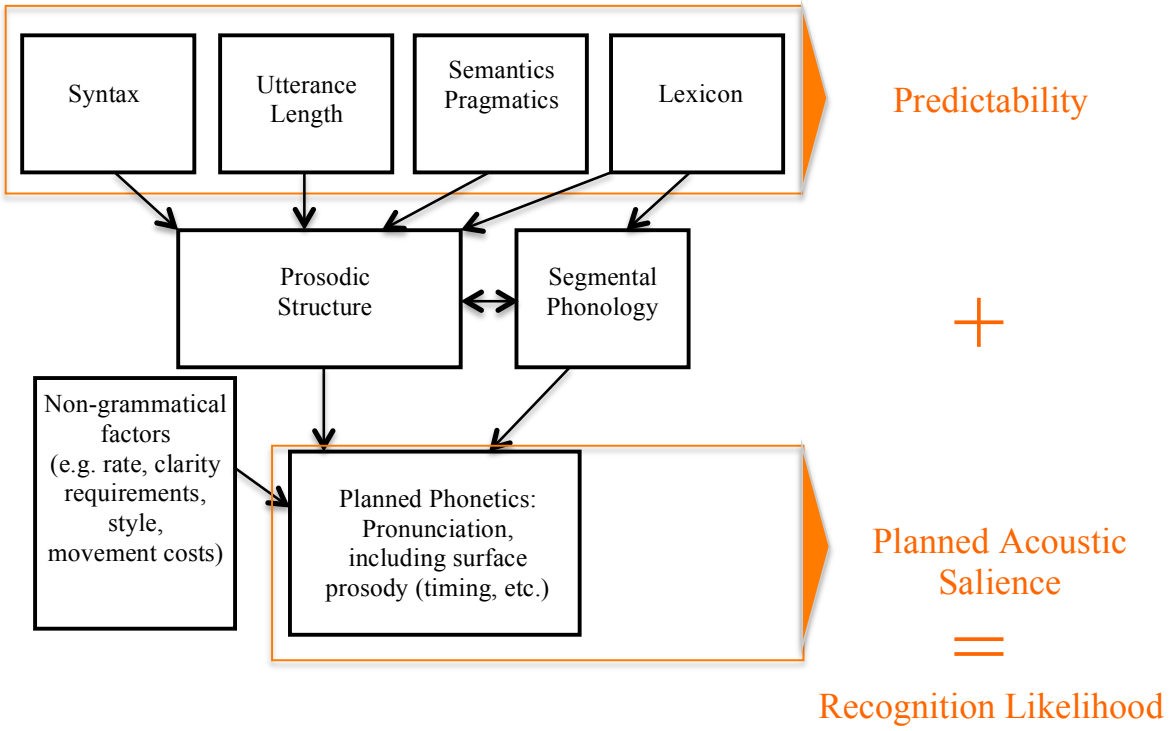

Figure 1: *Factors that shape planned surface phonetics and their relationship **to** predictability, acoustic salience, and recognition likelihood. Based on similar figures in [23,24]*

The timing parameters include:

1. Interval durations of various types, e.g. phrase-final rhyme durations for final lengthening, phrase-initial segment durations for initial lengthening, stressed syllable (or CV) durations for prominence-related lengthening; see [28] for more detail.
2. The timing of acoustic landmarks/constriction targets relative to the preceding one in a sequence.
3. The timing of movement onsets relative to the landmarks/targets
4. The time course of movement (tau, time-to-target achievement at the current movement rate, as a function of time [13]). When combined with spatial information, the tau function determines the velocity profile of movement. Following Lee [13], we assume that tau follows an *intrinsic tau guide*, represented by an equation that describes a family of finite movements (movements from rest that start with an acceleratory component and end after a finite duration): $tauG = k[½(t-T^2/t)]$. The parameters of the equation are T, the duration of movement, and k, which describes the shape of the movement. The variable t is the elapsed time from the start of the movement. Tau-guided movements will have a single-peaked velocity profile if $k < 1$.

5.1. Determining parameter values

It is well-known that surface phonetic characteristics, including timing, vary systematically with prosodic and segmental context, as well as non-grammatical factors such as clarity requirements, rate, and style. Movement timing also varies with movement distance and accuracy requirements (Fitts' law [29]), where longer distance movements take longer in spite of increased movement speeds, and movements with higher spatial accuracy requirements take longer than movements with lower spatial accuracy requirements. All of these factors need to be taken into account in computing timing values. We assume that phonetic characteristics are also constrained by processing demands and movement costs, such as energy, time, and the cost of inaccuracy (see Figure 1). Following Optimal Control Theory [30-32], we propose that movement parameters are determined that represent the optimal balance between prioritized (or weighted) task requirements and movement costs (see [33] for an OCT interpretation of Fitts' law phenomena, and [34] for an example of the use of OCT in a model of speech production).

We acknowledge that computing all of the parameter values for movement is non-trivial, one reason being that parameter values are inter-dependent. For example, the timing between targets in a sequence will depend on timing requirements for supra-segmental intervals such as phrase-final syllable rhymes), and, as we mentioned earlier, movement timing parameter values depend on spatial parameters such as movement distance and accuracy. In the examples which follow, we illustrate the factors involved in determining the values for three of the types of timing parameter specifications defined above.

Example 1: For the timing of at least some intervals that are the sites of durational effects of prosodic context, we hypothesize that requirements for these intervals will have an influence on the timing between movement targets. For example, the timing between targets within the word-final

syllable rhymes will be longer if they are phrase-final than if they are phrase-medial. Because the phrase-final durational requirement is balanced against the cost of time, we expect phrase-final lengthening to be minimized where it can be. Evidence consistent with this view can be found in [37], who observed that it is not the case that e.g. every phrase-final segment has the same duration, rather, all segments of a particular type are longer in phrase-final position than medially, but the amount of absolute lengthening is segment-specific. Nevertheless, the relative durational rank ordering among segments is preserved.

Example 2: For the timing of an acoustic landmark/movement target with respect to a previous landmark, we assume that there is a cost for time that penalizes time between speech landmarks. We hypothesize that the time between targets will additionally depend on prosodic context and other factors, such as rate and style of speech. For example, if the speech rate is slow, the duration between targets will be longer than if the overall speech rate is fast. In cases where the two targets (X,Y) in a sequence involve the same articulators, the duration between targets will additionally depend on the distance between them, and on the target's spatial accuracy requirements, as well as on the energy cost for reaching the second target.

Example 3: For the timing of movement onset with respect to movement target achievement, we assume that costs for time and energy will constrain overall movement time, and that movement time will increase with the spatial accuracy requirement of the target, and will decrease with its timing accuracy requirement, because faster movements are more accurate in terms of their timing [35]. We hypothesize that the relative weighting of these two requirements might vary with speaker and style. Other factors may also affect movement time, such as prosodic position, where some syllable-final movements may be longer than syllable-initial movements (e.g. velum lowering for nasal stops, [36]).

5.2. Coordination for synchronized targets

Lee [13] presents a way of planning movement coordination within an extrinsic timing framework (General Tau theory in this case). On this theory, movements are coordinated through tau coupling, whereby movements whose tau functions are in constant proportion will end at the same time. Coordination can be achieved by coupling one or more movements onto the internal tau guide (mentioned above), or by coupling a movement onto a sensed movement tau. As explained in [40], when two movement tau functions are in constant proportion, e.g. tauA = ktauB, tauA reaches zero as the target is reached, and because tauB is in constant proportion to tauA, it reaches zero at the same time. On this theory, movement coordination involves movement *offset* coordination. It does not require the time course of the movements to be the same, nor is there a strict requirement for the movements to begin at the same time. What this means is that two coordinated movements might have velocity peaks that don't occur at the same time, but as long as their taus are in constant proportion, they will reach their targets at the same time. In addition, if one of two coordinated movements starts later than the other, it is assumed that the later onset movement is accelerated until $tau_{later} = ktau_{earlier}$, and then that the relation is maintained so that the two movements end at the same time [41].

6. Phonetic implementation

Phonetic implementation involves producing movement kinematics to meet planned phonetic goals. Following the VITE (Velocities-into-terminal-endpoints) model of [38], cited in early versions of DIVA [27], we assume that speakers constantly monitor positions relative to a) the planned target (either actual or predicted, depending on the type of predicted and/or sensory information available), as well as b) the time until planned target achievement at each time point (the tau function, [13]). This information is combined to generate appropriate movement velocities to get the articulators to the target on time. Based on evidence in e.g. [39], and following proposals in Optimal Feedback Control Theory [31-32], we further assume that movement corrections and updates can be made during a movement on the basis of sensory feedback and predicted states, and that corrections will be more likely for prioritized parts of movement, e.g. movement offsets, compared to other parts of movement.

7. Coarticulation in sequential movements

One of the key contributions of AP/TD is its account of coarticulation. In our model, coarticulation falls out of the relative timing of movement targets, and of the movement times required to produce the targets on time with required spatial accuracy.

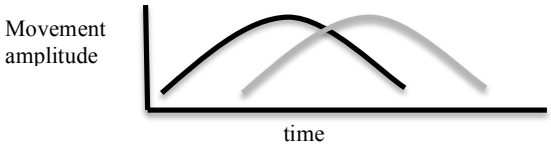

Figure 2. Schematic diagram of coarticulation, where the target of movement A (black) is timed to occur before the target of movement B (grey)

If movement targets are timed closely together, and are produced with different sets of articulators, then for a sequence of two targets AB, the movement onset of B will begin before the movement target A is reached. This is illustrated in Figure 2.

8. Conclusion

The main advantage of our proposal is that it is likely to provide a better fit to existing data in the literature than the AP/TD model, currently the best-worked-out model of speech production. In our experience, careful consideration of a well-motivated alternative to a dominant model can often result in improvements in both competing models. The major drawback to our proposal is that it is still only a model *sketch*. We have not implemented it, and as we note above, implementation will be non-trivial. Attempts to implement it will no doubt bring many deficiencies and oversights to light. However, we hope it will provide a framework for asking fruitful questions about how to model timing in speech production, and for interpreting timing data.

Abstract

This paper presents SLAM : a simple method for the automatic Stylization and LAbelling of speech Melody. The main contributions over existing methods are : the alphabet of melodic contours is fully data-driven, an explicit time-frequency representation is used to derive complex melodic contours, and melodic contours can be determined over arbitrary prosodic/syntactic units. Additionally, the system can handle some specificities of spontaneous speech (e.g., multi speakers, speech turns and speech overlaps). A preliminary experiment conducted on 3 hours of spoken French indicates that a small number of contours is sufficient to explain most of the observed contours. The method can be easily adapted to other stressed languages. The implementation is open-source and freely available †.
Index Terms : intonation, stylization, automatic labelling, prosody, syntax.

1. Introduction

The transcription of speech prosody aims at representing the variations of speech prosody that are considered as relevant with an alphabet of elementary symbols [1, 2, 3, 4], which each instantiates a function in the speech communication process. The inventory of this alphabet is desired to facilitate further studies on the function of speech prosody in speech communication, from prosody/syntax to prosody/discourse and dialogue interfaces, from formal to spontaneous speech.

The first representation of French intonation in terms of global contours [5] focused on modal intonation : a global melodic contour specifies the modality of a sentence (e.g., interrogation, exclamation). More recently, this paradigm was extended to the representation of intonation as the superposition of melodic contours over various syntactic units [6]. The main contribution of this paper tends to the generalization of this paradigm to any linguistic unit – prosodic and syntactic. In other words, we assume that a specific dictionary of elementary contours can be derived for each linguistic unit.

This paper presents a novel method for the automatic labelling of melodic contours over arbitrary prosodic/syntactic units. The main contribution of the method compared to existing methods [2, 3, 7, 8, 9] can be summarized as follows :

- The melodic system (i.e., the alphabet of melodic contours) is fully data-driven (bottom-up processing).
- An explicit time-frequency representation is used to describe complex melodic contours.
- The proposed representation handles a large variety of prosodic/syntactic units : from local (e.g., syllable) to global contours (here, prosodic and syntactic).

Additionally, the representation is normalized with respect to the average range of a speaker, and handles some particularities of spontaneous speech (e.g., multi speakers, speech turns, speech overlaps). Lastly, the implementation is open-source and freely available.

The remainder of this paper presents the main principles of the method used for the transcription of melodic contours over arbitrary prosodic/syntactic units. The compact form of the alphabet of contours proves the efficiency of the proposed method : around 10/20 elementary contours suffice to explain 95% of the observed contours.

2. Intonation Labelling

2.1. Speech Preprocessing

The only external requirements for the automatic labelling are : the estimation of the fundamental frequency of speech (F0), and the segmentation of speech into speech units that are desired for the description of speech prosody (arbitrary prosodic/syntactic units). For the F0 estimation, popular methods are freely available (e.g., STRAIGHT [10], YIN [11], and SWIPE [12]). Also, many refinements to the F0 estimation exist to facilitate further processing - from F0 periodicity estimation (and voiced/unvoiced decision - similarly to [8]), to F0 smoothing and interpolation methods. For the speech segmentation, speech-to-text alignment methods exist (IRCAMALIGN [13], EASYALIGN [14], and SPPAS [15] among others - usually based on the open-source HTK library [16]) for the segmentation of speech into phonemes, syllables, words, and phrases. Also, alternative methods exist for language-independent speech segmentation into syllables and phrases [17].

2.2. Acoustic Representation

The acoustic stylization of speech melody consists in representing the F0 variations that are considered as relevant for the description of speech prosody. In general, F0 stylization methods are based on the representation of F0 variations according

†. This study was supported by the French National Research Agency (ANR) for the RHAPSODIE project : reference prosody corpus of spoken French. The resource is implemented in python and freely available on : `https://github.com/jbeliao/SLAM/`. The current release supports PRAAT TextGrid input/output format for segmentation and labelling. There is no need for preliminary F0 estimation, which is processed automatically with the python implementation of the SWIPE algorithm (see `https://github.com/kylebgorman/swipe/` for details).

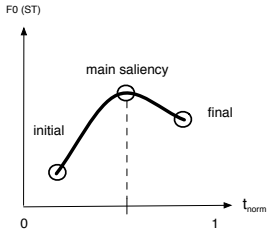

FIGURE 1 – *Acoustic representation of a contour.*

to a small set of parameters that are used to describe slowly time-varying F0 variations [18, 19, 20, 21]. In the proposed method, the F0 contour is represented by a set of 5 acoustic values for each given unit :

1. INITIAL : the initial value of the F0 on the unit. This value corresponds to the first F0 value for which the acoustic frame is considered as voiced ;
2. FINAL : the final value of the F0 on the unit. This value corresponds to the last F0 value for which the acoustic frame is considered as voiced ;
3. MAIN SALIENCY : the value corresponding to the most salient F0 peak – if one exists. The F0 variations over a unit can be decomposed into a main saliency (optional, if present) and a set of secondary salience (optional, if present). The method assumes that only the main saliency contributes to the definition of a global contour, while secondary salience contribute to the internal structure of the global contour, and can be neglected in a first-order approximation.

Finally, the following values are added to the description :

4. MAIN SALIENCY POSITION : the time position of the main saliency ;
5. LOCAL REGISTER : the mean F0 over the unit.

All frequency values are expressed in semi-tones (STs), with respect to the overall mean F0 of the speaker :

$$\text{F0[ST]} = 12 \times \log_2 \frac{\text{F0[Hz]}}{\text{F0}_{\text{mean}}\text{[Hz]}} \quad (1)$$

All time positions are expressed relative to the boundaries of the unit :

$$t_{norm} = \frac{t - t_{start}}{t_{end} - t_{start}} \quad (2)$$

This acoustic representation adapts automatically to the nature of the prosodic/syntactic unit. Here, the notion of micro and macro prosodic variations is assumed to be relative to the linguistic unit considered : for short units (and local contours ; e.g., syllable), the phoneme variations will be considered as micro variations compared to the syllable variations ; for large units (and global contours ; e.g., phrases), the syllable variations will be in turn considered as micro variations compared to the larger unit.

2.3. Symbolic Representation

The acoustic representation presented in the previous section serves as a time-frequency representation for the labelling of contours.

2.3.1. Frequency Quantization

First, frequency values are represented with respect to 5 pitch levels covering the whole F0 range of the speaker (table 1). Each pitch level covers a range of 4 semi-tones centred on the average F0 value of the speaker. For instance, the medium range covers from - 2 STs to + 2 STs around the average range of the speaker ; the high range covers from +2 STs to +6 STs ; and the extreme-high range covers all values that exceed +6 STs.

PITCH LEVELS	DESCRIPTION	RANGE (STs)
H	extreme-high	$>$ +6
h	high	+2/+6
m	medium	-2/+2
l	low	-2/-6
L	extreme-low	$<$ -6

TABLE 1 – *Pitch levels used for the symbolic representation.*

From this representation the sequence of initial/final/saliency values can be converted into a corresponding sequence of pitch levels. Then, this representation can be used to describe static tones, simple contours, and complex contours. An illustration is provided in figure 2.

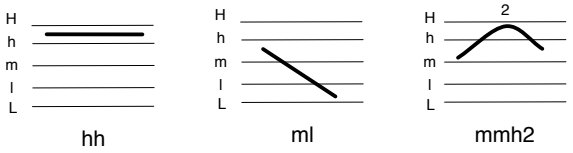

FIGURE 2 – *Types of contours that can be described. From left to right : a static tone (flat contour in the high range of the speaker), a simple contour (a falling contour from the medium to the low range of the speaker), and a complex contour (medium to medium with a saliency observed in the high range of the speaker in the middle part of the unit).*

Additionally, the main saliency is considered as significant only if the corresponding point differs by more than 2 ST from the initial and the final points. If this is not the case, the main saliency is not considered as relevant, and is removed from the symbolic representation of the contour. An illustration is provided in figure 5.

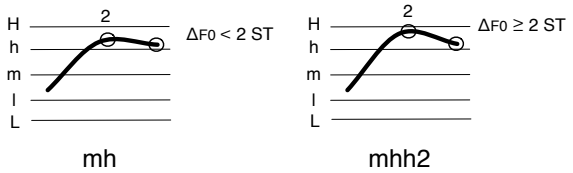

FIGURE 3 – *Determination of the presence of a saliency. On the left, the saliency is not considered as relevant, and the contour is transcribed as "mh" (medium to high) ; on the right, the saliency is relevant, and the contour is transcribed as "mhh2" (medium to high with the presence of a saliency in the second part of the unit).*

2.3.2. Time Quantization

Second, the time position of the main saliency is represented with respect to 3 time positions, which are determined from the relative position of the saliency within the unit and the decomposition of the unit into 3 equal parts 2. An illustration of contours with various positions of the main saliency is provided in figure 5.

TIME POSITION	MAIN SALIENCY
1/3	first part of the unit
2/3	middle part of the unit
3/3	last part of the unit

TABLE 2 – *Time position of the main saliency of a contour used for the symbolic representation.*

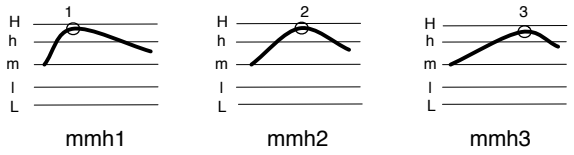

FIGURE 4 – *Contour labelling with regard to the position of the saliency within the unit. From left to right, a saliency is observed in the first/middle/last part of the unit.*

2.3.3. Formal Representation

Finally, the time-frequency representation is formally described as :

Initial Final [Saliency] [Position]

where [.] indicates optional fields dependent on the relevancy of the main saliency. Illustrations of the various contours that can be represented are shown in figure 2.

The alphabet of this formal representation is expressive in the sense that the alphabet can cover a large variety of contours - here, 400. Theoretically, the optimality of a phonological system assumes the smallest number of elements required to account for the largest number of observations. Practically, a compact alphabet is desired to facilitate labelling and linguistic interpretation. For instance, the inventory in the ToBI system (in order to describe phrasal tones and pitch accents) includes two elementary tones (H, L), and around 5 to 8 pitch accents have been proposed for American-English [22]. In order to address the efficiency of the proposed representation, a preliminary experiment will be described in section 3, which proves that a small number of contours (around 10/20) is sufficient to explain most of speech prosody variations in the real-conditions of ordinary speech. An illustration of the acoustic representation and the labelling of contours is provided in figure 5.

3. Experiment

A preliminary experiment was conducted on the RHAPSODIE treebank (prosody/syntax) of spoken French [23], composed of speech recordings of French ordinary speech and orthographic transcription. The transcription and the annotations are all aligned on the speech signal : phonemes, syllables, words, speakers, speech turns, speech overlaps. The RHAPSODIE treebank comprises : 57 speech recordings, 3 hours of ordinary speech, and 33,000 words ; multiple situations : monologue/dialogue, formal/informal ; multiple speakers : male/female.

Firstly, the analysis of contours reveals that a small number of contours suffices to explain most of the observed contours : around 10/20 elementary contours suffice to explain 95% of the observed contours, regardless of the prosodic/syntactic unit (table 3, see [23] for details). This can be interpreted as follows : a small number of elementary contours commonly serves for usual speech communication, and a variety of rare contours may convey specific speaker and/or expressive information (e.g. emotions). This constitutes a first validation concerning the acoustic/symbolic representation : the representation is efficient (a small alphabet explains most of the observations) and expressive (the representation can describe a variety of contours that are not accounted by the standard alphabet).

Secondly, the distribution of the most observed contours is detailed for some prosodic/syntactic units in figure 6 (here, syllable, discourse markers, and illocutionary units). In particular, the alphabet substantially changes depending on the prosodic/syntactic unit : in comparison with the common syllable unit, the discourse marker and illocutionary units present a larger variety of contours (e.g., extreme ranges, complex contours), that potentially instantiates various functions : from modalities, to semantic and pragmatic. This constitutes a second validation concerning the labelling of contours over various prosodic/syntactic units : an alphabet of contours can be derived specifically for each prosodic/syntactic unit.

In conclusion, the representation can derive a small alphabet of contours that is specific to each prosodic/syntactic unit, that can be advantageously used for automatic labelling. This is crucial for further research on the role of prosody in speech communication : the grail search for the mapping of forms and functions.

4. Conclusion

This paper presented a simple method for the automatic labelling of intonation. The proposed method presents various advantages over existing methods : the alphabet of contours is fully data-driven, an explicit time-frequency representation is used to derive complex contours, and contours can be determined over arbitrary prosodic/syntactic units. A preliminary experiment conducted on 3 hours of spoken French indicates that a small number of contours is sufficient to explain most of the observed contours. The method can be easily adapted to other stressed languages. The implementation is open-source and freely available. This representation will be further used to study the role of speech prosody in speech communication, from prosody/syntax and prosody/discourse interfaces [24, 25], to the modelling of speech prosody for text-to-speech synthesis and voice conversion [26].

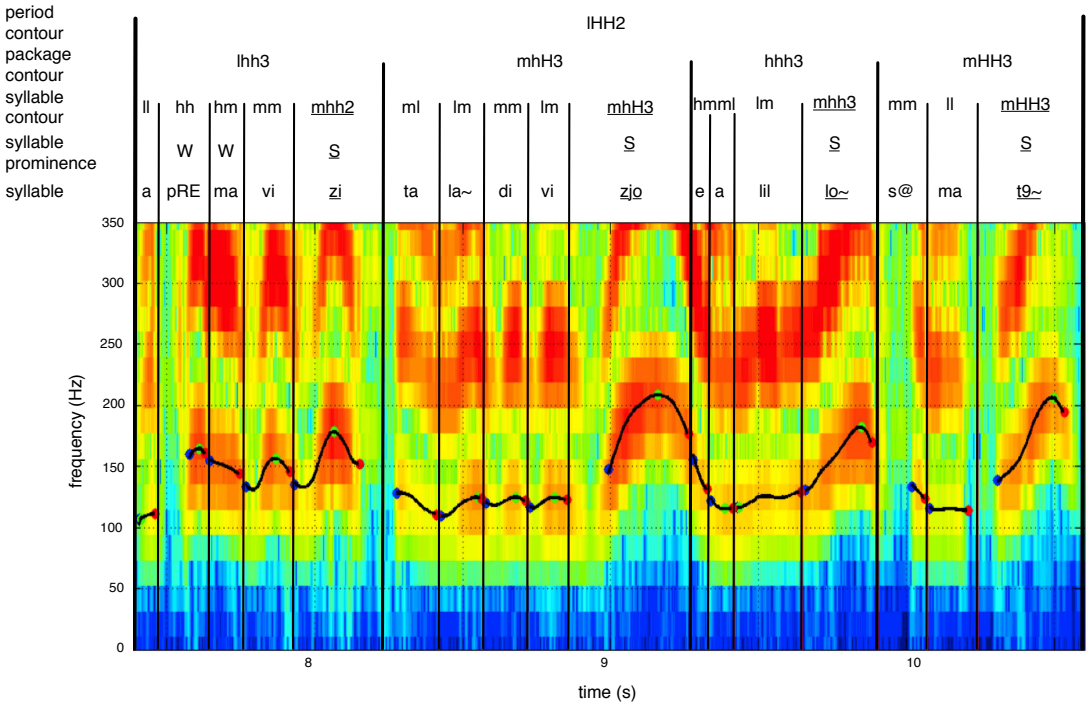

FIGURE 5 – *Acoustic representation and labelling of contours over syllable, prosodic package, and prosodic period for the speech sequence : "Après ma visite à Landivisiau et à l'île Longue ce matin" ("After my visit to Landivisiau and l'île Longue this morning"). Lexical Stress in Brazilian Portuguese in Contrast with Spanish

Antônio R.M. Simões

Department of Spanish and Portuguese, University of Kansas, Lawrence, USA

asimoes@ku.edu

Abstract

This study discusses stress assignment in prosodic, non-verbal words in Brazilian Portuguese, in comparison with descriptions of stress assignment for Spanish [9, 13, 15, 16, 17, 18]. Given the conflicting claims regarding stress assignment in Brazilian Portuguese (see [11, 1, 2, 10, 3]) there is still a need to revisit discussions on stress assignment in Portuguese. In general, stress assignment in Spanish has been explained through the interplay between the morphological and phonological domains. Similar descriptions for Portuguese still requires far more abstraction and use of artifacts than in Spanish, which makes Mattoso Câmara Jr.'s [4, 5] claim that lexical stress is unpredictable in Brazilian Portuguese surprisingly unchallenged.

Index Terms: stress assignment, prosodic stress, syllable weight, Spanish and Portuguese

1. Introduction

This is a phonological study in progress developed to provide the author with adequate grounds for future phonetic analyses of stress and intonation systems in Spanish (SP) and Brazilian Portuguese (BP) in contrast. Therefore, this study is not yet based on actual data analysis, but instead on current theoretical descriptions of stress assignment.

In BP and SP there is a strong pressure to stress words on the penultimate syllable, i.e. paroxytones. In both languages, the great majority of words are paroxytones. Despite this coincidence, predicting lexical stress BP is not as governable as in Spanish. Among the differences in phonological and phonetics patterns between both languages, the most significant is perhaps the phonetically weak or unstable surfacing of postonic syllables in BP and the relatively stable surfacing of postonic syllables in Spanish.

This different behavior of postonic syllable in both languages is reflected in versification. Spanish and Portuguese count syllables in verses differently, in ways that reflect their rhythmic patterns. Portuguese counts the number of syllables until the last stressed syllable, whereas in Spanish the number of syllables is computed until the last stressed syllable plus one, regardless of the physical existence of a postonic syllable.

Thus, Martí's verses below have eight syllables each. As an illustration, if we did the counting of Spanish verses in the way Portuguese versification does, these verses would have seven syllables each. But in fact, they have eight syllables each. The dot (.) indicates syllable boundaries after resyllabification, accounted as needed. The last lexically stressed syllables in each verse are in capitals.

Yo . soy . u . (also so . yu) nhom.bre . sin.CE.ro (8 syllables)
De . don.de. cre.ce. la. PAL.ma, (8 syllables)
Y an.tes . de. mo.rir.me . QUIE.ro (8 syllables)
E.char . mis .ver.sos. de.l AL.ma. (8 syllables)
(...)
Oi.go un . sus.pi.ro, a. tra.VÉS (7+1 = 8 syllables)
De . las . tie.rra.s y . la . MAR, (7+1 = 8 syllables)
Y . no e.s un . sus.pi.ro,—ES (7+1 = 8 syllables)
Que . mi hi.jo . va a . des.per.TAR. (7+1 = 8 syllables)
(Poesía de José Martí, Versos Sencillos, 1981)

These differences and similarities of both languages can be further refined. Similar trends to move stress in proparoxytones to paroxytonic position happen in both languages, although the phonological processes are different.

olimpíadas → olimpiAdas	*abóbora → aBObra*
¡Pórtate bien! → ¡PorTAte bien!	*xícara → XIcra*

The preceding examples show similar trends in both languages. There are, however, important differences to take into account when attempting to propose stress assignment algorithms in Portuguese. For example, in SP, and only to a certain extent in Portuguese, a great number of words stressed on the antepenultimate syllable are learned words or *palabras cultas* or *palavras cultas* in both languages, which are sometimes taken from Greek sometimes from Latin, e.g. *Arquímedes* in SP but *ArquiMEdes* in BP, *Demóstenes* in both languages, *hypérbaton* in SP and *hipérbato* in BP, *épsilon* in SP and *ép[i]silon*, *ép[i]silo*, *íp[i]silon* or *ip[i]diLOne* in BP, *máximum* or *máximo* in SP and *máximo* in BP, *régimen* in SP but *reGIme* in BP and many other examples. Thus, while trends in SP are relatively more predictable, BP shows no clear trends, i.e. less predictability. This lack of clear trends permeates BP, contrary to SP.

A comparison of trends to paroxytone patterns in SP hypocoristics with no such trends in BP further reveals the difficulty researchers face to create an algorithm to predict stress assignment in BP. Hypocoristics in both languages are enlightening in this discussion. Whereas SP has a predominant pattern of disyllabic paroxytones for hypocoristics, BP produces disyllabics, monosyllabics, paroxytones and oxytones hypocoristics, without particular trends, as the Table 1 illustrates.

SP does have dialectical variations that use monosyllables in hypocoristics, e.g. Daniel ~ Dan, Cristina ~ Cris, but it happens less frequently than the patterns above, and it usually happens in closed syllable (CVC), while monosyllables in BP have open syllables (CV). In BP the variations are much greater.

Penultimate stress is also more predictable in SP loanwords, acronyms and foreign proper names, but not in BP, as depicted in the comparison below in Table 2. These examples show further the greater tendency in SP to stress penultimate syllable, compared to Portuguese.

The next section will discuss the notion of prosodic words and metrical notions common in the American generative frame of Metrical Theory. This study is only using the generative frame to discuss metrical theory as it has been applied to SP, and to show how difficult if not impossible and unmotivated it is to attempt to predict lexical stress in Portuguese. In other words, although the generative frame is very useful to discuss stress

assignment in any language, this study does not support the claim that it can predict stress assignment in Portuguese.

Table 1. *A comparison of trends in Spanish hypocoristic and the lack of trends in hypocoristic in BP.*

Given the three types of syllable prominences in words of the two languages, e.g. the SP triplet *CÉlebre, ceLEbre, celeBRÉ*, the BP triplet *PÁssara, pasSAra*[1], *passaRÁ*, the two languages have proparoxytones, paroxytones and oxytones. In order to discuss stress assignment in the following sections, it would be helpful to firstly review the concepts of prosodic word, prosodic stress and syllable weight, and then discuss the case of the most common pattern, the paroxytones, then the proparoxytones and finally the oxytones.

[1] Postonic vowels in BP change considerable in quality, but in the case of the /a/, an inherently strong vowel and more resistant to significant changes in quality, the stress contrast in this triplet is still a valid one, especially in careful clear speech.

2. Discussion

Although I do not follow the common division of words into a simple classification of two main classes, **content** and **function** words, it is helpful to use them in this discussion. Thus, in Linguistics it is common to say that content words are the only ones that receive lexical stress, while function words are unstressed. By the same token, prosodic words have stress and function words or **clitics** do not. Although I do not see a problem to classify words in terms of content and function words, I do not agree that they correlate 100% with having or not having (lexical) stress. Function words sometimes have one **prominent** syllable if they have more than one syllable, e.g. the word for "while," *enquanto* in Portuguese and *mientras* in SP. But it is helpful to assume the notion of stress used here, because it makes it easier to compare stress assignment in SP and Portuguese within the generative frame of Metrical Theory. I am also using this view to make this discussion manageable. I am using this view to refuse current explanations that generative grammar is capable of predicting word stress in BP.

Taking the preceding remarks into consideration, mora (μ) is the unit that makes the prominent weight of prosodic feet. In SP, its weight is generally uniform, one mora. In SP, contrary to English, even in complex nuclei like diphthongs, all vocalic features of a syllable nucleus fit into one mora, as illustrated with the word *sentimiento*:

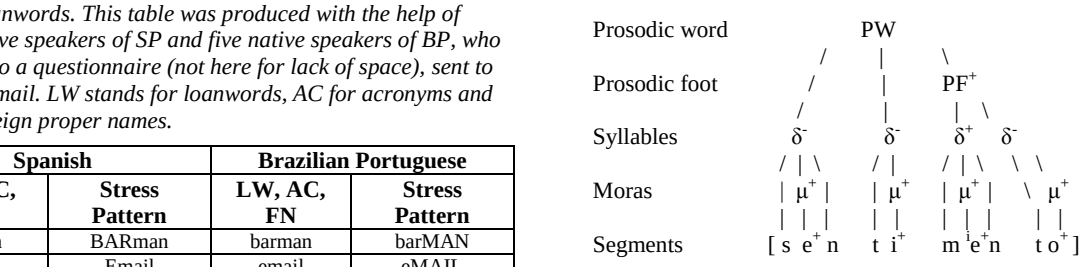

Figure 1. *The prosodic structure of the Spanish word* sentimiento*, to illustrate the concept of mora (μ).*

SP does not contrast the so-called heavy or bimoraic syllables and light or monomoraic syllables. The words "array, key, pie and tear (=rip)" in English, for example, contrasts heavy and light syllables: aᵘ.'rraᵘyᵘ, 'keᵘyᵘ, 'piᵘeᵘ, 'teaᵘrᵘ. Hence, in English one syllable words are binary in terms of the number of moras. The majority of English words have one syllable. SP needs two syllables to have two moras and the majority of SP words have two syllables. BP shows these SP characteristics without the regularity or uniformity found in SP. For example, in Rio, and maybe in some other areas of Brazil, but particularly in Rio, we find bimoraic and monomoraic contrasts, e.g. when answering the phone: "Alô!," "a ᵘ.loᵘaᵘ." It is important to keep in mind that we are thinking of a system found in social middle classes and higher. If we go into the SP spoken in rural areas of the Hispanic world and in the underworld of drug dealings, these will be completely different varieties of SP. The same can be said about Portuguese spoken in similar contexts.

The structure of paroxytonic words contains a nucleus in the two last syllables, identified with the symbols "<" and ">":

cua<derno>, <casa>, carre<tera>, pensa <miento>, <tráiga> melo, desespe<rándo>nos, desafortunada<mente>. These nuclei are *prosodic feet*, as illustrated with the word *final*<*mente*>, in Figure 2.

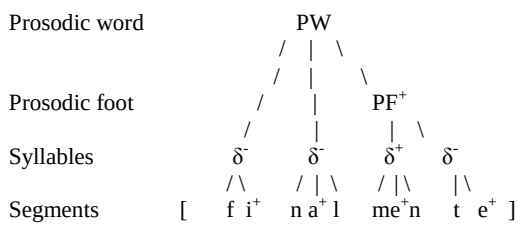

Figure 2. *The prosodic foot <mente> in the Spanish word* finalmente.

Given the framework used in this discussion, the preceding structure helps determining stress in SP paroxytones because words like "finalmente" contain all the basic structural requirements of finality, trocaicity and binarity. In BP we also find similarities in paroxytones. The obstacle one will find in BP is to fit proparoxytones and oxytones into these ideal structural property requirements. According to the generative frame, in SP, although oxytones seem, in a superficial look, to have unary foot (co.li.<brí>), and proparoxytones terciary foot (<sá.ba.do>), this can be solved with a morphological interpretation, as shown later in this discussion.

SP is known to have words with proparoxytonic stress because proparoxytones include vowels without morae, resulting in **extrametrical** elements.

Words like *mínimo, sábana, número* will have a non-moraic vowel in its root (mín<u>i</u>m-o, sáb<u>a</u>n-a, núm<u>e</u>r-o). Consequently, root morphemes such as these, with one syllable without weight, carry the potential to cause **retraction of stress**, as illustrated with the word *espárrag-o* in Figure 3, because their penultimate syllable *(-rra-* in the case of *espárrago*) is invisible to rules, or extrametrical. This characteristic or idiosyncrasy of proparoxytones leads to the conclusion in the generative framework that stress assignment in SP is morphologically conditioned. This morphological condition also applies in a different way to oxytones.

This invisibility, usually considered a relatively "small problem" in generative Metrical Theory, can be said to reduce the transparency of these processes. Other words carry this invisibility: *murciélago, máscara, árabe*. Portuguese for example, commonly deletes the non-moraic vowels like the one in *máscara* as *mascra*.

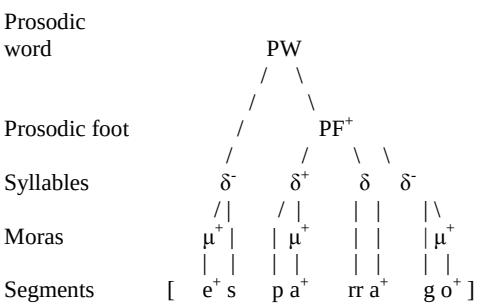

Figure 3. *The morphological interpretation of proparoxytones as underlying paroxytones.*

Therefore, root morphemes can result in stress retraction. Suffixes can also cause retraction. Derivative suffixes also result in retraction, as in words with the suffixes *–ic* as in *metál<u>i</u>co, canón<u>i</u>co.*

Here, as in other seemingly exceptional cases, morphological elements help understanding. The main explanation in cases such as *astronómico* is based on the concept of morphological nuclei. In other words, the morphemes in *astronómico* are *astr-o-nom-ic-o.* The morphemes *–nom* and *–ic* are some of the morphemes that have a non-moraic vowel. Given that *–ic*, and not *–nom*, is the morpheme that characterizes "astronómico" as adjective, then *–ic* is the nuclear morpheme that keeps the vowel invisible. In this exceptional case, *-nom* then is not a nuclear morpheme and consequently it carries one mora.

The same arguments can be attempted in Portuguese and most of the examples in SP are similar in BP: *mínimo, número, canônico, metálico, cronômetro, astrônomo*. Therefore, according to the preceding discussion, proparoxytones have the conditions of syllable foot on the right of the word, just as paroxytones do, as follows. (1) Only morphemes that function as morphological nucleus can retain non-moraic vowels. This also explains why this type of word is not common; (2) Given the condition above, the same principles of paroxytones apply to proparoxytones: binarity, finality and trocaicity.

If we keep the same view we have been using in this discussion, oxytonic words are also morphologically conditioned. Whereas derivative morphemes or morphemes with morpho-syntactic function interferes in the irregularity of stress assignment of proparoxytones in SP, in the case of oxytones the reason of irregularities has to do with morphemes whose function is exclusively morphological. In SP, the morphemes that have an exclusively morphological function are the class markers and markers of person/number, which normally appear at the very end of words. A distributive test helps knowing which ones mark class and the ones that do not. For instance, if we add *–er* morpheme to *joy<u>a</u>*, we obtain *joyero*, and not *joyaero. Therefore this *<u>a</u>* in *joya* is a class marker. Likewise, *guante* obtains *guantera* (not *guanteera).

In the case of *café*, we obtain *cafetera* with the insertion of *t* to preserve the *e*, which indicates that *e* in *café* is not a class marker. Likewise *maní – manicito, sofá – sofacito*, with the insertion of *c* to preserve the vowels *i, a*, in these cases with diminutive *–it*, these vowels are not class marker either. The conclusion is that oxytones ending in vowel behave as if they lacked class marker.

Oxytones ending in consonants also share this trait, *mujer*, *laurel*, *caimán*. Taking into account that in SP the majority of words ending in consonant are oxytones, there is a relation between oxytones and the lack of word markers. Furthermore, this lack of word marker leaves an "empty" slot at the end of words.

All common SP words or *palabras patrimoniales* have class markers. That is because some words have prosodic structure, but not segmental structure. In other words their morphemes are **catalectic**. Basically, SP has regular moraic class markers (all five vowels a, e, i, o, u) and catalectic class markers.

Having prosodic but not segmental structure creates opacity. Such a description of stress assignment in oxytones says that the segment is invisible although there is a prosodic structure.

There is evidence for this claim. For instance, if we take into account the singular and plural forms for *sofá* and *mujer*, this claim may be more easily accepted despite the opacity of the description with respect to the oxytones.

Therefore, plural formation in SP also supports this idea of catalectic class markers. SP forms plurals with the morpheme/suffix *–s*. Since *–s* is inflectional, it will go after derivate morphemes. In words with regular plural formation, the process is transparent: *pal-o-s, car-a-s, cruc-e-s, curs-i-s, trib-u-s*. But in the case of catalectic class markers adding plural morphemes forces the catalectic element to acquire a segmental content: *sofá-e-s, maní-e-s, mujer-e-s, caiman-e-s*.

This additional *e* with the plural morpheme reveals the "emptiness" of the catalectic space, as well as other characteristics of SP such as the preference for CV sequences and the use of epenthetic *e*, which is the only vowel that SP uses in epenthesis. In its plural form, the word becomes paroxytone. Given this argumentation, it is reasonable to say that all oxytones, regardless of its ending in vowels or consonants and contrary to paroxytones and proparoxytones, lack a class marker, that is to say inflectional morphemes.

A way to explain this lack of inflectional morphemes is to assume that the space is there, and it can be said to be a prosodic "space," not segmental. Therefore, the underlying structure of oxytones should have a prosodic mora that is filled out with a physical segment as needed. This leads, among other consequences, to assigning an underlying *e* vowel that will surface in plural forms of oxytones. This description has a number of advantages and the most obvious is the generalization of assigning only *-s* to plural, instead of two rules, one for adding *-s* and another to add *-es*.

In the case of words like *café* and *té* the insertion of *e* still happens, and in actual speech this fusion is common in SP (*mijito* for *mi hijito*) or *alcol* for *alcohol*). Some dialects have variations (e.g. *sofás, rubís*), but the description of stress assignment must be maintained within the same register of a dialect of reference. Otherwise, if one considers how different SP can be throughout the Hispanic world, stress assignment as a general trend would be unnecessarily difficult if not impossible to describe. It is simpler and desirable to stay within the limits of a given register that is considered representative, and then move on into different dialectical variations. For the intended description of stress assignment for this discussion, we used the acrolect as reference. Taking the educated register into consideration, we need to keep in mind that the morphological nucleus changes by adding a derivative suffix, e.g. *verd-e, verd-ur-a* or *verd+or+catalexis*.

As *–ur* and *–or* become the morphological nuclei, they select the segment *a* and a prosodic mora as class markers. Among morphemes that select class markers, the most commons in SP are *-dad*, *-itud*, *-ción*, *-zón*, *-dor*, *-al*, *-il*, and *–r*.

There are obviously serious flaws with the framework just discussed. It requires accepting an *adhoc* description and the assumption that the opacity is an acceptable price to pay, given the other advantages of the description. These flaws are even worse in the case of Portuguese.

In the case of oxytones in BP, for example, one can attempt to propose a process similar to the one in SP. All non-verbal plural would be formed with one rule, by adding *-s* to the singular form. Through this view, in BP, in the case of oxytones, there is no physical segment in the slot where normally an inflectional morpheme is expected. Words need a class marker to indicate its lexical class. The explanation then, seems to be similar to the one for SP, which would be desirable without flaws because it would require only one rule of plural formation. Therefore, if oxytones have an invisible prosodic unit that we can call mora, it materializes as *e*. Portuguese words like *sofá*, *café*, *colibri*, *mulher* and *mar* would then add *-s* in their plural. After the addition of *s*, *e* would be inserted before s, and finally carry on other known phonological processes of BP as needed:

sofá_ → sofá_s → sofáes → sofás
café_ → café_s → cafées → cafés
colibri_ → colibri_s → colibries → colibris
mulher_ → mulher_s → mulheres → mulheres
mar_ → mar_s → mares → mares
azul_ → azul_s → azules → azues → azuis

The processes above can also be viewed as tree diagrams in the singular and plural forms:

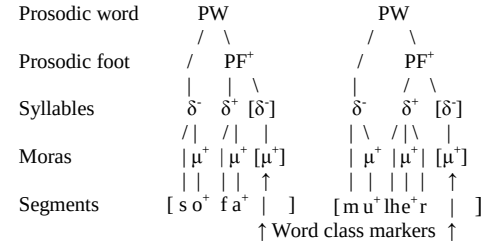

Figure 3. *Brazilian Portuguese words* sofá *and* mulher.

As it can be seen, however, it would be necessary to propose biased underlying forms based on historical forms for other words **brasiles*, **papeles*, **colchones*, which have no synchronic correspondences or motivation in BP. Then, it may be simpler, more efficient and more realistic to maintain Mattoso Câmara Jr.'s [4, 5] claim that lexical stress in Portuguese is unpredictable. One must use memory to learn stress placement in Portuguese.

3. Conclusions

This study examined lexical stress assignment in SP to help understanding why lexical stress is unpredictable in BP. The degree of abstraction, the creation of artifacts and various other flaws to create an algorithm for lexical stress assignment in BP make such an algorithm unnecessarily complicated. In the history of sciences we well know that the more complicated a description is, the far we are from truth.

Unpredictability should not be regarded as undesirable. It is just inherent in some aspects of natural human languages. Stress assignment is most likely unpredictable in Russian [12], to appear) and very likely in English as well [14], in spite of the claims in Chomsky and Halle [6] that it can be predicted.

4. Acknowledgements

I am very thankful to Juliette Blevins, at CUNY, and Seung Hwa Lee, at UFMG, in Brazil, for their helpful discussions with me, about lexical stress. I am also thankful to the anonymous reviewers who made valuabe comments to improve this study. The interpretations in this study are mine.

Prosodic Characteristics of Vocalic Hesitations in Comparison with Overlong Vowels in Estonian

Rena Nemoto

Institute of Cybernetics at Tallinn University of Technology, Tallinn, Estonia
rena.nemoto@phon.ioc.ee

Abstract

The goal of this paper is to investigate vocalic hesitations in Estonian and compare them to the related vowels of overlong (Q3) quantity degree. We wonder if there are some language-specific characteristics of hesitations. If yes, which kind of characteristics can be observed in Estonian language? We analyze duration, fundamental frequency (f_0), intensity, and first two formants using 39.5 hours of manually transcribed mono- or dialogue speech from a spontaneous speech corpus. Investigated vocalic hesitations and Q3 vowels are: */ee*, *ää*, *aa*, *õõ*, *öö/*. The characteristics of hesitations as compared to those of Q3 vowels show that hesitations have longer duration range. Hesitations generally include lower f_0 and intensity values. However, the values vary in terms of vowels. First two formants of hesitations tend to be located at more centralized positions in a vocalic triangle than related Q3 vowels.

Index Terms: vocalic hesitation, Estonian, spontaneous speech, prosody

1. Introduction

Hesitations carry language-specific information. The transcription of vocalic hesitations varies across languages, for example uh/um in American English, *euh* in French or *eh* in Spanish suggesting differences in their perception by native speakers [1]. So we wonder what kind of specific can be found in Estonian language. An early Estonian disfluency study by Hennoste [2] described particles and um-s as initiators of repair in Estonian spontaneous speech. One of the most frequent um in spoken Estonian is *ee*. The um *ee* contained 38% of all um-s in the studied corpus. The other frequent um-s were expressed by *õõ*, *ää*, *mm*, etc. But little study has been done to explore these um-s in Estonian at acoustic level. We are then interested in studying these vocalic hesitations at acoustic level. Hesitations are expressed by lengthened vowels (cf. Figure 1 from [3]) or consonant /mm/, or mixing a vowel with a consonant, etc.

Estonian is a language with word-initial lexical stress in general [4], even though some exceptions like loanwords [5] can be found. And Estonian has a three-way quantity system referred as short (Q1), long (Q2), and overlong (Q3) quantity degree. Most studies of the three-way quantity system concentrate on disyllabic words and compare first and second syllables at foot level: for example (Q1) *sada* /sata/, hundred, singular nominative; (Q2) *saada* /saata/, to send, verb: singular imperative; (Q3) *saada* /saa:ta/, to get, verb: infinitive [5]. The quantity system is complex combining durational and tonal components. Lippus [6] explained the f_0 peak as follows: the peak for Q1 and Q2 is located usually in the second half of the stressed first syllable, but for Q3, it usually appears in the beginning of the stressed syllable vowel.

As overlong (Q3) vowels have longest duration among quantity degrees, we compare prosodic and acoustic behaviors between five vocalic hesitations (lengthened vowels) and its related overlong vowels. In this paper, we address the question as follows: how prosodic features of vocalic hesitations behave from the beginning to the end of a segment in comparison with their related Q3 vowels.

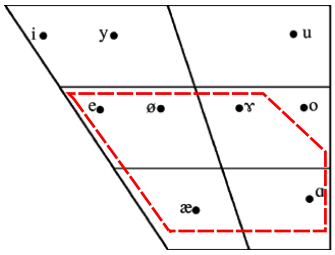

Figure 1: *Estonian vocalic system (vocalic hesitations are in red line).*

2. Corpus and methodology

2.1. Corpus

We used the manually transcribed phonetic corpus of Estonian spontaneous speech of the university of Tartu[1] [6]. Investigated corpus consists of 32 male and 39 female speakers of monologues or dialogues, including 18.5 hours for male and 21 hours for female speakers. The corpus is manually segmented at different levels: phoneme, syllable, word, quantity degree, voice quality, etc.

2.2. Methodology

Fundamental frequency (f_0), intensity, and two first formant (F1 and F2) values were extracted every 5 milliseconds (ms) by using Praat software [7]. Phonemic duration was taken from the manually segmented corpus. f_0, intensity, and first two formant measurements were averaged over segments. Also each phonemic segment was split in three parts (begin, center, end) and measurements of each part were also averaged. Voicing ratio was computed as following: for each segment, the number of voiced (f_0 >0 Hz) frames was divided by the total number of frames. F1 and F2 values were taken only when f_0 values were determined. The target vocalic hesitations and related overlong (Q3) vowels were extracted from the transcribed corpus. Hesitations were annotated by transcriptors. Table 1 gives the

[1] http://www.keel.ut.ee/en/languages-resourceslanguages-resources/phonetic-corpus-estonian-spontaneous-speech

number of occurrences of five vocalic hesitations and related Q3 vowels for male and female speakers. Analyzed Q3 vowels were intra-lexical vowels and vocalic hesitations occurred between silent pauses or words, after a word before a silent pause or inversely (cf. Figure 2).

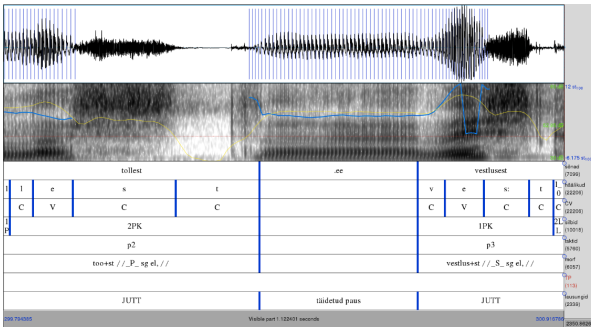

Figure 2: *Example of vocalic hesitation. Vocalic hesitation .ee is located between two words: "tollest (that, singular, elative)#.ee (vocalic hesitation)#vestlusest (conversation, singular, elative)".*

Table 1: *Number of vocalic hesitations and Q3 vowels for male (MS) and female speakers (FS).*

hesit./Q3 vow.	MS		FS	
	hesit.	Q3	hesit.	Q3
.ee/ee: [eeː]	1907	2166	1424	1936
.ää/ää: [ææː]	97	437	102	481
.aa/aa: [ɑɑː]	103	2205	89	2125
.õõ/õõ: [ɤɤː]	608	60	197	41
.öö/öö: [øøː]	68	358	65	359
Total	2,783	5,226	1,877	4,942

3. Acoustic and prosodic analyses

For this study, we compare duration, f_0, intensity, and two first formants (F1 and F2) between five vocalic hesitations and their related overlong (Q3) vowels. We hypothesize that Q3 vowels are intra-lexical vowels, so there are some acoustic and prosodic differences between vocalic hesitations and Q3 vowels.

3.1. Duration

Figure 3 shows duration distribution of five vocalic hesitations (red line) and their related Q3 vowels (black line). Mean hesitation duration reaches 318 milliseconds (ms) for male speakers (standard deviation (SD): 171 ms) and 270 ms for female speakers (SD: 142 ms), whereas mean duration of related Q3 vowels is 154 ms (SD 68 ms) for male and 174 ms (SD 82 ms) for female speakers. We notice that Estonian vocalic hesitations have much longer durations than related Q3 vowels as revealed in the literature like other languages. The profile of vocalic hesitation duration is more enlarged. The difference between hesitations and related Q3 vowels turned out to be statistically significant ($p < .001$) for both male and female speakers by Wilcoxon test using R software [8].

3.2. Fundamental frequency (f_0)

Estonian words in general have a stress with higher f_0 and intensity values on first syllable and these values gradually decrease

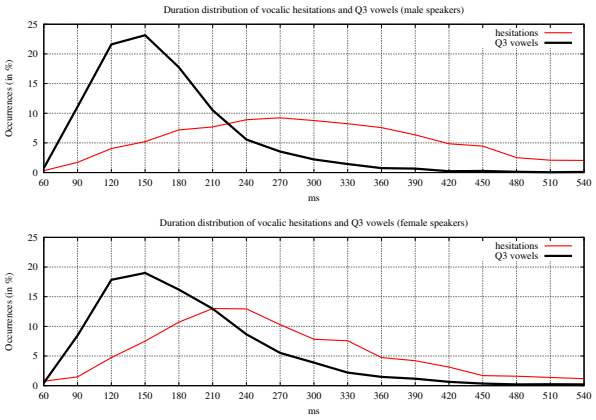

Figure 3: *Duration distribution of vocalic hesitations (in red line) and their related Q3 vowels (in black line) for male (top) and female (bottom) speakers.*

to last syllable. We hypothesize that f_0 contours are more stable for vocalic hesitations while Q3 vowel contours tend to fall within a segment. A segment is divided into three parts (begin, center, end) in order to compare f_0 contour movements of vocalic hesitations from Q3 vowels. Figure 4 presents average f_0 values of begin, center, and end parts over 70% of voicing ratios (to avoid extracting f_0 value errors) for each vocalic hesitation (left) and its related vowel (right). It is noticeable at a glance from Figure 4 that f_0 values are lower for vocalic hesitations than Q3 vowels for both male (top) and female (bottom) speakers. We can also observe that: (i) f_0 values slightly decrease from begin to center parts for both vocalic hesitations and Q3 vowels; (ii) for Q3 vowels, f_0 values continue to fall from center to end parts; (iii) however f_0 contours of vocalic hesitations are stable or they rise from center to end parts (except vocalic hesitation of *.aa* for female speakers where f_0 values continue to fall like Q3 vowels).

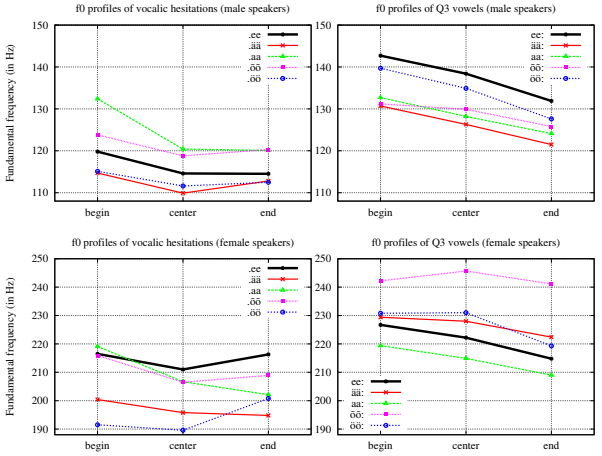

Figure 4: *f_0 contours of vocalic hesitations (left) and their related Q3 vowels (right) for male (top) and female (bottom) speakers.*

To verify whether these f_0 differences between vocalic hesitations and their related Q3 vowels are significant, we conducted statistical tests using Wilcoxon test. First, we compare mean f_0 values of each part (begin, center, end) between vocalic

hesitations and their related Q3 vowels. Three pairs (*ee*, *ää*, *öö*) of each part show statistically significant differences ($p < .05$) for both male and female speakers. Especially begin and center parts of these three pairs are strongly significant ($p < .001$) for both gender. However, for the *õõ* pair, only center part is statistically significant ($p < .05$) for both male and female speakers. No significance can be shown in the *aa* pair for both male and female speakers.

Next we compare the difference of f_0 values between begin and center, and between center and end. With respect to the difference of values between each part, the Wilcoxon test shows significant differences in the *ee*, *ää*, and *õõ* pairs for male speakers ($p < .05$), and the *ee* and *õõ* pairs for female speakers ($p < .001$). The difference between begin and center parts of the *aa* pair reveals significant differences for both male and female speakers ($p < .001$). The difference between center and end parts of the *öö* pair are statistically significant for both male and female speakers ($p < .001$) and of the *ää* pair has significant difference for female speakers ($p < .001$).

The *õõ* pair, showing significant difference only in mean center part, has significant difference between begin and center parts, and between center and end parts. The similar phenomenon is observed in the *aa* pair. These suggest that f_0 movements are important to separate vocalic hesitations and its related Q3 vowels.

3.3. Intensity

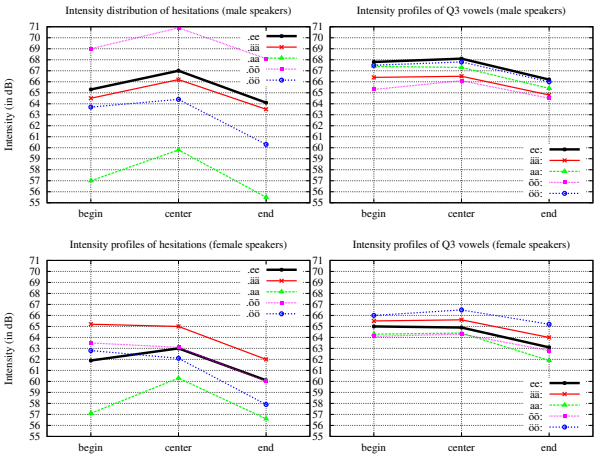

Figure 5: *Intensity distribution of vocalic hesitations (left) and their related Q3 vowels (right) for male (top) and female (bottom) speakers* .

Intensity values are expected to have similar contours as f_0 ones because Estonian words normally have a stress on first syllable. Like f_0, a segment is separated into three parts. Figure 5 (left) shows the mean intensity profiles of begin, center, and end parts of vocalic hesitations for male (top) and female speakers (bottom). For male speakers, intensity values of vocalic hesitations increase from begin to center parts and decrease from center to end parts. Intensity contours of the vocalic hesitations *.ee* and *.aa* for female speakers have also rise-fall contours, whereas the other *.ää*, *.õõ*, and *.öö* hesitation contours decrease from begin to end. However values fall more from center to end than from begin to center. The ranges of each vocalic hesitation values are large for both male and female speakers.

As for the related Q3 vowels (right), mean intensity values are quite stable or values rise slightly from begin to center parts and decrease from center to end parts for both male and female speakers. The range of each Q3 vowel values is not as wide as that of vocalic hesitations for both male and female speakers.

Like f_0, same statistical tests using Wilcoxon are carried out between vocalic hesitations and their related Q3 vowels. The comparison of mean intensity values of each part (begin, center, end) between vocalic hesitations and their related Q3 vowels shows significant differences in the *ee*, *aa*, *õõ*, and *öö* pairs for male speakers ($p < .005$). As for female speakers, the *ee*, *aa*, and *öö* pairs are statistically significant ($p < .001$). Mean intensity values of begin part for the *ää* pair are statistically significant for male speakers, however any statistical significance is not observed in center and end parts. Mean intensity values of begin and center parts do not show any significant difference in the *ää* and *õõ* pairs for female speakers, while significant differences are observed in the end part of the *ää* pair ($p < .001$) and the *õõ* pair ($p < .05$) .

The differences of intensity values between begin and center, and between center and end show significant differences in all pairs for female speakers ($p < .05$). As for male speakers, statistically significant differences are found in the *ee*, *ää*, and *aa* pairs for all pairs ($p < .005$). The difference of intensity values between begin and center part of the *öö* pair are statistically significant ($p < .001$) and also between center and end part of the *õõ* pair ($p < .001$). It is noticeable from statistical tests that not only mean intensity value comparison but also comparison of value difference between three parts are important to separate each characteristics like f_0 contours.

3.4. Formants: F1/F2

As F1 and F2 values of begin and end parts might be influenced by preceding and/or following segments, especially for Q3 vowels, which are in general located within a word, only center part values are taken into account for formant analysis. Center part values seem to give stable values than begin and end parts. Mean F1 and F2 values of center part are illustrated in Figure 6 for male speakers and Figure 7 for female speakers. Vocalic hesitations are presented in red on the top and their related Q3 vowels are in black on the bottom. It is noticeable from two figures that vocalic hesitations (top figures) are superposed each other. However it is observable that vocalic hesitation of *.aa* is less superposed and its ellipse is bigger than other vocalic hesitations for both male and female speakers. On the other hand, Q3 vowels (bottom figures) are distinguishable from each other, although ellipses of *õõ:* and *öö:* are quite superposed. Vocalic hesitation figures show that F1 and F2 positions of these five vocalic hesitations are more centralized to each other than their related Q3 vowels. Mean value of *.ee* is located in more posterior place and that of *.õõ* is more anterior than their related Q3 vowels. Two vocalic hesitations of *.ää* and *.aa* are situated at more closed positions. Concerning the *.öö* hesitation, it seems that mean F1/F2 values are close to those of its related Q3 vowel *öö:*. Vocalic hesitations were manually transcribed, so it might be possible that transcribed vowels and vocalic hesitations were influenced by each transcriptor's perception.

We conducted statistical tests (Wilcoxon test) to verify if these center part values of F1/F2 formants are different between five vocalic hesitations and their related Q3 vowels. Mean center values of F1 for male speakers show significant difference ($p < .001$) except the *öö* pair, whereas mean F2 center values are statistically significant for all pairs ($p < .05$), especially the *ee*, *õõ*, and *öö* pairs ($p < .001$). As for female speakers, statistically

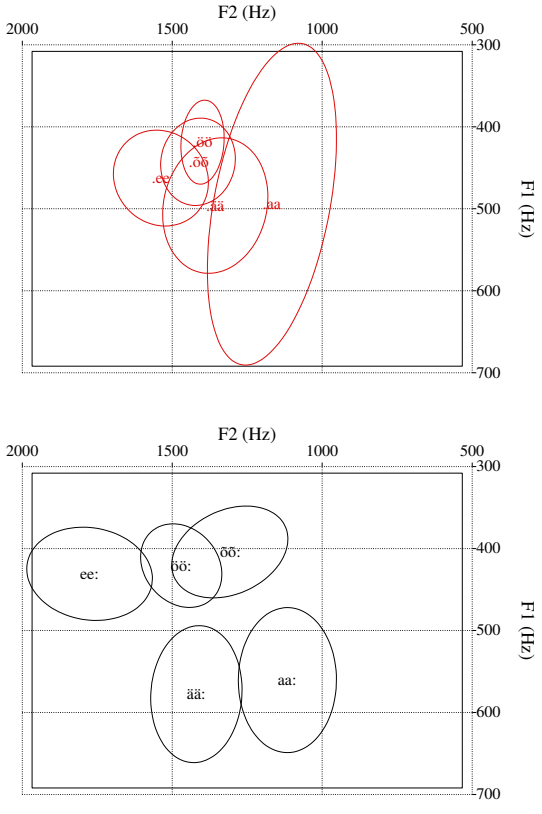

Figure 6: *F1/F2 center position plot of male speaker: hesitations (top, red) and their related Q3 vowels (bottom, black).*

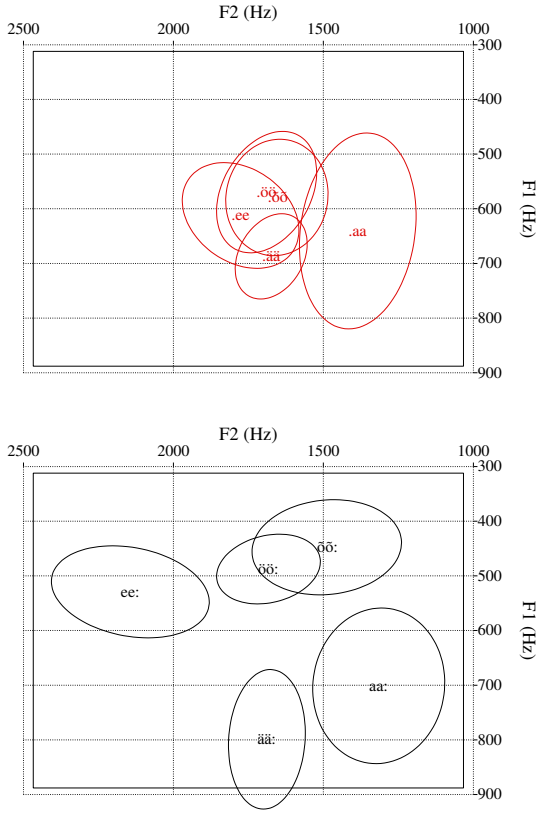

Figure 7: *F1/F2 center position plot of female speaker: hesitations (top, red) and their related Q3 vowels (bottom, black).*

significant differences of F1 values are observed in all pairs ($p < .005$). Concerning F2, no significant difference is found in the *ää* and *öö* pairs, whereas the other pairs show significant difference ($p < .001$). Statistical tests reveal the difference between vocalic hesitations and their related Q3 vowels in all pairs for both F1 and F2 values or for at least one of them.

4. Discussion

This paper described acoustic and prosodic characteristics (duration, fundamental frequency, intensity, and first two formants) of five vocalic hesitations and their related Q3 (overlong) vowels of Estonian language. Investigated five vowels were: *ee*, *ää*, *aa*, *õõ*, and *öö*. Both male and female speakers contained around 5,000 Q3 vowels and 2,800 vocalic hesitations for male speakers and 1,900 for female speakers in 40 hours of the spontaneous speech corpus.

Duration distribution revealed that longer durations were observed in vocalic hesitations than their related Q3 vowels. Duration range was more spread for vocalic hesitations. The f_0 contours of vocalic hesitations behaved differently in comparison with their related Q3 vowels. Lower f_0 values were found in vocalic hesitations. f_0 contours of Q3 vowels tended to decrease from begin to end parts, whereas vocalic hesitation contours decreased begin to center parts and were stable or rising from center to end parts. The results from intensity analysis confirmed different intensity contours between vocalic hesitations and Q3 vowels. The range of vocalic hesitations was bigger than Q3 vowels. Intensity contours of vocalic hesitations raised from begin to center parts and dropped from center to end parts, or decreased from begin to end parts, while Q3 vowel contours showed rise-fall contours. What differentiate vocalic hesitations from Q3 vowels was that intensity values of vocalic hesitations between center and end parts were bigger than those of Q3 vowels. Two first formant results showed that vocalic hesitations were superposed each other and they were more centralized than their related Q3 vowels.

This study concerned general tendencies of vocalic hesitations in comparison with their related Q3 vowels from averaged prosodic and acoustic values using large corpus. We wondered if vocalic hesitations depend on speaker specificities; one speaker might utter hesitations more opened, or other prefers more closed. Hesitations may be influenced by before and/or after phoneme or words. Further studies will include individual speaker aspects and take into account surrounding phonemes or words.

Articulatory Reorganizations of Speech Rhythm due to Speech Rate Increase in Brazilian Portuguese

Alexsandro R. Meireles [1], *Plínio A. Barbosa* [2]

Abstract

This paper examines how speech rate increase acts to change speech rhythm at the articulatory level. Main results show that speech rate increase worked to change articulatory parameters in the following way: a) decrease of acceleration duration; b) decrease of y-extremum; c) decrease of constriction displacement; d) decrease in modulus of peak and/or valley velocity; e) decrease of gestural duration; and f) constant proportional time-to-peak (or valley) velocity. Besides, results have shown that speech rate tends to affect all gestures in an utterance independently of their phrasal position. Nevertheless, there was evidence that some articulatory parameters could, if properly manipulated, provide cues for rhythmic restructurings in speech. Finally, results show that the dynamical speech rhythm model (Barbosa, 2007) is more appropriate to deal with Brazilian Portuguese acoustical data than the pi-gesture model (Byrd & Saltzman, 2003), and that both models could explain articulatory reorganizations due to speech rate increase.

Index Terms: speech prosody, speech rhythm, speech rate, EMA, articulatory study.

1. Introduction

The speech rate influence on speech rhythmic reorganization can be explained by two recently proposed prosodic models: (i) the speech rhythm model [1, 2, 3] (henceforth SRM); and (ii) the π-gesture model [5] (henceforth PG). A rhythmic reorganization is considered here as a change in the temporal prosodic structure of articulatory gestures [9]. Both models account for prosodic structuring using a dynamical systems approach (cf. [7, 8]).

Byrd and Saltzman [5] state the main features of prosodic gestures: (i) prosodic gestures have a temporal extension and overlap with constriction gestures; (ii) prosodic gestures' gestural scores represent the activity of a set of abstract point attractors, in order to make the model as abstract as possible; (iii) prosodic gestures do not have an independent articulatory realization. Therefore, they are only indirectly realized by its effect on the articulatory dynamics.

Barbosa [2, 3] highlights the linguistic characteristics of SRM, as follows: (i) the linguistic rhythm is a consequence of the way the phrase-stress oscillator pulses align with the onset of lexically stressed vowels; (ii) the hierarchy between the magnitude of phrase-stress oscillator pulses generates a dynamical metrics; (iii) the relative coupling force is language dependent; (iv) the prosody-segments interaction is different among languages; (v) syntactic information is crucial, though not alone, to explain the variability of placement and magnitude of phrase stresses; (vi) phrasal stresses are a superficial consequence of the prominences expressed by peaks of abstract duration of the syllabic oscillator; (vii) lexical stress is defined in the abstract gestural score.

These two prosodic models (SRM and PG) predict similar phonetic consequences to syllable-sized gestures, namely: (i) gestures adjacent to prosodic boundaries will be lengthened; (ii) degree of slowing will be greatest as the gesture approaches a prosodic boundary; (iii) boundaries of different strengths are only expected to be distinct in degree of effect. Nevertheless, the scope of action in the SRM model is global, i.e., the phrase stress oscillator acts throughout the whole utterance. The longer vowel-to-vowel (from the beginning of one vowel up to the beginning of the next vowel, henceforth VV) duration at the end of a stress group (Brazilian Portuguese is a right-headed language at this level) is a cumulative function of previous VV durations from the beginning of this group, while the scope of action in the PG model is local: "the π-gesture locally slows the clock that controls the timeflow of an utterance" [5, p. 160]. Another difference between them regards their units of action. While in the SRM these units are articulatory gestures on the lexical level whose stiffness is modified by the effect of the phrase stress oscillator pulses at the properly rhythmic level, in the PG model, these units are gestures spanning a phrasal boundary. Finally, π-gesture action is limited to phrase edges, as can be noticed in the passage: "effects will be limited to gestures near the domain edge and will not occur at gestures quite remote from it" [5, p. 162].

Despite these differences, it is worthwhile to highlight that both models fall into the category of the so-called intrinsic timing, for in the π-gesture model "the activation level dynamics of the clock and the constriction level dynamics of the gestural units are bidirectionally coupled and hence form a single higher-order dynamical collective" [5, p. 156]. Barbosa's dynamical model of speech production [2, 3] works likewise, for the two coupled oscillators, through prosody-segments interaction, is bidirectionally coupled with the gestural score and thereby also form a single higher-order dynamical collective. Furthermore, prosodic timing is explicitly controlled for utterance production in the SRM, that is, the coupled oscillators in interaction with the other levels of grammar control speech rhythm, so that a separate abstract executor is not needed to do this control.

Based on the assumptions of the speech rhythm model, this paper intends (i) to study how speech rate acts to change the temporal structure of articulatory gestures, as related to linguistic rhythm, and (ii) to compare the predictions of both dynamical prosodic models (SRM and PG). To study speech rhythm at the articulatory side, we used the jaw as the basis for articulatory rhythm as proposed by Erickson [6].

Pursuing Erickson's idea of the jaw as a rhythm articulator, we conducted an experiment to examine how speech rate acts to change the phrasal prominences throughout the utterance. The novelty of the present study is to make a fine articulatory description of how speech rate variation works to change the durational patterns of articulatory gestures (defined in [4]).

Our main hypothesis is that phrasal prominences along the utterance are restructured with speech rate increase, and, as a consequence, stressed vowels under a phrasal boundary are realized with lesser jaw opening at fast rates. Besides, it is hypothesized that at fast rates there is no jaw movement reset after some minor prosodic boundaries. This hypothesis is based on Barbosa's studies [2, 3], which show that Brazilian Portuguese (henceforth BP) VV durations exponentially increases up to a phrasal boundary and then a reset of VV duration values occurs, i.e., after reaching its maximal duration, VV duration decreases and starts increasing all over again up to the next phrasal boundary.

2. Methods

A female native speaker of BP (age 28-30) was recorded acoustically (sampling rate: 22.5 kHz) and articulatorily at the USC Phonetics Laboratory. The speaker was paid for the participation in the experiment and signed an approved informed consent form explaining the purpose of the experiment. A 2-D Articulograph AG-200 (www.articulograph.de) (cf. [12], EMA magnetometer system) was used for tracking jaw movement. The movement data was sampled at 200 Hz, head-corrected, rotated to the occlusal plane, and low-pass filtered at 25 Hz. Pellets were attached to the following articulators: tongue (close to the palatal region), lower lips, jaw (at the lower incisors). Two other pellets were used as reference for the signal acquisition system: one at the nose bridge, and one at the center anterior surface of the maxillary incisors. Only the y-movement of the jaw was measured. As in Erickson [6], jaw opening was measured "in terms of the lowest vertical position of the mandibular pellet in the syllable from the maxillary occlusal plane" [6, p. c-134].

The recorded sentences are displayed in Table 1. Ten repetitions of each sentence (randomized within blocks) at three speech rates were recorded. This results in a total of 120 utterances for analysis (4 sentences x 10 repetitions x 3 speech rates).

To obtain three distinct speech rates, the subject was asked to read the sentences according to the following instructions and order: (1) normal: speak in a comfortable way; (2) slow: speak as slow as you can preserving the sentence's meaning and without introducing pauses between words; (3) fast: speak as fast as you can without introducing distortions in speech.

Table 1. *Sentences used in the experiment with their respective translation (TR) and VV phonetic transcription (PT). Bolded words represent where phrasal prominence is expected to fall (no such markings appeared in the stimuli for reading.*

Sentence 1	Ela diz mão de **máfia** no carro da moça do **papai**.
PT	[ɛl.ɐdʒ.izm.ɐ̃ʊdʒ.ɪm.af.ɪɐn.ʊk.aɤ.ʊd.am.os.ɐd.ʊp.ap.aɪ]
TR	She says mafia's hand in the car of my father's girl.
Sentence 2	Foi bão gostar demais de **papai**, mas de **máfia**!?
PT	[f.ɔɪb.ɐʊg.ost.aɤdʒ.ɪm.aɪzdʒ.ɪp.ap.aɪm.azdʒ.ɪm.af.ɪɐ]
TR	It were good to love too much my dad, but not mafia... ["were" instead of "was" implies a very informal style]
Sentence 3	Mamãe não quer mais qu'eu **babe**, mas qu'eu **pape**.
PT	[m.ɐ̃m.ɐ̃ɪn.ɐ̃ʊk.ɛɤm.aɪsk.ɪeʊb.ab.ɪm.ask.ɪeʊp.ap.ɪ]
TR	My mother doesn't want that I dribble anymore, but that I eat [child language].
Sentence 4	Vou lá levar o **pavê** pra filha do **papai**.
PT	[v.oʊl.al.ev.aɾ.ʊp.av.epɾ.af.iʎ.ɐd.ʊp.ap.aɪ]
TR	I am going there to deliver the "pavê [kind of dessert]" to dad's daughter.

For transcription and labeling, MAVIS software [14], modified at University of Southern California, was employed to measure the jaw sensor movement in the vertical dimension (y-axis). The following articulatory variables were measured (see [9, p. 139] for details): (i) jaw maximum extension: measured at y-velocity zero-crossing at maximum opening; (ii) jaw constriction displacement: measured as the difference between the zero crossings at constriction onset and extremum; (iii) jaw gesture (related to acoustic) duration: measured as the interval between maximum peak velocity[1] and maximum (modulus) valley velocity; (iv) jaw gesture duration: measured between y-velocity zero-crossings at constriction onset and maximum; (v) constriction jaw gesture peak/valley velocity (y); (vi) jaw acceleration duration: measured from the time of zero-crossing at constriction onset up to the time of constriction peak (or valley) velocity; (vii) proportional time-to-peak (or valley) velocity: measured from the ratio of y acceleration duration to total constriction formation duration.

3. Results

As objective means of automatically detecting stress group boundaries is not yet available for articulatory data, acoustic analyses were run to detect the stress groups' boundaries following the procedures presented in Meireles' papers [9, 10, 11]. Also, subsequent statistical analyses have shown that the duration of the articulatory VVs were not significantly different from the duration of the acoustic VVs.

Our results suggest that speech rate increase tends to strengthen the right-headness characteristic of BP, i.e., the greatest phrasal prominences occur to the right of the sentence at fast rates. These greatest phrasal prominences are considered here as the greater duration of a VV unit in comparison with the other VV unit. For sentence 1, with VV duration as a function of the articulatory VVs (related to the acoustic one) [afɪ] and [aɪ], the greatest phrasal prominence occurred at [afɪ] for slow ($F(1,4) = 15.858$, $p < 0.017$) and normal rates ($F(1,10) = 72.681$, $p < 0.0002$), and at [aɪ] for fast rate (n.s.). For sentence 2, with VV duration as a function of the articulatory VVs [ap] and [afɪ], the greatest phrasal prominence occurred at [ap] for slow ($F(1,8) = 85.689$, $p < 0.00003$) and normal rates ($F(1,6) = 22.611$, $p < 0.0032$), and at [afɪ] for fast rate (n.s.). For sentence 3, with VV duration as a function of the articulatory VVs [ab] and [ap], no statistical difference was found for slow rate, and for normal ($F(1,6) = 6.0367$, $p < 0.0494$) and fast rates ($F(1,12) = 15.042$, $p < 0.003$) the greatest phrasal prominence occurred at [ap]. For sentence 4, with VV duration as a function of the articulatory VVs [epɾ] and [aɪ], there was no statistical difference among rates. Nevertheless, as these one-way ANOVAs confirmed this tendency only for sentence 3, further studies are necessary to corroborate this hypothesis.

A statistical comparison of the sentences' vowels (cf. table 2) as a function of rate indicates a significant general tendency for smaller displacements (y-extremum and constriction

[1] As we are using velocity in modulus, all general references to peak velocity also applies for valley velocity. So, the hypothesis in fig. 1 for peak velocity can also be extended to valley velocity.

[2] VVs with 2 vowels mean that the second vowel was acoustically produced with a voiceless pattern and, thus, included in this syllable-like unit.

displacement) with speech rate increase. High and mid-high vowels tend to be less high, and low vowels tend to be less low from slow to fast rates (see table 3 and [9, p. 148-149] for details).

A comparison of the peak velocity (consonants) or valley velocity (vowels) as a function of rate for all gestures suggests a decreasing of maximum velocity (modulus) from slow to fast rate. Although this decreasing pattern was statistically found for some gestures within the sentences (SENTENCE 1: 2 out of 15, SENTENCE 2: 5 out of 12, SENTENCE 4: 7 out of 12), only a general pattern of decreasing maximum velocity was found for the gestures in sentence 3 ($F(2,191) = 4.7334$, $p < .0099$, using maximum velocities with their absolute values). Therefore, future studies are needed in order to support this hypothesis of gesture's maximum velocity decrease with speech rate increase.

Table 2. *Vowels (bold type) used in a one-way ANOVA with y-extremum and constriction displacement as a function of rate. Some vowels were not analyzed, because they occurred at the same jaw movement of the preceding consonant/vowel.*

Sentence 1	Ela diz mão de m**á**f**i**a no c**a**rro d**a** m**o**ç**a** do p**a**p**ai**.
Sentence 2	Foi bão gostar dem**ai**s de p**a**p**ai**, m**a**s d**e** m**á**f**i**a**!**?
Sentence 3	Mamãe não quer mais qu'**eu** b**a**b**e**, m**a**s qu'**eu** p**a**p**e**.
Sentence 4	Vou lá lev**a**r o p**a**v**ê** pr**a** f**i**lh**a** do p**a**p**ai**.

Rate effects on both articulatory and acceleration duration revealed a decreasing duration pattern from slow to fast rate (ARTICULATORY DURATION: SENTENCE 1, $F(2,183) = 13.080$, $p < 10^{-5}$, SENTENCE 2, $F(2,141) = 9.1624$, $p < .0002$, SENTENCE 3, $F(2, 177) = 52.992$, $p < 10^{-4}$, SENTENCE 4, $F(2,273) = 76.072$, $p < 10^{-4}$; ACCELERATION DURATION: SENTENCE 1, $F(2,183) = 12.549$, $p < .00002$, SENTENCE 2, $(2,141) = 12.382$, $p < .00002$, SENTENCE 3, $F(2,176) = 34.077$, $p < 10^{-5}$, SENTENCE 4, $F(2,273) = 30.905$, $p < 10^{-5}$).

Analysis of the proportional time-to-peak/valley-velocity as a function of rate indicates no common pattern for the gestures. Some gestures had a downward pattern and others an upward pattern from slow to fast rate. Thereby, stressed and unstressed vowels were grouped together. This grouping still indicates no rate effects on proportional time-to-peak/valley-velocity, but it indicates that stressed vowels have smaller proportional time-to-peak/valley velocity than unstressed vowels (SENTENCE 1, $F(1,91) = 9.6706$, $p < .003$; SENTENCE 2, $F(1,70) = 5.4489$, $p < .023$; SENTENCE 3, n.s.; SENTENCE 4, $F(1,136) = 10.051$, $p < .002$).

In summary, the data indicate a stiffness increase from slow to fast rate, and, consequently, a shrinking of the gestures and smaller spatial movements. Therefore, rhythmic restructurings are more likely to occur at fast rates, since stress groups (henceforth SG) ending at weak boundaries in slower rates may delete due to stiffness increase in fast rates. It is worth to recall that longer durations are necessary to delimit phrasal boundaries in BP.

3.1. Kinematic sources of rhythmic restructurings

Based on the articulatory results outlined above, we proposed the following kinematic sources of rhythmic restructurings with speech rate increase (cf. figure 1): a) decrease of acceleration duration; b) decrease of y-extremum; c) decrease of constriction gesture displacement; d) decrease of peak/valley velocity (modulus); e) decrease of articulatory duration; and f) constant time-to-peak/valley-velocity.

Another kinematic source of rhythmic restructuring not related to speech rate change is the diminishment of the proportional time-to-peak/valley-velocity on stressed vowels compared to unstressed ones.

According to these sources of articulatory patterning, a general decrease of articulatory parameters from slow to fast rate is expected. Figure 1a represents an articulatory shortening caused by a stiffness change (cf. [13]), which indicates a shorter acceleration duration. Figure 1b exhibits a smaller y-extremum caused by a less open jaw position (low vowels) or less closed jaw position (high mid-high vowels), which can be understood as a gesture undershoot. Closely related to figure 1b is figure 1c that represents a smaller difference of y displacement at the initial and final positions of the gesture. If a smaller y-extremum is expected, a smaller constriction displacement at fast rates is also expected. Figure 1d shows a peak velocity decrease from slow to fast rate. This hypothesis can be explained by the fact that to reach a greater peak velocity followed by a change in movement direction at zero velocity (jaw goes up and down), a greater distance is needed, which can be found at slow rates, not fast ones. Figure 1e is merely a consequence of the previous kinematic sources, i.e., diminishment of articulatory duration. Finally, figure 1f shows that the time-to-peak/valley-velocity keeps constant with speech rate increase.

Table 3. *Significance of y-extremum as a function of speech rate. This table represents vowels with their respective word, ANOVA and significance for all sentences in the corpus. *means marginally significant.*

y-extremum			
vowel	word	Anova	p <
Sentence 1			
[a]	['kafiʊ]	$F(2,9) = 6{,}2189$	0.021
[a]	[da]	$F(2,9) = 7{,}4352$	0.013
[aj]	[pa'paj]	$F(2,9) = 3{,}9786$	0.06*
Sentence 2			
[a]	[pa'paj]	$F(2,9) = 6{,}1360$	0.021
[a]	[mas]	$F(2,9) = 12{,}116$	0.003
[a]	['mafɐ]	$F(2,9) = 18{,}273$	0.0007
[ɐ]	['mafɐ]	$F(2,9) = 9{,}1656$	0.007
Sentence 3			
[a]	['babɪ]	$F(2,12) = 4{,}1435$	0.043
[ɪ]	['babɪ]	$F(2,12) = 4{,}0615$	0.045
[a]	[mas]	$F(2,12) = 22{,}454$	0.0001
[a]	['papɪ]	$F(2,12) = 4{,}1749$	0.043
[ɪ]	['papɪ]	$F(2,12) = 5{,}6012$	0.02
Sentence 4			
[a]	[le'var]	$F(2,20) = 6{,}0484$	0.009

4. Discussion

As seen in the last session, main results have shown that speech rate increase seems to change the articulatory parameters in a uniform way, disregarding their phrasal position. Despite that, there is evidence that some factors may be able to explain the rhythmic restructurings found at the articulatory level in BP. More data and speakers are needed to

confirm these trends, however. Normalization in the articulatory signals is needed in order to be able to obtain a consistent methodology to work with them. Recall that acoustic stress group boundaries were found based on normalization procedures applied to the acoustical signal only (cf. [3, 9]). Furthermore, a comparison of the PG and SRM models have led us to different conclusions on the acoustic and the articulatory side

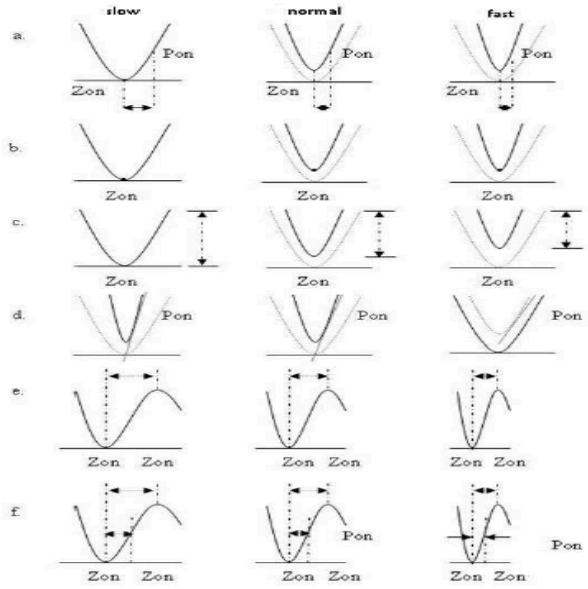

Figure 1. *Kinematic sources of rhythmic restructurings with speech rate increase: a. diminishment of acceleration duration (stiffness increase); b. y-extremum decrease; c. constriction gesture displacement decrease; d. peak velocity decrease; e. articulatory duration decrease; f. constant proportional time-to-peak velocity.*

On the acoustic side, according to Barbosa [1, 2, 3] and Meireles's acoustical data [9, 10, 11], since in BP the greater duration at the end of a SG is a consequence of a exponential increase from the beginning of this SG, SRM model better explains the rhythmic variations found in this paper. Recall that PG model only explains longer durations at (or near) a phrasal boundary.

Yet, on the articulatory side, since we only found some possible influence of articulatory parameters exactly at the places where rhythmic restructurings occurred, both models would work to explain the results found up to this point. However, we remind that because PG researchers have specifically worked with articulatory data, they are more advanced at the methodological side to work with articulatory gestures influenced by prosodic structure. Despite that, we have showed here some evidence that SRM model could perfectly deal with such data once more information about BP gestures is provided and new methods applied to articulatory data are designed.

5. Conclusions

The results of this articulatory study suggest that speech rate increase affects all gestures in a sentence disregarding their phrasal position. Nevertheless, future work is needed since acceleration duration, constriction displacement and articulatory duration seem, though not conclusive, to reflect the rhythmic restructurings found on the articulatory side. Also, results showed that the SRM model is more appropriate to deal with BP acoustical data than the PG model, and that both models could explain the articulatory variations due to speech rate increase.

Finally, this paper's main results have shown that rhythmic structure variation is modified gradually with speech rate increase, i.e., quantitative aspects of speech are acting to modify speech rhythm, showing how a dynamical systems approach to language perfectly suits to linguistic descriptions

Abstract

Results of a pilot study are presented which investigates the prosodic realization of information structure by six learners of German as a Foreign Language (GFL) with Turkish as first language. Question-answer pairs were read out loud, which systematically varied the position of narrow focus in the response by means of a preceding *wh*-question.
A qualitative analysis of the results shows deaccentuation of postfocal constituents in the case of subject focus for 4/6 GFL-speakers but no consistent pitch increase on focused constituents. Two speakers did not change prosody due to information structure.
The results are discussed in connection with the acquisition of prosody as a marker of information structure. Deaccentuation has been reported to cause problems in L2 prosody. In Turkish, deaccentuation occurs postfocally. The claim will be motivated that the occurrence of deaccentuation in the L1 is a necessary but not sufficient condition for early acquisition of deaccentuation in a foreign language.

Index Terms: L2 prosody, German, Turkish, focus, deaccentuation, production

1. Introduction

The acquisition of L2 prosody, i.e. linguistically relevant changes of fundamental frequency (F0), intensity and/or duration over the course of an utterance, has received comparatively limited attention in the literature on Second or Foreign Language Acquisition. According to [1:57] and referring back to the intonational typology in [2], phonological influences in L2 prosody must be differentiated from phonetic influences. Phonological influences on L2 prosody result from differences in the inventory of phonological tunes, their form, and in the meanings assigned to the tunes. Phonetic influences result from a difference in the phonetic realization of an identical phonological tune.
Previous studies on L2 of non-related languages have shown that the target-like placement of sentence accent (phonological level) as well as the target-like realization of pitch accents (phonetic level) cause difficulties in foreign language acquisition. One of the particular difficult features reported in studies like e.g. [3-7] lies in the function of prosody in languages like English and German, where sentence-level prosody indicates information structural notions such as topic, focus and givenness. For L2 prosody, a non-target-like reaccentuation of constituents that are given through the preceding discourse has repeatedly been reported in the studies cited above.
The article reports the results of a pilot study into the prosody of Turkish learners of German as a foreign language. The functional use of prosody as marking focused and given constituents will be central. The German-Turkish language pairing is interesting, because German, just like English, shows both prosodic focus marking through an increase in fundamental frequency (F0) and duration, as well as deaccentuation of given constituents. For English, prosodic focus marking and deaccentuation have been considered "opposite sides of the same coin" [8:67]. Turkish is not related to German. However, it can be considered to have a similar prosodic representation, being a stress language which also uses prosody at the sentence level. However, it shows less systematic prosodic focus marking (see discussion in section 2.2) but has postfocal deaccentuation[1].
The article is structured as follows: Section 2 gives the relevant background on the prosody of the two languages involved. Section 3 presents the experiment with a summary of the results in section 3.5. Section 4 provides a discussion.

2. Focus prosody in German and Turkish

2.1. German

German has been classified as an intonation-only language (cf. [9]) which has lexical stress. Postlexically, it uses different types of pitch accents together with boundary tones in order to express pragmatic contrasts (see [10]). The interaction of information structure and intonation is uncontroversial for German.
Default sentence accent (in all-new sentences) is assigned on the basis of syntactic structure: every argument of the verb is accented, and the verb might also be accented if there is phrasal integration of the verb and its immediately preceding argument. Perceptually, the last accent in a sentence is perceived to be the most prominent. In terms of phonetic implementation of the accents, downstepping of high-toned accents has been reported to occur, i.e. realization of a high tone at a lower phonetic level relative to a preceding high tone [11].
Under narrow focus, the most prominent accent occurs on the focused constituent. As experimental work by [11] for German confirms, pitch is raised under focus when compared to a baseline of all-new sentences. Givenness leads to a lowering of pitch, whereby the position of the given constituent with respect to the focus is relevant. If the given constituent occurs preceding the focus of the sentence (prenuclear position), the constituent will have a pitch accent with a comparatively low pitch. If the given constituent occurs following the focus of the sentence (postfocal position), it has been said to be deaccented. This overall pattern was confirmed by German native speaker controls, participating in the same experimental task as reported in the current article.

[1] The difference between deaccentuation and postfocal compression is not always clear-cut in actual data. The former refers to the deletion of a pitch accent whereas the latter refers to the compression of the pitch range of a pitch accent. Here, the term deaccentuation is used, bearing in mind that this issue requires further investigation.

Next to F0, increased duration on the focused constituent is a further cue to focus in German with given constituents only being shortened in prefocal position [12].

2.2. Turkish

Turkish is an SOV-language. Though differing in details of analysis, scholars agree that the default sentence accent occurs on the last argument before the verb, which is normally the object [13, 14]. In addition, an accent can occur on every argument.

As for the expression of focus, [15] differentiates between a syntactic strategy in which the preverbal position is used for information focus (e.g. question-answer pairs) where the answers is not accessible from context. In cases of e.g. correction focus where answer can be chosen from an explicit set of alternatives, a constituent is marked as focused in situ by means of a pitch accent. Along the same lines, [16] describes that for both contrastive and non-contrastive emphasis prosodic means such as strong stress and high pitch are used. However, in addition to these prosodic means, non-contrastive emphasis is further marked by placing the focused constituent in the immediately preverbal position. [17], on the other hand, do not assign the immediately preverbal position a primary role in focus assignment. In their examples, focused constituents always bear stress and can occur in any preverbal position.

To our knowledge, only one acoustic study on focus in Turkish exists. [18], in using a comparable methodology as outlined in the present paper, finds that there is no increase in F0 on the focused constituent in the Turkish data she collected. She found rather unsystematic significant differences for the other acoustic correlates: A sentence-initial focused subject differs acoustically from its neutral counterpart in terms of longer duration, a sentence-final verb differs in being higher in intensity. An object did not show differences between the focused condition and the neutral counterpart in any of the three acoustic measures F0, intensity and duration. Unexpectedly, an F0 increase on the preceding object is found when the final verb is in focus. For givenness marking, [18] found that in cases of subject focus there is a significant F0 drop in the post-focus domain. The same pattern does not hold for object focus though. As tested by means of a perception experiment, subject focus has the highest recognition rate, probably due to the salient F0 drop.

It is uncontroversial that in Turkish sentence accent never occurs in the postverbal domain. The prosody in the postverbal domain has been described as being without "any indicator of prosodic structure" [19:144]. [19: fig. 3] provide a pitch track showing that we can expect to find deaccentuation postfocally, not only postverbally. In their example, the pitch contour remains entirely flat following the constituent in focus, which in this specific case is a sentence-initial subject. Their observation is thus in line with the results on the F0 drop following a focused subject in [18].

2.3. Hypotheses

The research question is whether Turkish learners of German change prosody depending on information structure and if so, by means of which acoustic cues. More precisely:

- Do Turkish learners of German use increased F0 on the focused constituent? Both languages seem to differ on the acoustic cues used for prosodic focus marking: Whereas German relies on F0 as well as on duration, Turkish does not seem to rely on F0 as an acoustic cue to prosodic focus.
- Do Turkish learners of German use deaccentuation to signal givenness? Although both languages use deaccentuation for postfocal constituents, research on the acquisition of L2 prosody has reported that learners have difficulties with this feature ([3-7]).

3. Experiment

3.1. Task

An elicited-production study was conducted using the same methodology as in [20] and [18]. German target sentences were elicited that differed in the focused constituent only. The target sentences consisted of simple SVO-structures, and the focused constituent was either the subject, the verb or the object. As a baseline condition, a broad focus rendering was elicited first.

The target sentences were presented in writing, together with a preceding question unambiguously eliciting the desired focus structure, and accompanied by a picture illustrating the action. In addition, the focused target words were underlined in order to reduce errors (cf. [20]). This experimental setup has proven in various studies to be successful at eliciting the predicted focus structures (cf. [20] and subsequent studies).

3.2. Target sentences

Target sentences were constructed in such a way as to systematically control a number of factors and to be comparable across the five different target sentences. To this end, all sentences displayed the same number of words. To minimize segmental variation, the target words showed the same stress pattern (initial stress), the same phonological length in the stressed vowel, and the same segmental make-up (CV with sonorant consonants wherever possible). The object nouns were disyllabic to allow for pitch accents and boundary tones to be realized without tonal crowding.

In constructing five different target sentences as shown in (1), we opted for type repetitions instead of token repetitions in order to increase the diversity of the targets.

(1) Target sentences
   a. Lena malt ein Lama.
      PROP.NAME paint ART llama
      'Lena is painting a llama.'
   b. Nele wohnt in Meißen
      PROP.NAME live PREP PROP.NAME
      'Nele lives in Meißen.'
   c. Nina webt das Leinen.
      PROP.NAME weave ART linen
      'Nina is weaving the linen.'
   d. Heiner baut die Mühle.
      PROP.NAME build ART mill
      'Heiner builds the mill.'
   e. Maya liest die Bücher.
      PROP.NAME read ART books
      'Maya is reading the books.'

3.3. Participants

Nine Turkish learners of German participated in the study. Participants were students of Translation Studies in German at Ege University in Izmir, where the recording took place in

September 2012. The data were collected by the second author, communicating with the participants in German. The data of one speaker (speaker 1) was not recorded properly due to technical problems, the data of two further speakers (sapeakers 2 and 7) had to be excluded because only two target sentences were recorded.
Of the remaining 6 speakers, 5 were female and one was male. The participants were between 20 and 25 years old. They all spoke Turkish as an L1, had good to very good knowledge of English (self-reported) and had studied German as a Foreign Language (GFL) for 3 to 6 years, including a preparatory language course at the University which has been designed to lead to level B1/B2 (Common European Framework of Reference for Language Teaching (CEFR)).

3.4. Analysis

The analysis concentrates on fundamental frequency (F0) as the main correlate of sentence prosody, and more specifically prosodic focus marking and deaccentuation in the target language German. All target sentences were segmented into syllables and 10 measurements of F0 were taken for each syllable, using ProsodyPro [21]. Data were checked manually for spurious pitch values. The datapoints were averaged across the five utterances of the same focus condition for each speaker, and are presented in figure 1 (see next page) for each speaker individually (in the same pitch range of 50-250 Hz, maintaining individual differences in F0 expansion).
In addition, a ToBI annotation of the averaged pitch contours is provided in table 1. Tone labels were assigned following these conventions: H* for each discernible pitch peak, H*+L for a pitch peak with a clear fall on the same constituent, !H* if the pitch peak is lower than the preceding pitch peak, ↑H* for a pitch peak that is higher than the preceding pitch peak. In some cases (e.g. speaker 9), labels had to be assigned based on deviations from expected pitch transitions if there had been no tone target. No evidence was found for boundary tones at intermediate phrases. However, the ToBI annotation should be seen as a phonetic rather than phonemic annotation of the produced intonation, given that further research needs to be done for the phonemic status of the pitch accents transcribed.

Table 1: ToBI annotation based on the averaged pitch tracks

speaker	focus	S	V	O
3	broad	H*+L	!H*+L	↑H*+L L%
	subject	H*+L		L%
	verb		H*	↑H*+L L%
	object	H*+L	!H*	↑H*+L L%
4	broad	H*+L	↑H*	L%
	subject	H*+L		L%
	verb	H*+L	↑H*	L%
	object	H*+L	↑H*	L%
5	broad		H*+L	!H* L%
	subject	H*+L		L%
	verb		H*+L	L%
	object		H*+L	!H*+L L%
6	broad		H*+L	!H* L%
	subject		H*+L	!H* L%
	verb		H*+L	H* L%
	object		H*	H* L%
8	broad		L+H*	!H* L%
	subject		L+H*	!H* L%
	verb		L+H*	!H* L%
	object		L+H*	!H* L%
9	broad	L*H	!H*	!H*+L H%
	subject	L*H		!H*+L H%
	verb	L*H	L+H*	LH%
	object	L*H	H*	!H*+L H%

3.5. Results

The observations are given for each speaker individually first, before they are summarized (number refers to speaker):

- 3: on-focus increase in F0, deaccentuation only in case of subject focus
- 4: no on-focus increase in F0, deaccentuation only in subject focus
- 5: on-focus increase in F0, deaccentuation in subject and verb focus
- 6: no on-focus increase in F0, despite a lower F0 in subject focus, the F0 patterns are qualitatively the same across all focus conditions
- 8: identical F0 contours across all focus conditions
- 9: on-focus increase in F0 in verb focus only, deaccentuation only in subject focus

All speakers realize intonation in broad focus context similar to object focus. Beyond that, as can be expected in a group of learners, we find considerable heterogeneity in the data. The speakers can be described to fall into roughly two groups: speakers 6 and possibly 8 do not show any change in the F0 pattern dependent on the focus structures of the sentences uttered. The other speakers do show a change in prosody related to information structure, as detailed above.
To sum up, of the speakers investigated, most (though not all) use some kind of prosody in connection with information structure (cf. discussion section). Deaccentuation is the most reliable cue used by four out of six speakers, but only in the case of subject focus. Half the speakers also use an increase in F0 on focused constituents. It needs to be noted though, that only speaker 3 links the overall F0 pattern to information structure in a way comparable to the target language.
Given that [18] reported duration and intensity as cues to focus in Turkish rather than F0, these parameters were checked quantitatively for those two speakers who did not show any F0 changes due to information structure (speakers 6 and 8). Only for speaker 6 we find higher duration and intensity on a focused constituent, when compared to the broad focus condition, although the differences are not significant.

4. Discussion

The production data show that some Turkish learners of German do not change prosody according to information structure, neither using phonetic cues of the L1 like intensity and duration [18], nor phonetic cues of the L2 such as F0 increase on focused constituents nor phonological features shared by L1 and L2 such as deaccentuation on given constituents.
Others learners, however, do show a change of prosody due to information structure. Interestingly, these speakers have in common that they show deaccentuation in the case of subject focus. Postfocal deaccentuation in the case of subject focus is a prosodic feature shared by the L1 Turkish and the L2 German and it is a very prominent cue to a shift of focus to the subject ([18] for perception results, auditory impression suggests the same for our data). Some of those speakers also show an increase of F0 on the focused constituent when compared to the broad focus condition and/or deaccentuation on given constituents other than the subject.
Two results thus need further discussion: First, the observation that some learners produce postfocal deaccentuation in cases

of subject focus, although deaccentuation has been reported as a difficult feature to be acquired in foreign language acquisition. Second, the observation that some learners do not change prosody at all under the influence of information structure.

The studies on L2 prosody which constitute the claim that deaccentuation is a difficult feature, investigate language pairings with English as L2 and L1s which either show equivalents to deaccentuation in English but whose prosodic systems are typologically very different (e.g. English, Korean and Japanese in [4] or English, Mandarin and Korean in [7]) or which do not have deaccentuation themselves [5, 22, 23]. [24] have argued that phonological representation is crucial in foreign language acquisition in that representational differences between two languages cause difficulties. If transferred to the suprasegmental domain, Korean and Japanese learners of English are predicted to have difficulties with English prosody due to the representational differences between the two prosodic systems involved, independent of any specific function of the target prosody.

[5, 22, 23] investigate the use of prosody by Spanish learners of English. Spanish and English can both be classified as stress and intonation-only languages and thus share a similar prosodic representation. Postfocal deaccentuation was still found to be difficult for these learners. Here we need to note that L1 Spanish is said to not use deaccentuation (e.g. [25]).

Prosody used for information structure is a typologically marked feature [26]. Following the Markedness Differential Hypothesis [27], this makes it a difficult feature to be acquired, which has been confirmed by the studies on Spanish learners of English. However, in the case of Turkish learners of German, the L1 shares the marked feature as discussed in section 2.2. This might be the reason why even learners at the level of B1/B2 show the use of this feature. The lack of prosodic marking of focused constituent by a gradient increase of F0 on these constituents can be interpreted along the same lines. Prosody used for information structure is a marked feature whose acquisition is difficult, especially if the feature is not shared with the L1. As Turkish does not use F0 increase on focused constituents, this new feature has been acquired by very few learners only.

It can thus be argued that the presence of a marked feature in the L1, such as postfocal deaccentuation, is a necessary condition for the acquisition of that feature in the L2. The results of our production study equally show that it is by no means a sufficient condition. Two speakers do not show any changes in prosody due to information structure, not even in those acoustic correlates which are allegedly used in Turkish (intensity and duration according to [18]). How can the lack of any prosody in speech production be accounted for? We follow [28] and [7], who observe that under certain circumstances learners seem to fall back on some default intonation patterns. [28] investigated the prosody of advanced German learners of English and speculated that observable errors in the placement of pitch accents give "room for the assumption that non-native speakers develop a consistently simplified assignment of tonal categories, a kind of default accent" [28: 87]. This would be in line with [29]'s "basic variety" and a corresponding reduced prosodic realization of the target language. In some of her experimental tasks, [7] observes that Mandarin and Korean learners of English rely on common prosodic patterns used for broad focus.

We thus interpret the results of our pilot study as evidence for the following developmental path in the acquisition of IS-related intonation by Turkish learners of German:

1. Default intonation: One all-purpose default pattern, not differentiating e.g. different kinds of narrow focus.
2. Transfer of L1 feature: Transfer leads to postfocal deaccentuation with subject focus. This is possible because L1 Turkish shares this marked feature with German.
3. Acquisition of a new phonetic feature, namely the gradient increase of F0 on the focused constituent, shown by only very few learners of our group.

Further research is clearly needed though in order to confirm the results.

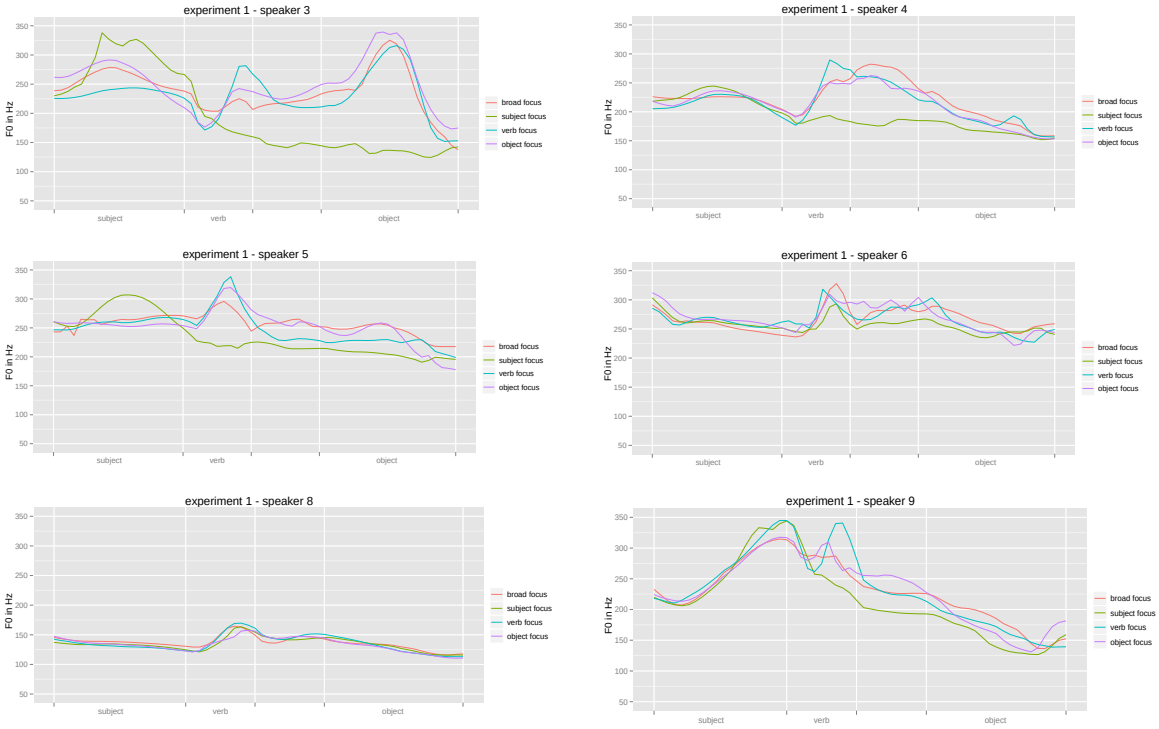

Fig. 1: averaged F0 contours for the four focus conditions for each speaker individually (pitch range of 50-250 Hz)

Synthesizing sports commentaries: One or several emphatic stresses?

Abstract

Emphatic stresses are known to fulfill essential functions in expressive speech. Their integration in speech synthesis usually relies on a prosodic annotation of the training corpus. Emphasized syllables are then assigned a single label or can receive several labels according to their acoustic realization. While it is more complex to predict those various labels for a new text to synthesize, it might allow for a better rendering of the stress in the synthesized speech. This paper examines whether the use of more than one emphatic label improves the perceived expressivity of the synthesized speech. It relies on a manually-annotated expressive corpus of sports commentaries. Statistical acoustic analyses show that four distinct realizations of emphatic stresses can be distinguished. However, perceptual tests indicate that the integration of this distinction in HMM-based speech synthesis does not lead to a significant improvement in expressivity. This seems to imply that the different acoustic realizations of the stress are not required to be explicitly annotated in the training corpus.

Index Terms: Emphasis, Emphatic stress, Expressive speech, HMM-based speech synthesis, Prosody.

1. Introduction

Recent research in speech synthesis has been targeting the generation of expressive speech [1, 2, 3]. Strategies have been proposed to modify both voice quality and prosody so as to produce the most natural quality of expressivity. Albeit rather unfrequent in neutral speech, emphasis plays a crucial role in the prosody of expressive speech [4, 5]. This phenomenon relates to highly prominent syllables which are sometimes seen as (particularly prominent) 'pitch accents' [6, 7]. Emphatic stresses are known to fulfill various functions like contrasting or highlighting elements and contribute to the liveliness of the message [4]. Their generation in expressive speech is therefore essential. It is even more the case when synthesizing sports commentaries which have been shown to display high rates of emphatic stresses, falling on specific positions like numbers in scores [8, 9].

Several attempts to integrate emphasis have been proposed, both in unit-selection [10, 4, 5, 11] and HMM-based speech synthesis [7, 12]. They usually rely on a prosodic annotation of the corpus in terms of emphatic stresses. The acoustic characteristics of the corresponding syllables are then learned to be reproduced at synthesis stage. While some annotations present various labels associated with different acoustic realizations of the emphatic stress (like ToBI [13]), most studies only use a single label for emphasis [12, 14].

The obvious advantage of using one single label is that it makes it easier to predict it for a new sentence. Most studies investigating the automatic prediction of emphasis from text have, for that matter, considered only one single emphatic label [5, 6, 14]. Conversely, predicting several emphatic labels from text requires a correlation between the labels and specific distinct functions, which is rarely the case.

However, emphatic stress is often regarded as a gathering of different kinds of stresses with various functions, positions, and, importantly, different acoustic realizations (as proposed in ToBI [13]). While some studies have mentioned the potential existence of different *levels* of emphasis [4, 15], we rather believe that different *kinds* of emphasis may co-exist, with no specific order relation between them. If one label is associated with each type of acoustic realization, it allows the training of more acoustically-consistent models, more inclined to generate suitable emphatic stresses in speech synthesis.

The question that still remains is whether the use of a single emphatic label in HMM-based speech synthesis still allows for an appropriate rendering of the various acoustic realizations. In other words, it should be assessed whether the acoustically-different emphatic stresses are learned by the models, based on the linguistic context, or if the distinction requires to be made explicit by annotating with distinct emphatic labels.

This study investigates the benefit of annotating emphatic stresses for expressive HMM-based speech synthesis with several labels instead of one. For that matter, it relies on a large corpus of sports commentaries. The corpus is spontaneous while containing a natural variety of prosody, conversely to studies relying on artificially-produced emphatic stresses by actors (see e.g. [5]). Besides, sports commentaries are characterized by a high density of emphatic stresses with strong acoustic correlates [8], which makes them much more suitable for the study of emphasis than rather neutral read speech as used in [12]. Emphatic stresses were manually annotated in the corpus and were statistically analyzed in order to define several sets of labels, corresponding to stresses with distinct acoustic realizations. The manual annotation having been realized on a functional basis, our study partly answers Hirst's critics [16], i.e. the fact that prosodic function and form tend to be merged in prosody annotation. The objective is here to distinguish between various forms of a single emphatic function and assess the resulting improvement reached in the expressivity of the synthesized speech.

The paper is organized as follows. Section 2 presents the corpus and its emphatic annotation. The statistical acoustic analysis of the emphatic stresses is further described in Section 3. The integration of different sets of emphatic labels in HMM-based synthesis is investigated in Section 4 through a perceptual evaluation. Finally, Section 5 concludes the paper.

2. Corpus design

This study is based on a corpus of live commentaries of two basketball games, uttered by a professional French commentator and recorded in sound-proof conditions. The speaker watched the game and commented it without any prompt. The issue with sports commentaries corpora is usually the high level of background noise which precludes their precise acoustic analysis [17]. Conversely, our corpus exhibits the advantage of being spontaneous and of high acoustic quality, being therefore suited for speech synthesis. Both matches star the Spirou Belgian team with very tight final scores, which induces a high level of excitation. The corpus lasts 162 minutes, silences included.

The corpus was orthographically and phonetically transcribed with [18], with manual check. The phonetic transcription was aligned with the sound using Train&Align [19] and other linguistic information (syllables, parts of speech, etc.) was generated by Elite [20]. Manual annotation of emphatic stresses was realized by assigning a 'F' label to syllables for which an emphatic function was perceived. The annotation results from two or three listenings of each sequence of 4-5 words and was submitted to a second check by the same annotator. In total, 803 syllables were annotated 'F'. Twenty percents of the corpus were annotated by a second expert, and rather high kappa scores were reached (see [8] for the complete analysis of the prosodic annotation).

3. Statistical analysis of emphatic stresses

The statistical acoustic analysis of the emphatic stresses in the corpus consists in four steps. First, a set of acoustic features is extracted for each emphasized syllable (Section 3.1). Dimensionality reduction techniques are then used to minimize the set of features and delete potential redundancy (Section 3.2). The reduced feature set is then used to cluster the emphasized syllables, as an attempt to find the more suitable number of distinct emphatic stresses (Section 3.3). These new sets of stresses are then investigated for potential correlations with specific linguistic contexts (Section 3.4). For further information about the exploited statistical methods, see [21, 22].

3.1. Extraction of acoustic features

For each emphasized syllable, 65 acoustic values are extracted. The first features consist in prosodic measurements: F0 extracted with SRH [23] (mean, max, etc.), energy (mean, max, etc.) and duration (both of syllable and nucleus). A prominence value is added by PromGrad [15] which assigns a prominence score from 0 to 4 to each syllable, on an acoustic basis. Two additional features indicate the presence of a preceding or following silence and its duration. Finally, contextual information, i.e. comparisons with the acoustic values of the two previous and the next syllable, are also computed as they were shown to be efficient for prominence detection in French [24, 15]. These latter measurements are only extracted if both syllables are not separated by a silence, as it is known that silences tend to be associated with a resetting of the prosodic parameters.

It should be noted that, as in [25], duration values are normalized with respect to the average and standard deviation of the duration of the corresponding phonemes. This choice relies on the fact that the nature of the phoneme clearly affects its duration [26, 27]. Missing values (for contextual information) are replaced by the average value of the feature. Finally, all variables are normalized into standard scores.

3.2. Dimensionality reduction

The second stage of our analysis aims at reducing the number of features. For that matter, a principal component analysis (PCA) is carried out on the data. The scree plot (see Figure 1) shows the contribution of the components to the global variance. Since there is no universal technique for selecting the natural number of dimensions, we relied on two popular rules of thumb: (i) keeping the dimensionality accounting for 70% of total variance and (ii) removing the dimensions for which the contribution to the global variance remains stationary. Based on these considerations, we chose to keep ten and four dimensions.

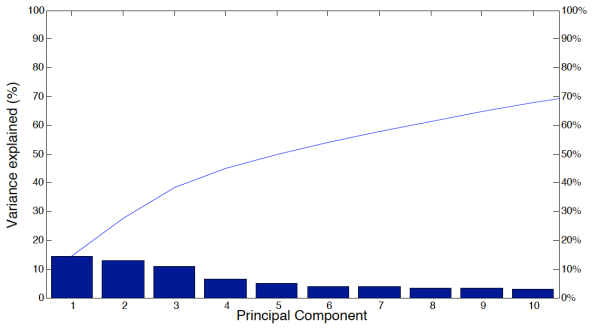

Figure 1: *Scree plot displaying the proportions of global variance carried out by the ten first components of the PCA.*

An insightful analysis regards the weights assigned to the different variables for each component. Interestingly, the first component is clearly related to energy, all 20 higher weights being assigned to energy values. The second component is linked to F0 with the 18 first weights corresponding to F0-based features. Finally, duration-based measurements have most of the heaviest weights in the third PCA component. The fourth dimension is a mix of different types of variables (esp. F0 and energy). The three higher weights for the first three components are assigned respectively to mean energy, mean F0 and syllable duration.

3.3. Clustering

A clustering is now carried out on the reduced data obtained by PCA. The main objective is to define different sets of emphatic stresses characterized by distinct acoustic values.

We first apply a Ward dendrogram [28]. The advantage of this clustering technique it that it visually shows the gathering of the various clusters, which helps in determining the natural number of clusters. Figure 2 shows the dendrogram obtained on the first four PCA components of our data. The algorithm assigns a unique color to each group of nodes where the linkage is less than a specific fixed threshold. This dendrogram clearly shows 4 distinct groups of syllables. Interestingly, when applied to the first 10 PCA components, the dendrogram also points at four distinct clusters.

A second advantage of first applying a dendrogram algorithm is that the centroids of the generated clusters can then be exploited for the initialization of a K-means clustering, which is done in this second stage of our analysis. To assess the quality of the clustering obtained when using various numbers of clusters, we also compute K-means clusterings with 2 to 10 clusters. For that matter, initialization points are selected randomly and the algorithm is run 50 times, the best clustering being kept for

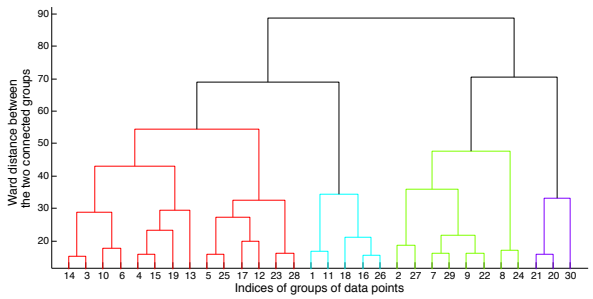

Figure 2: *Ward dendrogram applied to the first four PCA components of our data (the leaves in the plot correspond to more than one data point).*

analysis.

The silhouette value provides an evaluation of the clustering quality, the higher the value, the better the distinction between the various clusters [29]. Figure 3 interestingly shows that, even when launching a K-means with random initialization on the 4 PCA components of our data, the algorithm achieves the best clustering quality with four clusters, which confirms what was shown by the dendrogram. It should be noted that a similar curve, with a peak for 4 clusters, is also observed when launching the K-means on 10 PCA components instead of four. Another interesting finding is that the silhouette value reached with 4 clusters and random initialization is identical to that obtained when initializing the K-means on the centroids of the dendrogram, which might indicate a potential similarity between both clusterings. It should be highlighted, however, that the obtained silhouette values are rather low, indicating a rather uncertain distinction between the clusters.

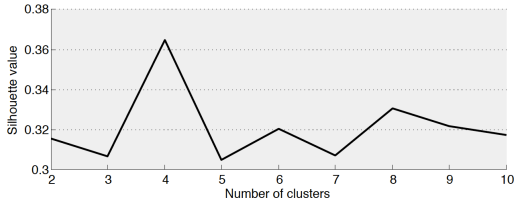

Figure 3: *Value of the silhouette of the K-means on four PCA components according to the number of clusters, with random initialization.*

The rand-index [30] allows comparing two clusterings. Its value ranges between 0 and 1, 1 corresponding to two identical clusterings. Paired comparisons were performed for four K-means clusterings in 4 clusters: with initializations on centroids of dendrogram on 4 (i) and 10 PCA components (ii) and with random initialization on 4 (iii) and 10 PCA components (iv). All rand-index values reach a level above 0.93 which indicates a certain stability, all clusterings converging towards the same solution.

The first of the four clusterings is used in the remainder of this study. A prosodic analysis of the syllables contained in the four clusters indicates that each cluster can be associated to a specific realization in terms of the three main prosodic features (i.e. energy, F0 and duration), as shown in Table 1. To investigate whether the increase in the number of clusters goes in line with an increase in the naturalness of the expressivity, the version with 10 clusters, as obtained with random initialization on the 4 PCA components, is also assessed in the perceptual evaluation. This clustering provides a vectorial quantification of the acoustic space, each region being assigned to a different cluster. It should be noted, however, that it is obviously more complex to predict such a high number of tags from a text to synthesize.

Table 1: *Acoustic characteristics of the clusters, compared to average acoustic values of emphatic stresses.*

Cluster	Energy	F0	Duration
Cluster 1	-	+	-
Cluster 2	-	-	-
Cluster 3	+	+	-
Cluster 4	+	+	+

3.4. Correlation between clusters and linguistic contexts

Potential correlations between the four defined clusters and linguistic information (syllable position, structure, etc.) are investigated. HMM-based speech synthesizers relying on such contextual criteria to cluster the models, correlations would indicate a possible automatic distinction between the various acoustic realizations. This would imply that the clusters would not need to be explicitly distinguished in the annotation.

We analyzed 13 linguistic variables used as contextual information for synthesis: position of the syllable or word in the word or rhythmic group (RG), amount of syllables in word and RG, amount of (content) words in RG, structure of the syllable, nature of the nucleus and part of speech of the word. Seeing the high amount of samples, Chi-square tests tend to be significant for most variables. Cramer's V [31] allows interpreting chi-squares for high effectives. Table 2 shows that only weak associations (i.e. $V < 0.2$ [32]) can be seen between the acoustic clusters and contextual linguistic information.

Table 2: *Correlation between the four clusters and linguistic contextual information (first five variables).*

Variable	Cramer's V
Syllable position in word	0.1379
Nature of the vowel	0.1165
Word position in rhythmic group (forward)	0.1164
Syllable position in word (forward)	0.1141
Syllable position in word (backward)	0.1137

Interestingly, the highest value (i.e. 0.14) is assigned to 'syllable position in word', mainly informative about whether a syllable is initial or final. The omnipresence of both syllable and word position in the ranking drove us to investigate whether some acoustic differences may be due to final syllables at the end of the RG. In that case, they might coincide with what is commonly referred to as boundary tone [13], which could influence their realization. Table 3 shows that the acoustic values of those syllables are significantly higher compared to the other emphatic stresses (respectively p=4.1e-05, p=1.2e-04 and p=1.6e-08 for a bilateral ranksum test performed on 82 final emphatic syllables and 721 other emphatic syllables). This indicates that the distinction between the clusters can partly be explained by linguistic contextual information. Associations

are however rather weak, suggesting that other factors probably play a role in the acoustic realization of emphatic stresses.

Table 3: *Acoustic realizations of final emphatic stresses (end of word at the end of RG) and other emphatic stresses, together with their 95% confidence intervals.*

Emphatic stress	Mean F0 (Hz)	Syllable Dur (z-score)	Mean Energy (dB)
Final	262.9 ±7.4	1.9 ±0.6	49.4 ±1.8
Other	242.9 ±3	0.84 ±0.1	44.2 ±0.4

4. Speech synthesis: A perceptual study

4.1. Evaluation protocol

In order to assess the quality of the expressivity produced when integrating various types of emphatic stresses, several HMM-based speech synthesizers [33] were built, relying on the implementation of the HTS toolkit (version 2.1) publicly available in [34]. For each synthesizer, 90% of the corresponding database was used for the training (called the *training set*), leaving around 10% for the synthesis (called the *synthesis set*). As filter parameterization, we extracted the Mel Generalized Cepstral (MGC) coefficients traditionally used in parametric synthesis. As excitation modeling, the Deterministic plus Stochastic Model (DSM [35]) of the residual signal was used to improve naturalness. Emphatic annotation was used as contextual information, in the same way as linguistic information.

Three models are compared: the baseline model (*Baseline*), using only one emphatic stress, and the models with 4 (*4 Stresses*) and 10 (*10 Stresses*) emphatic stresses, as obtained by annotating the emphatic syllables with the 4 and 10 clusters defined in the previous section. Test sentences were automatically selected from the synthesis set, as being shorter than 5 seconds and displaying at least two emphatic stresses in their annotation. It is indeed much easier to compare short sentences in which more than one difference appears. The test consisted in 18 pairs of sentences, 6 from each comparison, randomly selected from 63 pairs (21 for each comparison).

30 native French-speaking testers, mainly naive listeners, participated in the evaluation. During the test, they could listen to the pair of sentences as many times as wanted. For each comparison, they were first asked whether they heard any difference between both versions of the sentence. If so, they were asked to compare them in terms of naturalness of the expressivity. The scale ranged from -3 (much less natural) to +3 (much more natural). A score of 0 was given if both versions were found to be different but with equivalent naturalness of the expressivity.

4.2. Results

A first interesting finding is that the testers did not hear any difference between both versions for around 20 % of the pairs. This percentage is even higher (i.e. 28%) for models with 4 and 10 clusters which tend to display rather similar intonational patterns. Figure 4 shows the preference percentages for the remaining pairs. Middle sections correspond to pairs which were considered as similarly natural in terms of expressivity. We can observe that the model with 4 emphatic stresses slightly outperforms both other models. This might be explained by the fact that it more accurately synthesizes the various acoustic realizations of the stress. In the10-cluster model, we notice a degradation which may be due to the reduced number of occurrences for each stress, which is partly alleviated with the 4-cluster model. However, the preference for 4 clusters rather than one single stress (i.e. the baseline) is quite weak and is not statistically significant (p=0.11 with a unilateral ranksum test comparing the average percentage of preferences on the 30 testers).

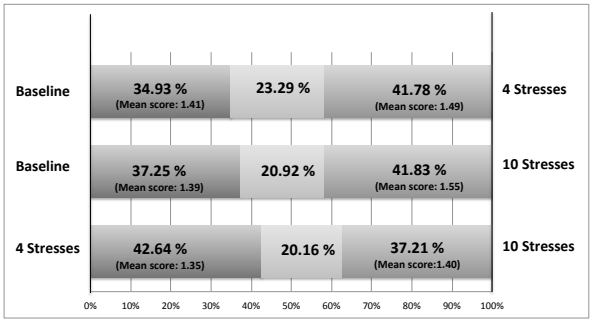

Figure 4: *Percentage of preferences for each model in the three comparison pairs.*

Figure 4 also shows, in parenthesis, the mean score obtained by the three models when preferred in the comparison. These scores are barely higher than 1 because testers mostly assigned a score of '1', reflecting only a 'slight' preference.

5. Conclusion

Emphasis is known to play a crucial role in expressive speech. Its generation in speech synthesis usually relies on a prosodic annotation of the training corpus. For that matter, emphatic stresses can be assigned a single label or be divided into distinct labels according to their acoustic realization. While the prediction of a single label from text is easier, the use of different tags might allow for the generation of more suitable stresses. The question is then whether the use of several emphatic labels effectively improves the naturalness of the expressivity.

The objective of this paper was precisely to answer this latter question by investigating HMM-based speech synthesis using one or several emphatic labels. Statistical acoustic analyses allowed determining 4 and 10 distinct emphatic labels based on a set of extracted acoustic features at the syllable level. The definition of 4 clusters was shown to achieve the best clustering quality. The model with 10 labels was computed to propose a vectorial quantification of the acoustic space. Both models were compared to a baseline model using a single emphatic label.

Perceptual tests showed that the model with four emphatic stresses is slightly preferred over both other models. However, the differences are not significant. While participants did not perceive any difference in 20% of cases, more than 20% of the remaining pairs were scored as 'similar' regarding the naturalness of expressivity. For pairs for which a preference was given, the score was usually low, denoting a weak degree of preference. These results tend to indicate that it might not be required to explicitly annotate different kinds of emphatic stresses in the corpus, when using HMM-based speech synthesis. This is a clear advantage for the annotation of the text to synthesize. However, this finding should be confirmed with further investigations on data with other speaking styles and languages.

Sources of variation of articulation rate in native and non-native speech: comparisons of French and German

Jürgen Trouvain, Bernd Möbius

Department of Computational Linguistics and Phonetics, Saarland University, Germany
trouvain|moebius@coli.uni-saarland.de

Abstract

Speech tempo including articulation rate is often considered as a good predictor in the diagnosis of foreign language proficiency and its comprehension. In this study we investigate various sources of variation of articulation rate such as the L2 proficiency level, individual tempo habits in L1 and L2, and more extensive exposure to native speech. In addition, we also discuss the difficulty of defining the most informative unit for rate metrics which allows comparisons between French and German. The materials used are French and German read sentences, produced as L1 and L2 speech. In contrast to other studies individual habits of articulation rate in the L1 was only partially observed in the corresponding L2 data (a slow L1 speaker does not necessarily articulate slowly in the L2). The convergence of most French learners to the German model speakers shows the advantage of having additional input for phonetic exercises. The fastest German learners also converge to the rather slow French model speaker.

Index Terms: articulation rate, L1, L2, convergence, individuality, French, German

1. Introduction

Speech tempo is often considered as a good predictor for various important concepts in the diagnosis of second and foreign language (henceforth L2) including the level of

- L2 proficiency [1],
- intelligibility and comprehension [2], and
- perceived foreign accent [2].

Articulation rate as the key component of speech tempo would thus be an optimal and easy-to-handle indicator of the level of the *spoken* language learning process.

It can be seen as established that *on average* speech in the first language (L1) is articulated faster than L2 speech, be it that the same speakers are faster in their L1 than in their L2 [3, 4, 5] or that L1 speakers are faster than L2 speakers in a given language [4, 6, 5]. Therefore the quantified tempo, whatever be the metrics, should reflect this difference between L1 and L2 speech. In addition, L2 speakers with a lower level of L2 proficiency will in general be slower than L2 speakers with a higher level of L2 proficiency [7].

Another factor of variability is the fact that languages show different measured rates. When we compare German with French, French usually shows 'faster' syllabic rates than German. One could argue that articulation in French is actually *produced* faster because it is *perceived* as faster than German – by German listeners. However, this argument can be applied in the other direction as well: articulation of German is also perceived as faster than 'usual' – by French listeners.

Cross-language studies on speech tempo either compare L1 speakers of one language with L1 speakers of another language (ideally with comparable text material), or L1 speakers of a given language with L2 speakers of the same language (ideally with identical text material).

A further source of variation lies in the fact that individual speakers differ in their tempo [10]. Some speakers articulate faster than others, be it in their L1 or in an L2.

From a learning perspective it can be assumed that L2 speakers perform better when material to be read is not only presented in its orthographical form but also provided in spoken form by a native speaker. In the latter case the learner's articulation should be faster and thus converging to the native-like articulation rate [8]. Reading only would then be slower than reading after listening to L1 speech.

In total we can thus identify four main sources of variation due to L2 proficiency, rate metrics, individuality and convergence. These sources of variation with expected patterns are illustrated schematically in Fig. 1 and described in more detail in the following subsections. Other sources of variation of articulation rate like for instance sex and age [9] are not considered here because they are not of primary relevance.

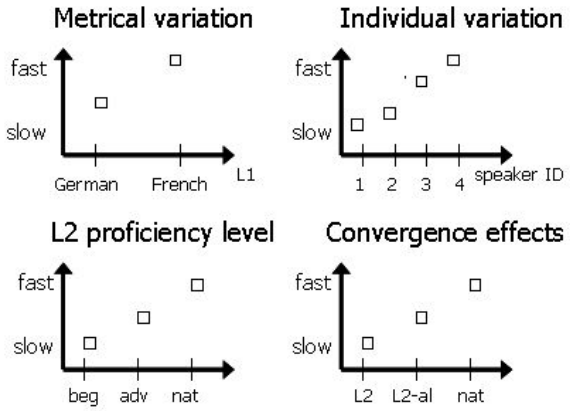

Figure 1: *Sources of variation of articulation rate with expected patterns (beg=L2 beginners, adv=advanced L2 learners, nat=native speakers, L2-al=L2 speech after listening).*

1.1. Speech rate metrics

When considering speech tempo or speech rate we distinguish between the *speaking rate* as the gross rate *in*cluding all pauses and *articulation rate* as the net rate of articulated speech, i.e. *ex*cluding all pauses.

In the concept of *fluency* (which is beyond the scope of this paper) articulation rate would be part of speed fluency which can be distinguished from repair fluency and breakdown fluency (cf. e.g. [10]).

Another issue in speech rate metrics is the choice of the basic linguistic unit. Possible candidates are the word, the syllable and the segment. The most popular unit seems to be the syllable [11, 9], thus having syllables per second or conversely the mean syllable duration as the preferred metrics. The advantage of the syllable in comparison to the word is that it is less variable in length within and across languages (compare for instance the mean length of words in Finnish or Turkish with those in French or English). The disadvantage of segments and syllables as basic units is that counting is not as easy as words. Another disadvantage of the segment is that they are more frequently elided than syllables or even words.

The aspect of elision leads to the next challenge selecting the optimal speech rate metric. Do we operate with phonological units which can be assumed as underlying representations and used as planned units, or should we focus on the actual realisation of these units (cf. [9, 12])? An argument in favour of the phonological units would be that the omitted segments or syllables or words are likely to be accounted for in speech planning and probably in speech perception, too. Thus, one strategy of speaking faster is to omit more units. An argument against the phonological units would be that speech with a moderate speed of articulation but with many omissions would reflect sloppiness but not necessarily fast articulation. For pragmatic reasons the use of phonological units often seems to be the preferred option, because for scripted material the number of units would be the same and the working load of analysing all speech samples with regard to omissions does not apply (apart from the fact that omission of segments is not always as clear as wished).

1.2. Research questions

1.2.1. Rate metrics

What is the most informative unit for rate metrics which allows comparisons between French and German? We are looking for a metric that facilitates the comparison of the speaking tempo between various speech modes such as L1 speech of different languages, L2 speech of different languages, different levels of proficiency in L2 speech, and further individual differences, in L1 *and* L2 speech. Probably there is not a single metric reflecting all these levels of variation.

However, we expect that syll/s is not the best metric to reflect articulation rate in L1 and L2 speech for the French-German language pair. Comparisons of syllable rates between German and French show substantially higher values for French, e.g. 7.3 syll/s (Fr.) vs. 5.6 syll/s (G.) in [13] or 7.18 syll/s (Fr.) vs. 5.97 syll/s (G.) in [14]. This phenomenon can be explained by a higher complexity of syllables in German where more time is required to articulate more segments in a syllable.

1.2.2. Native speech and the level of L2 proficiency

Regarding native speech and the level of L2 proficiency we ask: Do beginners articulate slower than advanced learners, and do native speakers articulate faster than advanced learners? For both questions we would expect an affirmative answer for both languages.

1.2.3. Individual habits of articulation rate

Are individual articulation rate habits in L1 visible in L2 speech? Following [15, 10], who found partial evidence for rate variation on the learner's personal speaking style irrespective of L2 proficiency, we can expect an affiramtive answer to this question, too.

1.2.4. Convergence to L1 speech

Can we observe any convergence of articulation rate to native speakers when learners get more extensive exposure to native speech, e.g. reading a sentence after listening to that sentence read by a L1 speaker? The use of more than one sensory channel is generally assumed to be helpful in teaching and learning foreign language phonetics [16, 17]. We would expect an affirmative answer to this question as well.

1.3. Outline

The remainder of the paper is structured as follows: in section 2 we describe the materials and subjects used for this study, followed by an analysis of various metrics of articulation rate. In section 3 we present the results with regard to rate metrics and the research questions, which will be discussed in section 4 which concludes the paper with an outlook on future work.

2. Method

2.1. Material

We used a part of a phonetic and phonological learner corpus for the language pairs French-German and German-French [18]. The data are from 7 speakers with French as their first language and 7 speakers with German as L1. Each language group consisted of five speakers at a beginner level (A1 or A2 according to the European reference frame CERF) and two at an advanced level (C1 or C2 at CERF). All speakers were recorded in their L2 *and* their L1.

Samples from two conditions were selected, viz. (i) read sentences ("read"), (ii) repeated sentences ("repeated"). In the latter condition only L2 speech was recorded: the sentences were prompted orthographically (as in the "read" condition) but synchronously with an audio file spoken by a native speaker. These native model speakers were not subjects in this corpus. The task was to repeat the written sentence just heard. Note that the repetition was produced a few seconds after listening in order to avoid a direct imitation.

For each of the 14 speakers we analysed 10 sentences in the "read L1", 10 in the "read L2", and 10 in the "repeated" condition in the respective L2. As a consequence the sentences "Read French" and the sentences "Read German" were produced by all 14 speakers, either in their L1 or in their L2. The sentences "Repeat French" were produced only by the German speakers, and the sentences "Repeat German" only by the French speakers. In total the analysis included 30 (sentences) x 14 (speakers) = 420 sentences.

2.2. Analysis

Start and end of the articulation of the sentences as well as silent and breathing pauses (if present) were first determined by means of an automatic speech recognition procedure using forced alignment. In a second step all labels were auditorily and visually checked with the speech editor Praat and manually corrected, if needed. We noted the appearance of possible addi-

tional syllables due to repetition, reflecting a disfluency that is not uncommon in L2 speech.

For each sentence the speaking rate (as a gross rate) and the articulation rate (as a net rate) were calculated for phones per second (phon/s), syllables per second (syll/s), and words per minute (wds/min).

The unit for syll/s was a *phonological* syllable, i.e. as produced in a canonical form. For phon/s the basic unit was the segment as predicted from the canonical form. The unit for wds/min was the word as counted in a text processor, e.g. the French "c'est" or "s'est" was counted as one word.

3. Results

3.1. Rate metrics

In about half of the sentences of L2 speech a pause was inserted. Pause insertion in L1 speech happened infrequently (less than 5 percent).

Fig. 3 shows that the syllable rates for French L1 and German L1 differ substantially whereas this is not the case for the phone rate (Fig. 2) and the word rate (Fig. 4).

The individual values of syll/s for the German speakers (S8-S14) show for the majority of speakers higher rates in their L2 than in their L1.

The distinction between L1 and L2 for each speaker group is achieved best for the metric phon/s. Thus, we present the data in phon/s in the following sections.

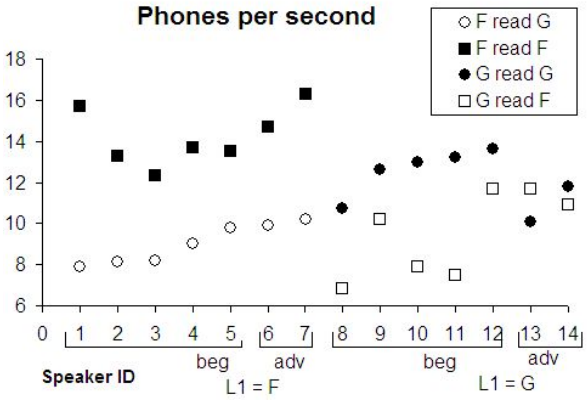

Figure 2: *Articulation rate of speakers in phon/s for the "read" condition. Speakers 1-7 with L1 = French (F), 8-14 with L1 = German (G). Speakers 6-7 and 13-14 are more advanced L2 speakers.*

3.2. L2 proficiency

In Fig. 2 the differences between native and non-native speech are clearly visible. For the French sentences the slowest L1 speaker is faster than the fastest L2 speaker which clearly marks a distinctive line between L1 French and L2 French speech. Similarly, in German the slowest L1 speaker (S13) articulates as fast as the fastest L2 speaker (S7). Both groups are clearly distinguishable.

For the level of L2 proficiency we see that the fastest L2 speakers (S7 for French, S13 for German) belong to the advanced learners. Analogously the slowest L2 speakers are L2 beginners (S1 for French, S8 for German). However, selected

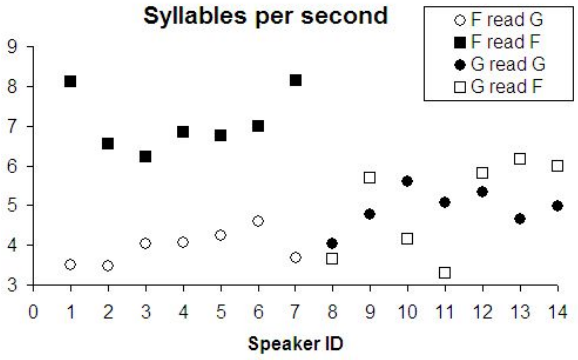

Figure 3: *Articulation rate in syll/s for the "read" condition. Speaker grouping as in Fig. 2.*

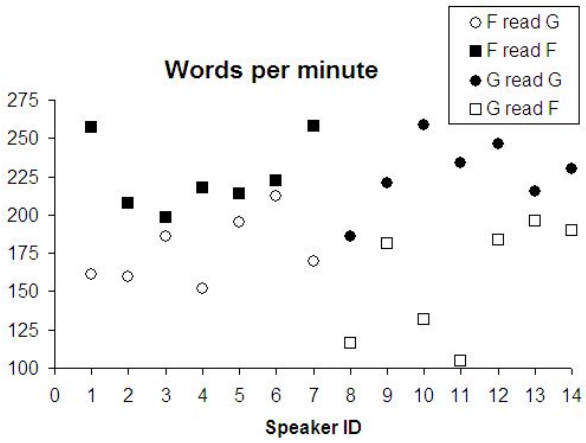

Figure 4: *Articulation rate in wds/min for the "read" condition. Speaker grouping as in Fig. 2.*

beginners such as S5 (for French) and S12 (for German) are also very fast.

3.3. Individuality

Fig. 5 shows that the range of articulation rate for French L1 speech lies between 12 and 17 phon/s, whereas German L1 speech shows values between 10 and 14 phon/s. Thus, the difference between the slowest and the fastest speaker in each L1 group is between 4 phon/s (G.) and 5 phon/s (Fr.).

When looking at the L2 groups these differences change: the French speakers with L2 German articulate with a rate between 8 and 11 phon/s, thus reducing the range to 3 phon/s. The articulation rate of the German speakers with L2 French lie between 7 and 12 phon/s, thus expanding the range to 5 phon/s.

Individual tempo habits also lead to the rather unexpected outcome that one speaker (S13) shows 'faster' values in L2 than in L1 speech. This example and also S14 show that slow talkers in their L1 can be fast talkers in their L2. Likewise, fast L1 speakers are not necessarily fast L2 speakers: the fast L1 speaker S1 is in his L2 speech as slow as S3 who is the slowest L1 speaker in French. Counterexamples are the German speakers S8, who is slow in his L1 and L2, and S12 as a fast counterpart.

3.4. Convergence

To compare the "read" and the "repeat" conditions for the two L2 groups Fig. 5 shows that all French beginners articulate faster when they have additional auditive input of L1 speech. Among the German beginners of French only three out of five were faster in the "repeat" condition.

The convergence effect is diminished for the advanced learners where only one out of four speakers was faster than in the "read only" condition. In general it can be seen that the learners with the slowest rates in "read" speeded up in "repeat".

The mean rate for the sentences by the two German model speakers in the "repeat" condition was 11.9 phon/s (11.7 phon/s for the one speaker, 12.1 phon/s for the other speaker). The speakers S5 (beginner) and S7 (advanced) nearly approached this articulation rate after listening but not for reading only.

The French model speaker was a rather slow speaker with 10.3 phon/s. All L2 speakers were slower than him, although three speakers (S12-S14) were faster in the "read" condtion.

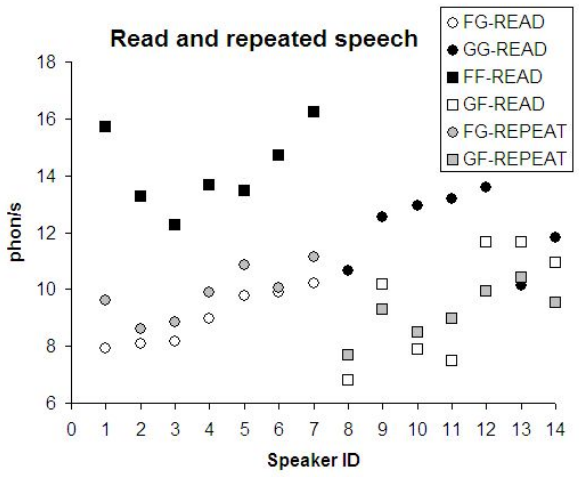

Figure 5: *Articulation rate for the "read" and "repeat" conditions. Speaker grouping as in Fig. 2.*

4. Discussion and conclusion

The rather low number of subjects per language and proficiency level allows only a limited interpretation of the results. Thus we need to be cautious with respect to generalisations. However, the explorative approach taken here has yielded interesting observations worth reporting and they represent good starting points for follow-up studies.

The best reflection of the L1-L2 difference for each speaker in our data seems to be phon/s. However, the phone rate for French is still considerably higher than for German (by 2.1 phon/s). A correction by this difference for the L1 German speech would result in a balanced picture with comparable ranges for L1 French and L1 German on the one hand, and comparable differences between L1 and L2 for the French speakers and the German speakers on the other hand. However, such a correction would ignore a correction for L2 German which would be a theoretical flaw. Although studies on speech rhythm often apply a normalisation of articulation rate between different languages (e.g. [13]), this usually concerns L1 speech and not L2 speech of the same speakers.

L2 proficiency is only to a limited extent reflected by articulation rate in our data. We deliberately left out learners at a medium level (B1 or B2 at CERF), but the distinction between beginners and advanced learners is not as clear-cut as expected.

The expectation regarding the transfer of the individual articulation rate habits from L1 to L2 is not entirely met. There is a huge variation among L2 speakers that *only partially* reflects L1 rate habits – in contrast to other studies [15, 10].

Our hypothesis about converging articulation rates of an L2 speaker after listening to an L1 speaker was confirmed. There is a positive effect of additional listening on speeding up for beginners with slow articulation rates. The extremely slow articulation rate of the French model speaker had a slowing-down effect on the fastest German speakers after listening. In both cases convergence in terms of articulation rate has evidently occurred. Since speaking slower may also indicate a more careful speaking style the slowed down L2 speakers possibly felt motivated to speak more clearly as well. Future studies are needed to clarify what kind of speaking style and what articulation rate can help which type of learner to improve the intelligibility and the fluency in L2 speech production.

Further topics for future research include the choice of rate metric. First, the metrics syll/s and phon/s are calculated based on the phonological structure rather than its actual realisation. Second, it is currently unclear how far the metrics applied here reflect the *perceptual* tempo [12, 19]. Another question in the context of speech perception is how comprehension is correlated with articulation rate. A last but not least point concerns the speech materials. In this study we used read sentences. It remains unclear how we can generalise from this sort of data to scripted and non-scripted styles, particularly when the discourse units are larger than a sentence. Nevertheless, read sentences, also with additional listening, are quite useful for exercises in learning and teaching environments.

The basic idea we started with was that articulation rate as the key component of speech tempo would be a good and easy-to-handle indicator of the level of the *spoken* language learning process. We have shown that for a comparison of different languages a correction for the variation caused by different phonological complexities should be considered.

As expected, more proficient L2 learners show remarkably high articulation rates, although not as high as L1 speakers. It is important to note that among the beginners there are speakers with similarly high articulation rates. One possible explanation for this finding is that different phonetic talents [20] also influence the speed of articulation.

An interesting observation is that there is generally an improvement in the temporal control of articulation when the L2 speakers had an additional auditory input of the sentence to be read. Although this is not the case for all L2 speakers, most of the *beginners* speeded up. It can be expected that this group benefit most from the input in multiple modalities when learning an L2. This point is important for the selection of exercises where speed of articulation should be part of a test and evaluation scheme which also includes computer-assisted pronunciation training.

Abstract

This paper describes our exploratory work in applying the Automatic ToBI annotation system (AuToBI), originally developed for Standard American English, to European Portuguese. This work is motivated by the current availability of large amounts of (highly spontaneous) transcribed data and the need to further enrich those transcripts with prosodic information. Manual prosodic annotation, however, is almost impractical for extensive data sets. For that reason, automatic systems such as AuToBi stand as an alternate solution. We have started by applying the AuToBI prosodic event detection system using the existing English models to the prediction of prominent prosodic events (accents) in European Portuguese. This approach achieved an overall accuracy of 74% for prominence detection, similar to state-of-the-art results for other languages. Later, we have trained new models using prepared and spontaneous Portuguese data, achieving a considerable improvement of about 6% accuracy (absolute) over the existing English models. The achieved results are quite encouraging and provide a starting point for automatically predicting prominent events in European Portuguese.

Index Terms: prosody, automatic prosodic labeling system, spontaneous speech.

1. Introduction

The role of detecting prosodic events is becoming more and more pervasive in different automatic speech processing tasks. The detection of prosodic events has proved to be useful for, *e.g.*, improving speech summarization [1], in ASR models [2, 3, 4], in predicting ASR recognized turns in dialogue systems [5], in predicting structural metadata events [6, 7, 8, 9], in improving unit-selection synthesis [10] or in detecting phonological units for expressive speech synthesis [11], and in identifying paralinguistic events [12].

The literature has documented a set of acoustic and visual correlates of prominence - duration, intensity, pitch, voice quality, and visual cues [13, 14, 15, 16, 17, 18, 19, 20, 21]. Systems built to predict prominence based on acoustic correlates are being used for cross-language studies. One such example is the **Au**tomatic **ToBI** annotation system (AuToBI) for Standard American English (SAE) by [17, 22]. AuToBI is a publicly available tool[1], which detects and classifies prosodic events following SAE intonational patterns. AuToBI relies in the fundamentals of the ToBI system, meaning it predicts and classifies tones and break indices using the acoustic correlates - pitch, intensity, spectral balance and pause/duration. AuToBI uses a modular architecture, which allows to perform six tasks separately and provides English trained models for spontaneous and read speech (for further details, *vide* [17] and references therein). The six tasks correspond to: i) detection of pitch accents; ii) classification of pitch accent types; iii) detection of intonational phrase boundaries; iv) detection of intermediate phrase boundaries; v) classification of intonational phrase boundary tones; and vi) classification of intermediate phrase boundary tones. Previous work on prosodic event detection using AuToBI [17, 22, 23, 24] have shown that prominence and phrase boundaries can be predicted in a cross-language (American English, German, Mandarin Chinese, Italian and French) context, albeit with language specific properties. Those studies also found little support for the hypothesis that language families are useful for cross-language prosodic event identification. Taking into account the described results, the aim of this work is to extend the AuToBI prosodic event detection system from English to Portuguese in two stages. First, English models are used to predict prosodic events in European Portuguese (detection and classification of pitch accents). Second, AuToBI capabilities are adapted using a relatively small amount of annotated data to train Portuguese models.

This paper is organized as follows. Section 2 comprises the description of the corpus used in the experiments. Section 3 presents the process of converting of tone inventories from P-ToBI to SAE, a pre-requirement to apply AuToBI to European Portuguese. Section 4 describes the experiments conducted and the main results achieved. Section 5 presents our conclusions and future work.

2. Corpus

This study uses a subset of CPE-FACES [25, 26], an European Portuguese Corpus Spoken by Adolescents in School Context. The corpus consists of spontaneous and prepared unscripted speech from 25 students (14-15 years old) and 3 teachers, all

[1]http://eniac.cs.qs.cuny.edu/andrew/autobi/

Corpus subset →	train	test	total
total time (minutes)	33.4	10.9	44.2
useful time (minutes)	20.6	6.6	27.2
number of pitch accents	2061	717	2778
number of phrasing units	1382	489	1871
number of words	4361	1456	5817

Table 1: Properties of the CPE-FACES subsets.

speakers of standard European Portuguese (Lisbon region), totaling approximately 16h. It was designed to represent some of the speech tasks that are common in school context and it was collected in the last year of compulsory education (9th grade), in three Lisbon public high schools. It was recorded in a natural setting – the speakers classroom of Portuguese as L1 – in different communication situations: two dialogues (both spontaneous) and two oral class presentations (one spontaneous and another one prepared, but unscripted). In the spontaneous presentation, students and teachers were unexpectedly asked to relate an (un)pleasant personal experience. It was assumed that the involvement of speakers on topics related to their personal interests and day-to-day life would manifest in the naturalness and spontaneity of their talks [27]. The prepared situation corresponds to typical school presentations; the presentation was about a book the students must read following specific programmatic guidelines. For students, a variety of presentations on Ernest Hemingway's "The Old Man and the Sea" and on Gil Vicente's "Auto da Índia" was recorded. As for the teachers, all prepared presentations were related to the study of "Os Lusíadas" by Luís de Camões, and two address the same episode - the lyric-tragic episode of Inês de Castro.

Basically, spontaneous and prepared presentations differ in the degree of planning involved, the type of information communicated, the speakers' attention to the speech task and effort to speak clearly. In spontaneous presentations, the speakers can talk freely about any topic of their choice; they can change topic and move on to another topic whenever they feel like it. As far as typical (prepared) oral presentations at school are concerned, it was argued before that "more than talking about a pre-determined theme, an oral presentation presupposes the capacity to individually produce a greater amount of utterances, organizing the information that is given to the public in a clear structured form" [25].

The recordings of the two female teachers and all the students were done with an UHER 400 Report Monitor recorder with a BASF LPR 35 magnetic tape and a SENNHEISER MD 214 V-3 worn suspended from the neck microphone. These recordings were latter digitized at 44.1 kHz, using 16 bits/sample and afterwards downsampled to 16 kHz. CPE-FACES was recently extended with the recordings of a male teacher, using a TASCAM HD-P2, a Portable High Definition Stereo Audio Recorder, and a head-mounted microphone Shure, a Sub-miniature Condenser Head-worn Microphones, model Beta 54. The sound was recorded in mono, with 16-bit at samples rates of 44.1kHz, and afterwards downsampled to 16 kHz.

The subset of the corpus used in this study comprises 9 spontaneous presentations and 9 prepared unscripted presentations, from 6 teenage students (balanced by gender) and 3 teachers (2 female and 1 male). The data was split into train and test subsets, where the training part corresponds to about 75% of each speech file and the test part corresponds to the remaining 25%. Both subsets include portions of each speech file, which reduces the bias of training and testing using different conditions. Even so, one should note that the test set of our data is harder to automatically process, mostly due to the fact that by the end of a presentation interlocutors tend to interrupt more, leading to more overlapping speech. These rich interactions result in harder stretches of speech to process. The overall statistics about the subset of the corpus are presented in Table 1, where "total time" correspond to useful time and silences. The useful time is similar to other corpora subsets used by [23] for cross-language detection of prosodic events with AuToBI, namely the Italian subset (25 minutes of read speech by a single speaker). Having an equivalent amount of data (at this point a small sample of 27 minutes) allow us to make more direct comparisons with previous studies applying AuToBI.

The data was annotated by two expert linguists using the ToBI prosodic system adapted to European Portuguese (Towards a P_ToBI by [28]), in order to conduct experiments on automatic ToBI-labeling in European Portuguese, as part of the ongoing project[2] that funded this research. All the pitch accents (H+L*, H*+L, L*+H, L+H*, H*, L*, H+!H*) and the final boundary tones (L%, H%, !H%, LH%, HL%) that are covered in the Towards a P_ToBI proposal were used in this subset (see the schematic F0 contours in Figure 1). For further details on the annotation of the corpus, *vide* [26, 29].

3. Converting tone inventories

As previously said, AuToBI relies on the fundamentals of SAE. Therefore, as a pre-requirement to apply AuToBI to European Portuguese, the tonal inventory of P_ToBI, displayed in Figure 1, had to be converted converted to the SAE inventory. Since this work is our first step towards fully automatic prosodic labeling, at this stage no feature adaptation (pitch, intensity, spectral balance and pause/duration) was done. The conversion process was jointly carried out with one of the American co-authors of this paper. This task involved the analysis of a considerable amount of examples for each pitch accent and boundary tone in the P_ToBI inventory. Table 2 summarizes the conversions that have been made.

The main differences concern falling pitch accents and single boundary tones at intonational phrases (IPs). First, H+L* - a very frequent nuclear accent in European Portuguese (associated with declaratives and wh- question), which is absent in the SAE inventory. Second, H*+L - relatively uncommon in the subset analyzed, which is also absent in the SAE inventory. Third, H% and L% - single boundary tones at intonational

phrases, as proposed by [30, 28]. In [30, 28], two different levels of phrasing are equated both to the intonational phrase: the major IP and the minor IP, in line with [31]. Minor and major IPs are marked with breaks 3 and 4, respectively, and the diacritics "-" and "%" represent the different strengths of the IP boundaries. Although [32] proposes a reanalysis marking both IP levels as "%", the labels "-" and "%" were kept in the subsets of CPE-FACES. Table 2 also displays the tones shared by both intonational systems (H*, L*, L+H*, L*+H, H+!H*, LH%, L-, H-, !H-).

4. Results

This section presents our first efforts towards the automatic detection of prominent prosodic events in European Portuguese. We have started by identifying prominent events using exclusively English models. The evaluation of such models was initially performed using the Portuguese data as a whole and later using the test set exclusively. Finally, we have trained new Portuguese models and verified their impact on prominence detection. Portuguese models were trained firstly using the whole training set (which includes students and teachers data) and later using exclusively teachers data. In all steps, results were evaluated using standard performance metrics [33]: precision, recall, f-measure, and accuracy, which can be expressed in terms of true positives (*tp*), true negatives (*tn*), false positives (*fp*), and false negatives (*fn*) as follows:

$$precision = \frac{tp}{tp+fp},$$

$$recall = \frac{tp}{tp+fn},$$

$$accuracy = \frac{tp+tn}{tp+fp+fn+tn},$$

$$Fmeasure = \frac{2 \times precision \times recall}{precision+recall}$$

4.1. Prominence detection using English models

After the conversion process described in Section 3, existing English (EN) models were applied to the Portuguese (PT) data. The English models used correspond to the 1.3 version, which includes training material from three corpora: Boston Directions Corpus, Boston University Radio News Corpus, Columbia Games Corpus ([17] and references therein). Building upon previous studies using AuToBI [23, 24], we hypothesized that prominence could be fairly detected by using English models on Portuguese data, with no further adaptations of the system rather than the conversions of tonal inventories.

EN models	Accented			Unaccented			
PT.all	Prec	Rec	F	Prec	Rec	F	Acc
Overall	80.8	64.9	72.0	70.0	84.1	76.4	**74.4**
Students	73.7	47.6	57.8	64.3	84.7	73.1	67.1
Teachers	83.4	73.8	78.3	74.3	83.8	78.8	78.5

Table 3: Prominence prediction, using EN models and PT data.

EN models	Accented			Unaccented			
PT.test	Prec	Rec	F	Prec	Rec	F	Acc
Overall	74.0	70.8	72.3	67.9	71.3	69.6	**71.0**
Students	61.1	63.1	62.1	55.8	53.8	54.8	58.8
Teachers	82.4	75.3	78.7	74.0	81.5	77.6	78.2

Table 4: Prominence prediction, using EN models and PT test set.

Table 3 presents the results of prominence prediction after applying the English models to the Portuguese data, discriminating between students and teachers. Results show that overall prominent events are detected with 72.0% of f-measure (80.8% of precision and 64.9% of recall). The accuracy of prominence prediction using English models is 74.4%. Thus, the results provide evidence that a considerable percentage of prominent events may be predicted from English to Portuguese, supporting previous research using AuToBI [23] for West-Germanic and Romance Languages, Portuguese not included. Table 3 displays a striking difference of around 11% accuracy between speakers (67.1 for students *vs.* 78.5% for teachers). Results are clearly better for teachers than for students, evidencing an age/status dependent effect on the prominence detection tasks.

English models were also applied to the test set of the Portuguese data exclusively. It is important to emphasize that, as previously stated, the test set of our data is harder to automatically process due mostly to very lively interactions between interlocutors. We believe that this is the core reason for the poorer results presented in Table 4 when compared with the ones in Table 3: the overall accuracy decreases by about 3% in the Portuguese test set. This result is mostly related to the overall prediction for students. For teachers the results are quite similar, with a slight improvement in prominence prediction (from 78.3% to 78.7% f-measure). To sum up, using exclusively the Portuguese test set, the overall accuracy decreases from 74.4% to 71% and the main differences between speakers still stand.

4.2. Prominence detection using Portuguese models

Previous results suggest that the prediction of prominence in Portuguese is fairly accounted for with English trained models. In this section, we target the training of Portuguese models and their impact on prominence detection. We expect that Portuguese trained models improve the overall accuracy of

Table 6: Confusion matrix for prominence prediction.

prominence detection, as language-dependent models usually enhance a system performance.

At this point, we have extended AuToBI capabilities to Portuguese by training Portuguese models with the Portuguese train set. No feature adaptation was performed, since we aim at evaluating the impact of language specific data integration in the overall accuracy. Table 5 summarizes the results achieved, showing an overall accuracy increase of around 6% in prominence prediction (77.2%), when compared with previous results obtained with English models (71.0%, see Table 4). Moreover, better performances are achieved for both students and teachers, with accuracy improvements of 11% for students and 3% for teachers. Comparatively, prominence detection show a higher gain for students than teachers, however, there are still striking inter-speaker differences in terms of age/status. Results show that training with language specific data improves prominence detection, in line with our expectations.

The confusion matrix in Table 6 shows prominence (mis)detection, displaying a higher percentage of non-prominent events classified as prominent (24.6% *vs.* 21.2%).

Along this work we have been pointing out striking differences between speakers, showing that teenage data is clearly more difficult to deal with than teachers data. Taking such differences into account, we have trained a new model using exclusively teachers training data. Such model allows us to perform more direct comparisons with previous experiments for other languages, which are commonly based on adult speech, either read or spontaneous speech (task-oriented). The training material for this final evaluation corresponds to 18.8 minutes (silences included) of teachers data only, aiming at producing a more homogeneous training data. In this final evaluation, the overall accuracy decreases to 59.7% (53.7% for students and 63.2% for teachers), which clearly demonstrates that the amount of training material is insufficient. Moreover, these results also show that is preferable to have large amounts of training material from English than having small language dependent samples (see Table 4). This also suggests that increasing the amount of Portuguese training data will likely lead to even better results than the ones already achieved (see Table 5).

The comparison between language dependent or cross-language models applied to the same test set is on its own very informative. Namely, we could verify that using models trained with large amounts of English data captures a considerable amount of prominent events. Our results for European Portuguese are closer to the ones presented in [23], which reported an accuracy ranging from 62.9% to 82% for West-Germanic and Romance languages, as French and Italian. This may suggest that a considerable amount of acoustic information is shared amongst different typological languages.

5. Conclusions and future work

This paper presented our first steps towards the extension of the AuToBI prosodic event detection system to European Portuguese. The first step concerned the prediction of prominent prosodic events based on models trained for English. In the second step the AuToBI models were retrained with a moderate sample of Portuguese ToBI annotated data. This training corpus includes both spontaneous and prepared unscripted speech from both adults and teenagers (teachers and students). This is not the typical starting point for such cross language experiments, but could not be avoided. As expected, the results showed poorer performance in prominence prediction for teenagers, contrasting with state-of-the-art results achieved for adults' data, regardless of the models used. This shows a clear age/status dependent effect present in our data.

Regarding the experiments conducted using the English models on Portuguese data, results showed an overall accuracy of 74.4% of prominence detection, comparable to state-of-the-art results [23]. This result further supports previous predictions using the same English models, which show that prominence detection is fairly accounted for one language to another [23]. When adapting AuToBI capabilities to train Portuguese models, as expected, the prediction of prominent events further improved in about 6% absolute. We may interpret those results as pointing out to two main directions: first, a considerable amount of prominent prosodic events may be cross-language predicted, even when tackling a sample of different typologic languages; second, albeit the reasonable cross-language prediction rate, there are language specific traits captured only with language-dependent trained models. This raises several research questions, *e.g,* on cross-language universal acoustic correlates of prominence vs. language dependent acoustic correlates; on genre free or genre dependent prosodic properties; on tonal density across languages; or even on informational structure. With this work we hope to contribute to prominence detection research, still scarcely studied.

Our preliminary results for European Portuguese are quite encouraging and a starting point to further enrich large amounts of (highly spontaneous) transcribed data available for our language. Therefore, future work will tackle the prediction of other prosodic events (phrasing and tonal boundaries), and the evaluation of the trained Portuguese models for different genres (university lectures, map-task dialogues, broadcast news, broadcast interviews, meetings, etc.). This will also allow us to address the study of age-specific and status-specific properties.

Abstract

Prosodic prominence, a speech phenomenon by which some linguistic units are perceived as standing out from their environment, plays a very important role in human communication. In this paper we present a study on automatic prominence identification using Probabilistic Graphical Models, a family of Machine Learning Systems able to properly handle sequences of events. We tested the most promising members of such models on utterances selected from a manually annotated Italian speech corpus, obtaining very good recognition results crucially converging with the prominence detection responses provided by a pool of native speakers.

Index Terms: prosody, prominence, probabilistic graphical models, prominence annotation.

1. Introduction

A fairly uncontroversial definition of *prosodic prominence* due to Terken [29: 1768] states: "*prominence is the property by which linguistic units are perceived as standing out from their environment*". These prominent units typically contain relevant information for discourse and their correct perception is crucial for a successful communication strategy. Speakers use prominence to draw the listener's attention on specific point of the utterance, to express their emotion or attitude about the topic being discussed, to indicate the focus of an utterance, to mark the introduction of new topics, to indicate the information status of a word (new or given), to change speaking style, etc.

For all these reasons, the automatic management of prosodic prominence is crucial for both recognition and synthesis in order to build systems able to properly handle information in speech.

There is a long-standing agreement among scholars to consider the syllable as the prominence-bearing unit in connected speech. This position is not uncontroversial, however, and various studies analyse prominence at word level, especially if they mainly concern information extraction from speech utterances. In this paper we will consider the syllable, and its constituent units, as the relevant domain for prominence computation.

Several recent contributions handle prosodic prominence from a computational point of view, proposing different models (both Rule-Based and Machine Learning Systems - **MLS**) for the automatic detection of prominence in various languages, e.g. [2, 5, 11, 12, 15, 24, 25, 26]. Some of them are specifically devoted to Italian, or handle the identification of prosodic prominence in Italian among other languages [1, 8, 17, 26].

In this paper we present a procedure for the identification of prosodic prominence in Italian in the framework of MLS, based on training procedures that extract data and models from annotated corpora. These systems only take acoustic features into consideration, such as nucleus / syllable duration, energy measures in the nuclei / syllables and analysis of specific pitch profiles in the utterance.

Adopting the above reported definition [29], we consider prominence as a phenomenon establishing precise syntagmatic relations with respect to the neighbouring syllables. Its identification requires MLS able to properly model sequences of events, because the immediate context information, both in the feature sequence of the input and in the label sequence of the output, are crucial for the correct identification of syllable prominence. A syllable can be defined as prominent only by considering the relationships with other syllables, in line with the classical figure – ground contrast proposed by Gestalt psychology, rather than by considering it – and its features – in isolation.

Probabilistic graphical models (**PGM**) represent a class of MLS that, taking advantage of discriminative stochastic models, can successfully handle recognition problems that heavily depend on sequences. PGM, in some of their various configurations / models, have been applied to the task at stake with encouraging results [8, 21]. Despite these findings, PGM and their complex family of model variations have not yet been extensively applied to this problem, especially considering hidden or latent dynamics detection in speech data and the possibility of extracting and using high order relations among the acoustic features.

2. Probabilistic graphical models

PGM are powerful frameworks for representation and inference in multivariate probability distribution. They use a graph-based representation as the basis for compactly encoding a complex distribution over a high-dimensional space representing the conditional dependence structure between random variables.

In this paper we considered some of the most powerful and widespread discriminative models to identify prosodic prominence in continuous speech, as well as some recently presented new models.

PGM consists of a large family of different methods that constrain the graph structure in specific ways. Conditional Random Fields (**CRF** - see [10, 22] for general introductions) are no doubt the most used PGM in various fields. However, most CRF models use linear functions to represent the relationships between input features and the classification output and a simple graph structure for the entire model. This way of coding relations presents severe limitations for real-world applications, because: (a) in many cases the

relationships between inputs and outputs are complex and nonlinear, and (b) some problems require modelling relevant sub-structures in the label sequence.

In this work we used different PGM, each addressing in its own way the shortcomings of CRF models, considered as a baseline. Conditional Neural Fields (**CNF**) [20], inserting a small neural network between input and output, are able to capture the nonlinearities required by constraint (a) above; Latent-Dynamic Conditional Random Fields (**LDCRF**) [18], in turn, can learn latent sub-structures in output class labels. Latent-Dynamic Conditional Neural Fields (**LDCNF**) [16] can combine the advantages of both previous approaches in a single model.

PGM are able to manage sequences of input-output data predicting the output sequence considering both the input feature configuration, in a specific window centered on the generic input vector of features x_j, and the previous output sequence. Figure 1 outlines the different structures of the PGM used in this work.

Given the input sequence of local features $x_1,\ldots,x_n$, typically consisting of vectors of features, and given the output sequence $y_1,\ldots,y_n$, linear CRF assign the most likely label to output y_j conditioned by the feature vectors belonging to the local window and the previous output label y_{j-1}.

CNF extends CRF by adding one level of gate units, acting as a neuron tier (more precisely a perceptron), between the input and the output layers. These gate neurons are a sort of feature extractor able to capture nonlinear relationships between input and output.

A further, completely different way of extending CRF is implemented in LDCRF adding a layer of hidden-state units between input and output layers: these units are able to model the sub-structure of the label sequence and can learn complex dynamic behaviours between output labels.

Finally, LDCNF take advantage from both approaches, combining them in a unique structure. The LDCRF model is modified by adding the neural network introduced in CNF between input and hidden units; in this way, LDCNF models can both identify sub-structures in the output sequence and learn nonlinear relationships between input feature vectors and output class labels.

For lack of space, we refer to the cited papers for all mathematical and algorithmic details that define these approaches, especially for what concerns the learning algorithms, inference and parameter setting.

3. Corpus building and data collection

The materials used in this study were utterances extracted from the API/AVIP corpus [3] and from a selection of sentences read by a subset of the same speakers. The corpus consisted of semi-spontaneous conversations between native Italian speakers elicited with the map-task method for different Italian language varieties. The speakers used for the present purpose were from the Pisa area (central Italy).

The selected utterances presented a neutral intonation contour, without emphatic stress or pauses, and presenting at least 8 syllables. Care was taken to avoid any disturbing phenomena such as speakers' overlap, laughters, background noise, etc.

A perception experiment, divided into two different sessions (sets A-C vs D-G in table 1), was carried out using 120 selected corpus utterances (90 spontaneous and 30 read), produced by female and male speakers. The average utterance length was 18 syllables, ranging from 9 to 35. The task was performed by 35 Italian native speakers.

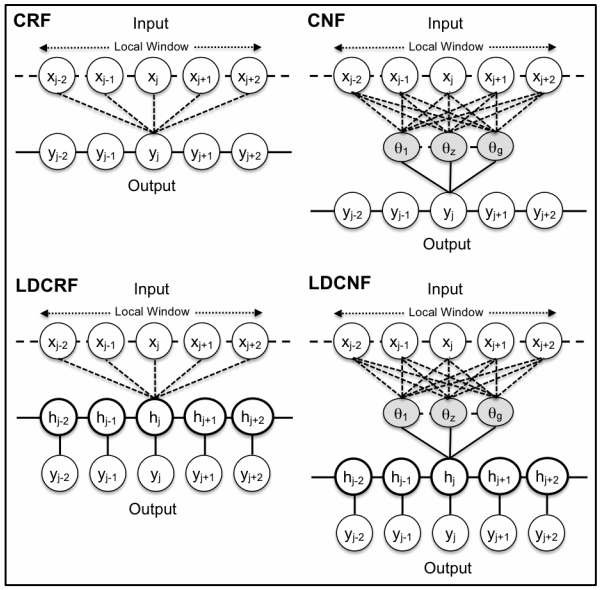

Figure 1. *The various PGM considered in this study. The gate units $\theta_1 \ldots \theta_g$ are in gray while the hidden units $h_1 \ldots h_n$ present a thick border. For clarity, only the region of the model net surrounding the generic input feature vector x_j is represented in the pictures.*

Table 1*: The latin square scheme applied to the 120 utterances composing the corpus.*

Utterance Sub-list	Annotators IDs
A (20 utt.)	1, 2, 3, 4, 5, 6, 7, 8, 9, 10
B (20 utt.)	1, 2, 3, 4, 5, 11, 12, 13, 14, 15
C (20 utt.)	6, 7, 8, 9, 10, 11, 12, 13, 14, 15
D (15 utt.)	16, 17, 18, 19, 20, 21, 22, 23, 24, 25
E (15 utt.)	16, 17, 18, 19, 20, 26, 27, 28, 29, 30
F (15 utt.)	31, 32, 33, 34, 35, 21, 22, 23, 24, 25
G (15 utt.)	26, 27, 28, 29, 30, 31, 32, 33, 34, 35

The experimental task was to identify the sentence prominences. The participants could listen to each sentence as many time as they wanted. To reduce the task difficulty, participants were presented with a transcription of the given sentence whereby each syllable (as the possible prominence-carrying unit) was separately indicated; in addition, the lexically stressed syllables were explicitly pointed out. However, participants were warned during the training phase that not all lexically stressed syllables were actual targets of sentence prominence, while prominence could also land on lexically unstressed syllables. As soon as the participant had made her/his own choice by clicking on the square corresponding to the intended syllables, s/he was immediately presented with another sentence.

Since this task is very demanding in terms of attention, the sentences were divided into sub-lists according to a latin square scheme, so that each utterance was judged by 10 speakers. As a consequence, no participant heard/read all the sentences. Table 1 depicts the annotation scheme: the total number of utterances was divided into seven sub-lists each assigned to 10 annotators.

For each test utterance extracted from the AVIP corpus, the phonetic transcription and the phoneme level segmentation were available in the source. The selected utterances were further segmented manually in order to identify the syllable boundaries.

3.1. First-step: data annotation and overall judgment convergence

As a first step, the participants judgments were pooled together and evaluated with respect to the degree of convergence relative to the identification of any given syllable as prominent. The convergence level was assessed with respect to four criteria (60%, 70%, 80% and 90%), indicating the percentage of shared prominence identification. In practice, considering that each sentence was judged by 10 participants, the 60% criterion implied the convergence of 6 out of 10 listeners (and similarly for the other levels).

Needless to say, the 90% agreement level involves a smaller number of prominent syllables within any given sentence, since almost all participants have to agree on their judgment concerning the given syllable. By contrast, the more generous 60% level concerns a larger number of syllables. Interestingly, there was full agreement as for the last prominence of each sentence, evidently due to unequivocal durational cues, although the energy and frequency levels at the end of an utterance are usually fairly low.

As is well known, while the identification of emphatic prominences is undisputable, there usually is considerable divergence among human judges on the identification of non-emphatic prominences. As a consequence, the 80% level was selected as bench-mark for the automatic detection of prominences as a first approximation. The dataset contains 480 prominent syllables out of 2037, thus close to one prominent syllable out of four (23.56%).

3.2. Second-step: best annotators selection

Capitalizing on the well-known lack of overwhelming convergence among human judges as for the localization of sentence prominences, a second type of comparison between the automatic detector and the human judges was adopted. For each of the two sub-lists of utterances, the three most reliable judges were selected, i.e. the three participants presenting the highest level of mutual agreement according to the Fleiss K index (this schema will be referred to as the "best-3" annotation agreement). Subsequently, the syllables judged as prominent by the majority of the "best-3" were considered prominent. The correlation data are reported in Table 2. In this dataset, 33.46% of the syllables are prominent (one out of three).

4. Acoustic features

The acoustic features used in this study are the same used in some previous studies of one of the authors [25, 26]. These works proposed a rule-based system resting on four acoustic features that exhibited good performances in prominence detection. One of the major challenges in predicting syllable prominence is the correct identification of the various sources of influence, such as: fundamental frequency excursions, duration, intensity-related parameters and listeners' linguistic expectancies.

The automatic prominence detection system described in [25, 26] is based on the global prominence model proposed by Kohler [13, 14]. In his view, there are two main 'actors', at the linguistic-prosodic level, playing a relevant role in supporting sentence prominence. The first, *pitch accent*, coincides with a concept first introduced by Bolinger [4] and concerns specific movements in F0 profile. The second, *force accent*, is completely independent from the intonational profile and is connected with different acoustic phenomena, such as intensity (or spectral emphasis), segmental durations and possibly others. Both 'actors' seem to play a relevant role in supporting prominence perception at utterance level, mutually reinforcing each other.

Table 2*: The "best-3" annotators for each utterance sub-list.*

Utterance Sub-list	Best 3 annotators	Fleiss-K
A	2, 3, 6	0.875631
B	1, 2, 13	0.876340
C	6, 9, 13	0.859735
D	16, 18, 20	0.836450
E	16, 19, 20	0.857646
F	31, 33, 25	0.863555
G	31, 33, 34	0.812559

In the present study, we considered the four features used in the cited work (reported in Table 3 with brief reference to their actual computation) and added one further acoustic feature, namely syllable duration, following the good results obtained in [8]. All these features, except syllable duration, are computed within the syllable nucleus domain. Thus, using the phonetic and syllabic segmentation provided in the source corpus, all we had to do was to define the duration of the syllabic nuclei, deriving it automatically from the other two measures.

5. Results and discussion

We made a number of experiments, considering various PGM and different parameter configurations in order to maximize the agreement between the automatic procedure and the human annotators. We tested the best system on the above-described corpus, applying a random sub-sampling validation to define the training and test set (respecting a 5/1 proportion, 100/20 utterances), repeating this procedure 20 times and averaging the obtained results.

The best performances so far obtained, in comparing the automatic classifications with the gold standard, are depicted in Table 4 and 5. The first table refers to the "80%" level of annotation agreement described in section 3.1, the second refers to the "best-3" agreement described in section 3.2. There is a clear performance improvement considering the "best-3" annotation schema: the larger inter-human agreement produces a more consistent annotation and, thus, better performances of the MLS trained on these data.

The accuracy obtained by our automatic systems is very high, considering that the typical inter-human agreement accuracy reported in the literature, when annotating prominence by means of two levels (prominent vs non-prominent) is in the range 70-90%.

However, considering that the distribution between the two prominence classes is rather skewed, one should best adopt the

F-measure as a more reliable metric of the actual system performance. An F-measure of 0.770 is quite high, considering that:

a) The training corpus used to set up the model, in the various permutations composing the 20-random-sub-sampling validation, is rather small to properly train a MLS, as it only contains 100 utterances (1800 syllable, on average);
b) We only used acoustic information and did not consider any linguistic feature that might improve the system's behaviour, as showed, for example, by [21].

Table 3. *Acoustic features used to set up the PGM models for prominence identification.*

Acoustic Feature	Description
Nucleus Duration	Duration of the syllable nucleus normalised w.r.t. mean and variance duration of the syllable nuclei in the utterance (z-score), as based on the manual segmentation available in the database.
Spectral emphasis	Normalised SPLH-SPL parameter [9] (z-score).
Pitch movements	Computed as the product of A_{event} and D_{event} parameters of the TILT model representation [28] of pitch movements. The raw pitch contour is the median of three pitch tracking algorithms [27]: RAPT [23], SWIPE' [6] and YAAPT [31]. The raw pitch profile was stylised by using a quadratic spline function, interpolating the control points derived from the OpS algorithm proposed in [19].
Overall intensity	RMS energy computed in the frequency band 50-5000 Hz, normalised to mean and variance of intensity inside the utterance (z-score).
Syllable Duration	The same as the nucleus duration but referred to the entire syllable.

Table 4. *Results obtained by the PGM tested, in terms of Accuracy, Precision & Recall and F-Measure, as referred to the 80% level of annotation agreement described in section 3.1. The parameters considered with the various PGM are:* w *– local window size (symmetric),* h *– number of hidden units,* g *– number of gate neurons and* α *– regularization factor.*

Model	Parameters	Results			
		Acc.	Prec.	Rec.	F
SVM	w=2, C=0.5	0.858	0.765	0.592	0.665
CRF	w=1	0.856	0.735	0.609	0.665
LDCRF [18]	w=1, h=2	0.856	0.720	0.640	0.676
CNF [16]	w=2, g=40 α=0.5	0.871	0.784	0.642	0.705
CNF [20]	w=1, g=20	0.872	0.769	0.667	0.713
LDCNF [16]	w=1, h=4, g=40, α=0.5	**0.875**	**0.788**	**0.658**	**0.716**

Table 5. *Results obtained by the PGM tested, as referred to the "best-3" level of annotation agreement described in section 3.2. The parameters are described in the caption of Table 4.*

Model	Parameters	Results			
		Acc.	Prec.	Rec.	F
SVM	w=1, C=50	0.833	0.791	0.681	0.732
CRF	w=2	0.838	0.795	0.695	0.741
LDCRF [18]	w=1, h=2	0.842	0.792	0.713	0.750
CNF [16]	w=1, g=20 α=0.5	0.845	0.803	0.712	0.754
LDCNF [16]	w=1, h=4, g=20, α=0.5	0.851	0.823	0.706	0.759
CNF [20]	w=1, g=20	**0.855**	**0.831**	**0.718**	**0.770**

Our results cannot be directly compared with other similar studies, because there are no standard corpora for evaluation, both in general and for Italian in particular, nor specific standardised metrics. In any case, it is worth observing that the best-obtained results are equivalent or better than those of the already cited studies (e.g. [8, 15, 17]).
The best PGM for the problem at hand seems to be CNF in the implementation proposed by [20]. LDCNF and CNF from [16] obtained slightly lower performances, especially using the "best-3" annotation schema. This is probably due to the small set of utterances used to train these models, since while performing some other tests not reported here, using more utterances and a different corpus, LDCNF performed best.
In order to compare the PGM results with standard non-sequential MLS, we included in our experiments the results obtained using classical Support Vector Machines (**SVM**). All PGM exhibit significant performance improvements when compared with SVM, confirming their superiority when applied to intrinsically sequential problems.

6. Conclusion

This paper presents some experiments on the automatic detection of prosodic prominence in continuous Italian speech. Considering that in order to properly define prosodic prominence one needs to take contextual information into account, we tested a number of versions of MLS, able to correctly manage problems involving sequences of input features and sequences of output label classes, to be related in a complex way. In particular, we tested MLS belonging to the large family of PGM.
We thus performed several experiments with CRF, CNF, LDCRF and LDCNF models, obtaining very good classification results (F-measure = 0.770) despite using a small Italian corpus consisting of only 120 utterances.
Considering that, as outlined by [7, 30], prominence perception is highly influenced by the listener's linguistic expectations, there is room for large improvements in the system's performance by including linguistic features in the automatic system.
We are planning to test these models on different corpora and different languages, in order to verify the effectiveness of the proposed approach to automatic prominence detection.

Integrating variability in loudness and duration in a multidimensional model of speech rhythm: Evidence from Indian English and British English

Robert Fuchs[1]

[1] Englisches Seminar, Westfälische Wilhelms-Universität Münster

robert.fuchs@uni-muenster.de

Abstract

Most research on speech rhythm has focussed on duration. For example, [1] suggested the normalised pairwise variability index for vocalic intervals (nPVI-V) in order to measure the variability of vocalic durations. This paper argues that speech rhythm research should also take into account other correlates of prominence as well as their interaction. The duration-based nPVI, or nPVI-V(dur), is supplemented by an nPVI that measures variability in average loudness, nPVI-V(avgLoud). These two metrics account for variability in duration and loudness, but cannot measure if loudness and duration reinforce each other by varying simultaneously in the same direction. This simultaneous variability is accounted for by the combined nPVI-V(dur+avgLoud), which is higher than the average of the other two measures if vocalic intervals that are longer than average are also louder than average. The three metrics are subsequently applied to recordings of a reading task performed by 20 speakers of Indian English (IndE) and 10 speakers of British English (BrE). Results indicate that IndE has less variability in duration and less variability in loudness than BrE. In addition, IndE has less simultaneous variability in duration and loudness than BrE. This indicates that duration and loudness are less often used together as cues to prominence in IndE compared to BrE.

Index Terms: speech rhythm, duration, loudness, Indian English, British English

1. Introduction

Early definitions of speech rhythm held that languages fall into discrete rhythm classes: English, for example, was said to be stress-timed [2], as opposed to the syllable-timed rhythm of French [3]. However, a more nuanced view of varieties of English around the world resulted in descriptions of only some, mainly more established varieties such as British English (BrE) and American English, as stress-timed. By contrast, many of the younger national varieties of English (such as Indian, Nigerian and Singapore English), which are used in administration, education and as a national link language in their respective countries, have been classified as syllable-timed. This is often explained with transfer from the local syllable-timed languages [4–6].

The categorical view of rhythm with two separate classes of languages has in the last years given way to a gradient analysis. Accordingly, languages can be placed at any point on a continuum between a prototypically stress-timed and a prototypically syllable-timed pole. This analysis is supported by quantifications of rhythm based on the durations of vocalic intervals, consonantal intervals and syllables, and their variability, as suggested by [1,7–15]. One widely used rhythm metric is the normalised pairwise variability index for vocalic intervals, or nPVI-V [1]. It is computed by calculating the mean of the differences between successive vocalic intervals divided by their sum, multiplied by 100:

$$nPVI-V = 100 \times \frac{\sum_{k=1}^{m-1} \left| \frac{d_k - d_{k+1}}{(d_k + d_{k+1})/2} \right|}{m-1}; \qquad (1)$$

where m is the number of vocalic intervals

and d_k is the duration of the kth vocalic interval

Some of these rhythm metrics have been shown to predict language discrimination in perception experiments [16]. Comparisons of vocalic and consonantal metrics by [17, 18] suggest that vocalic, speech rate normalised metrics are the most reliable measures of speech rhythm. However, even these metrics are influenced by variation between speakers, texts and transcribers. It is therefore recommended to use phonetically balanced or large samples from a greater number of speakers, and adhere to a clearly defined set of transcription rules. How crucial these suggestions are is demonstrated by [19], who was unable to replicate the results of [17, 18], perhaps because (1) she relied on samples from each language that were not representative but specifically designed to elicit sentences that differed from each other in rhythm as much as possible, and (2) because segmentation criteria and the treatment of hesitations were not specified and possibly not controlled for.

However, an approach that measures rhythm on the basis of durational variability alone may present a lop-sided account of speech rhythm. Most studies on rhythm in the last 15 years have concentrated exclusively on duration, which means that they considered only one correlate of prominence. Exceptions are [20–23], who suggested rhythm metrics based on variability in intensity, f_0, and sonority. Together, these metrics may form a multidimensional account of rhythm, as demanded by [24–26]. A comparison of two languages might show that one has less variability in all these correlates of prominence and is therefore more syllable-timed than the second language on all these dimensions. On the other hand, the first language might also turn out to have less variability in intensity, but more in duration than the second language. Any language might therefore have multiple co-existing and different rhythms [26], which contribute in different ways to a succession of elements relatively similar in prominence (syllable-timing) or relatively different in prominence (stress-timing).

2. Integrating variability in loudness and duration

While a consideration of multiple correlates of prominence contributes to a multidimensional analysis of rhythm, the metrics suggested so far rely exclusively on acoustic correlates, not perceptual correlates of rhythm. This is particularly important for the relation of intenstiy, an acoustic property, to loudness, a perceptual property. Sounds with equal intensity but different frequencies have been shown to differ in loudness [27, 28]. Therefore, this paper suggests that loudness instead of intensity should be considered as a perceptual correlate of rhythm.

A second shortcoming of a multidimensional analysis of rhythm as outlined above is that different acoustic or perceptual correlates are considered separately. In addition to an individual analysis of these correlates, their interaction should also be taken into account. For example, if stressed vowels are both longer and louder than unstressed vowels, then variability in duration and loudness may be said to reinforce each other. By contrast, if stressed vowels are only longer but not usually louder than unstressed vowels, there is no reinforcement between these two cues of prominence.

In order to derive a measure of loudness, the computer programme Praat can be used [29]. After extracting the relevant vocalic interval from the recording, first its spectrum, then excitation, and finally maximum loudness in Sone can be derived (a Praat script is available from the author upon request). As a measure of variability in loudness, a PVI can be computed by entering these loudness values (instead of duration values) into formula (1). This metric will be called nPVI-V(avgLoud), and the duration measure will be referred to as nPVI-V(dur).

The next step, accounting for simultaneous variability in loudness and duration necessitates a change to the PVI formula. For every pair of successive vocalic intervals, the difference in duration and in loudness are computed separately and divided by their sum. These relative differences in duration and loudness are then added and squared. Squaring this sum of relative differences in duration and loudness gives an advantage (higher values) to simultaneous in- or decreases in both correlates of prominence, and a disadvantage to cases where duration in- but loudness decreases (or the other way around).

$$nPVI-V(dur+avgLoud) = \quad (2)$$
$$100 \times \frac{\sum_{k=1}^{m-1} 2 \times \left(\frac{d_k - d_{k+1}}{d_k + d_{k+1}} + \frac{l_k - l_{k+1}}{l_k + l_{k+1}} \right)^2}{m-1};$$

where m is the number of vocalic intervals,

d_k is the duration of the kth vocalic interval

and l_k is the loudness of the kth vocalic interval

For example, if the second vocalic interval is twice as long and twice as loud as the first, then the square of the differences is $(\frac{1-2}{1+2} + \frac{1-2}{1+2})^2 = 0.444$. By contrast, if the second vocalic interval is twice as long as the first, but equal in loudness to the first, then the square of the differences is lower: $(\frac{1-2}{1+2} + \frac{1-1}{1+1})^2 = 0.111$. And if the second vocalic interval is twice as long as the first, but half as loud as the first, the square of the differences is zero: $(\frac{1-2}{1+2} + \frac{1-0.5}{1+0.5})^2 = 0$. The measure therefore accounts for whether loudness and duration increase (or decrease) simultaneously, thereby reinforcing each other in the generation of prominence, or whether one decreases and the other increases, which causes them to offset each other in the generation of prominence.

3. Indian English

IndE is a postcolonial variety of English used mainly in public contexts such as education, administration, business and politics, but also by Indians who travel or reside in a region whose local language they do not speak. English is the primary domestic language for only a small minority, although many others use it at home when discussing topics belonging to the public domain, as for example when a parent asks their child what happened at school that day. Around 23 % of the population of India have at least basic knowledge of English, and 4 % are fluent [30]. Based on the 2011 census [31], this means there are 50 million fluent speakers.

Although standard IndE still lacks full official recognition, it is the de facto standard taught in schools and universities is standard IndE [32, 33]. Nevertheless, this standard has not yet been fully codified, and in such a context the kind of language used by educated speakers can be used as a yardstick for what is considered acceptable by the speech community [34–36]. The phonology of IndE differs in several respects from that of BrE [37–42], likely due to transfer from Indian languages [43]. While they belong to several different language families, these languages have converged over time in several respects and form a *sprachbund* [44–46].

IndE has been suggested to be syllable-timed or more syllable-timed than BrE [32, 43, 47–52]. On the basis of these descriptions, the present paper hypothesises that IndE has lower variability of vocalic durations, lower variability in average loudness in vowels, and lower simultaneous variability in duration and loudness in IndE compared to BrE. This suggestes that nPVI-V(dur), nPVI-V(avgLoud) and nPVI-V(dur+avgLoud) are all smaller in the IndE group than in the BrE group. Additionally, it is expected that duration and loudness as correlates of prominence also reinforce each other less often in IndE than in BrE, even when lower levels of variability in loudness and duration (considered separately) are taken account of. This suggests that the difference between the group means for IndE and BrE in nPVI-V(dur+avgLoud) is greater than both the differences between the group means in nPVI-V(dur) and nPVI-V(avgLoud).

4. Data

Recordings of a text read by 10 speakers or Standard Southern BrE and 20 speakers of IndE were used. The BrE data was taken from the DyViS database [53]. The IndE speakers were recorded by the present author reading the same text. All speakers were university students at the time of recording. The IndE speakers were equallly divided between four different L1 groups, and had either Hindi or Bengali (both Indo-Aryan languages), or Telugu or Malayalam (both Dravidian languages) as first languages. L1 was determined on the basis of a sociolinguistic interview involving questions on when speakers first started using what language. They were between 20 and 28 years of age, and, with the exception of one speaker each, had exclusively attended English-medium schools and universities, and had not resided outside of India.[1]

[1] Only one speaker did not attend English-medium schools throughout, but went to a Telugu-medium primary and English-medium secondary school. Another speaker spent several years in an Arab country, but had only interaction with the local South Asian expat community in

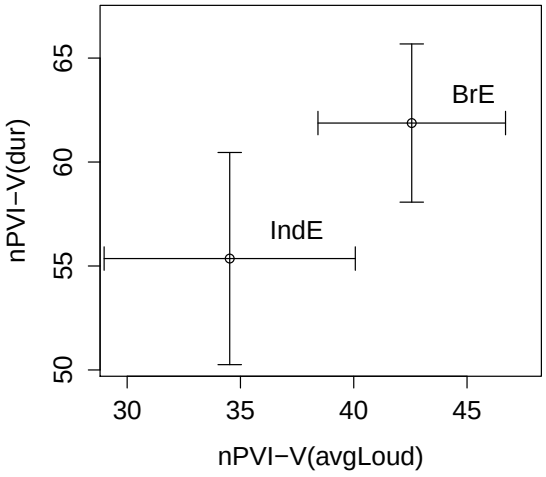

Figure 1: Group averages and standard deviations for variability in average loudness (x-axis) and in duration (y-axis).

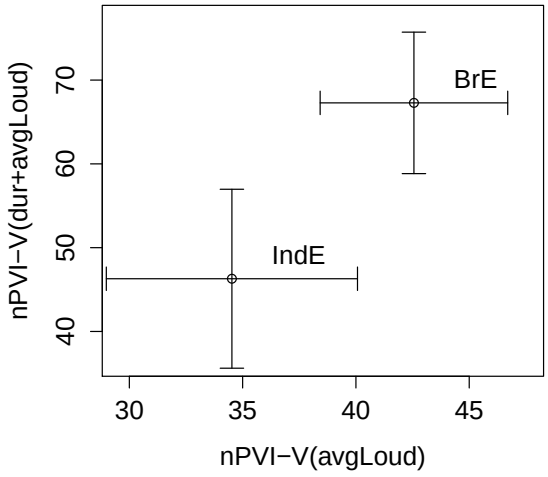

Figure 2: Group averages and standard deviations for variability in average loudness (x-axis) and simultaneous variability in duration and average loudness (y-axis).

Two thirds of the reading passage, or 392 words, were segmented according to the recommendations provided by [17, 18, 54]. nPVI-V(dur), nPVI-V(avgLoud) and nPVI-V(dur+avgLoud) were computed individually for utterances comprising at least three vocalic intervals, excluding the final interval. Next, for each individual speaker, the median of the rhythm scores of all utterances produced by this speaker was computed.

5. Results

Variability in duration was significantly lower in the IndE group (55.4) than in the BrE group (61.9, $p<0.0001$, t-test). Average variability in duration was 10.5 % lower in IndE than in BrE. Variability in average loudness was also signifcantly lower in the IndE group (34.5) than in the BrE group (42.7, $p<0.0001$). Average variability in loudness was 19.0 % lower in IndE than in BrE. The average values for variability in loudness and duration for both groups are shown in figure 1.

Scores for individual speakers are shown in figure 3, with crosses for IndE and circles for BrE speakers. Using both metrics, separation between the two groups is relatively good, although there is some overlap between the two groups. Two BrE speakers have less variability in duration and loudness (nPVI-V(dur) and nPVI-V(avgLoud)) than the other BrE speakers and are close to some of the IndE speakers. Likewise, there are two IndE speakers who have high values for variability in duration and loudness so that they are similar in this respect to the BrE group.

Combined variability in duration and average loudness was significantly lower in IndE (46.3) than in BrE (67.3, $p<0.0001$). The average combined variability in duration and loudness was 31.2 % lower in IndE than in BrE, which means that the difference in combined variability in duration and loudness (nPVI-V(dur+avgLoud)) was higher than the variability in either variability in duration (nPVI-V(dur)) or average loudness (nPVI-V(avgLoud)). The average values for variability in loudness and simultaneous variability in duration and loudness for both groups are shown in figure 2.

Scores for individual speakers are shown in figure 4. Considering simultaneous variability in loudness and duration, there are again two IndE speakers (crosses) with values for variability similar to the BrE group. There is also one BrE speakers (circles) with a variability slightly lower than the IndE speakers with the highest variability.

6. Discussion

The results have shown that IndE has

- significantly less variability in duration
- significantly less variability in loudness and
- significantly less simultaneous variability in duration and loudness

than BrE. Crucially, the difference in simultaneous variability in duration and loudness between IndE and BrE was higher than either the difference in variability in loudness or duration. This result shows that a measure of simultaneous variability in duration and loudness, the nPVI-V(dur+avgLoud) suggested in this paper, captures an important aspect of variability in prominence between successive vocalic intervals. If variability in duration on the one hand, and variability in average loudness on the other hand, were both randomly distributed, one would expect that the difference between IndE and BrE in the simultaneous variability in loudness and duration were equal to the average of the difference between the two varieties in loudness, and in duration (i.e. 14.75 %). However, this was not the case. Instead, the difference in combined variability in loudness and duration turned out to be much higher than the variability in either loudness or duration taken separately. This result also implies that in BrE, vocalic intervals that are longer than average also tend to

her daily routine.

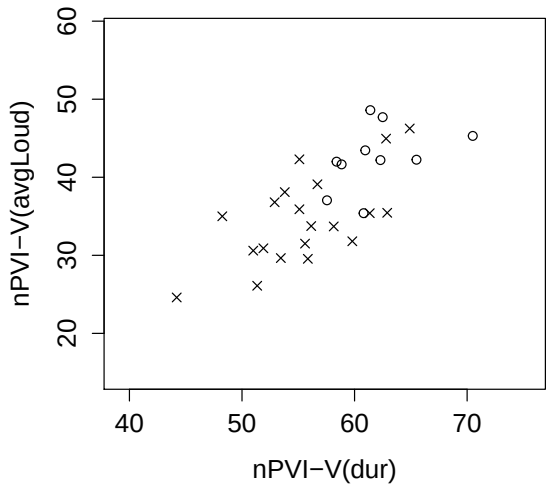

Figure 3: Variability in average loudness (x-axis) and in duration (y-axis) for individual speakers of IndE (crosses) and BrE (circles).

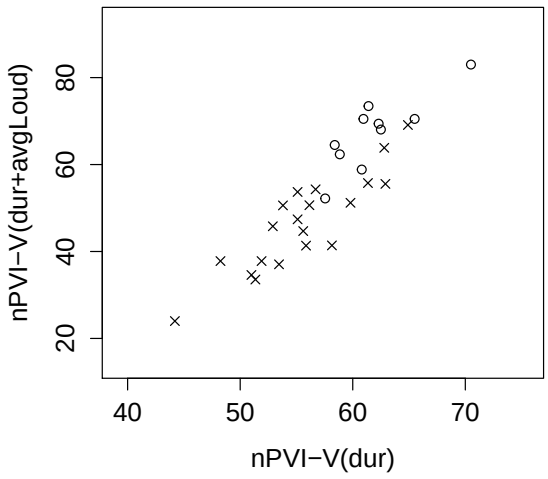

Figure 4: Variability in average loudness (x-axis) and simultaneous variability in duration and average loudness (y-axis) for individual speakers of IndE (crosses) and BrE (circles).

be louder than average, and vice versa. By contrast, in IndE, vocalic intervals that are longer than average are not as frequently and to the same extent also louder than average, and vice versa, as in BrE.

This comparison of variability in duration, loudness and simultaneous variability in loudness and duration also contributes to a better understanding of how speech rhythm is realised in different dimensions, using different acoustic and perceptual correlates of prominence. Duration is but one of these correlates of prominence. Loudness is another, and the simultaneous in- or decrease of loudness and duration is a third, and separate, aspect that needs to be considered within a multidimensional model of speech rhythm.

The results also substantiate previous descriptions of IndE as more syllable-timed than BrE [32,43,47–52]. Such a description, using a relative expression ("more syllable-timed") appears to be adequate since syllable- and stress-timing are probabaly better regarded as poles of a continuum, and perhaps as ideals that are rarely or never realised in actual speech.

Furthermore, a small number of outliers with values for variability similar to the other group occured. This shows that differences in variability in duration, loudness and simultaneous variability in loudness and duration do not constitute a categorical contrast between IndE and BrE. However, the differences are highly significant. Taking into account that a relatively long text of 392 words was used, it is very likely that the results can be generalised to other speakers of BrE and educated IndE. Considering the background of the IndE speakers, who were all engaged in university studies, it is likely that they speak a variety of IndE that is a good example of the emerging standard of IndE. This standard appears to involve a rhythm that is more syllable-timed than BrE speech rhythm.

Abstract

This study focuses on the temporal and metrical features of the German speech produced by Chinese speakers. German is described to be a stress-timed language, while standard Chinese is regarded as a syllable-timed language. It has been suggested that the rhythm of the target language can be influenced by the learners' native language. In this study we conducted an investigation of ten sentences with 18 Chinese students in the low intermediate proficiency level in comparison with six native German speakers. We compared the duration values in terms of pairwise variability indices, and found that most of these Chinese speakers have a lower *nPVI-V* and a higher *rPVI-C* than the German speakers. We illustrate that the conventional duration measures of *nPVI-V* can be influenced by the syllable structures of the utterance and the classification approach of vocalic intervals, and a comparable *nPVI-V* can hardly be expected from different investigations. Furthermore, we argue that duration values alone cannot fully capture the rhythmic patterns of speech because other prosodic parameters such as pitch and energy also join to contribute to rhythmic characteristics of the speech.

Index Terms: durational study, learning German, Chinese learners

1. Introduction

It is well known that Pike [16] and Abercrombie [1] argue that the languages of the world can be classified into two types of rhythm patterns: *a) stress-timed rhythm* and *b) syllable-timed rhythm*. According to this hypothesis, both types of rhythm show rhythmical units of equal duration: *stress-timed* languages tend to have isochronous inter-stress intervals, while *syllable-timed* languages tend to have rather equal syllable durations. Classic examples for a stress-timed language are English and German; while Chinese belongs to syllable-timed languages [13]. The classification of rhythm-classes turned out to be based solely on intuition since a large amount of experiments carried out to provide direct correlates for the isochrony in languages remained without success [17].

In the recent decades many researchers tried to classify languages in other ways. Ramus et al. [17] proposed to divide speech into vocalic and consonantal parts, and to calculate the proportion of the vocalic intervals (*%V*) and the standard deviation of consonantal intervals (ΔC) in a sentence. They showed that stress-timed languages have a higher ΔC and a lower *%V*, whereas syllable-timed languages have a lower ΔC and a higher *%V*. Grabe and Low [9] based their pairwise comparison of successive vocalic and intervocalic intervals and calculated speech rhythm with the *Pairwise Variability Index (PVI)*, which computes the sum of the durational differences between adjacent vocalic or consonantal intervals in an utterance. They found that stress-timed languages have a higher variation in vowel durations, whereas syllable-timed languages (including Mandarin) show a lower variation in vowel length. Lin et al. [13] followed the studies of Ramus et al. [17] and Grabe and Low [9], and measured *%V*, ΔC, normalised variation of the pairs of two adjacent vowel intervals (*nPVI-V*), and raw variation of the pairs of two adjacent consonant intervals (*rPVI-C*) of Mandarin Chinese. Except for *nPVI-V*, all other measures confirmed the auditory impression of Mandarin Chinese being syllable-timed [13].

On the other hand, it has been suggested that the rhythm of the target language can be influenced by the learners' native language [10, 18]. Gut [10] described that L2 German is influenced by L1 of Chinese, English, French, Italian and Romanian in terms of ΔC, *%V* etc. In our previous study [6], we demonstrated that Chinese learners of German in the low intermediate proficiency level have a clearly higher *%V* and roughly higher ΔC than German native speakers, because they insert many vowel epentheses and speak at a slower rate. In this investigation we aim to investigate non-native rhythm of Chinese speakers in terms of *nPVI-V* and *rPVI-C* values, and to discuss the efficiencies and deficiencies of these measures with regard to our investigation material.

2. Method

This study followed the same method which was described by Grabe and Low [9] to investigate metrical features of German speech produced by Chinese speakers. The syllable-timed rhythm in the German speech of the Chinese subjects was so striking for their German teachers, it was thus interesting to find out whether these rhythm measures can reflect the perceptual impression of the rhythmic deviation for native German listeners. In order to ensure comparability, the annotation technique used by Grabe and Low [9] was adopted in the investigation. The durations of vowels and intervals between vowels (excluding pauses) in each sentence were measured. Indices of *rPVI* and *nPVI* were calculated according to equation (1) and (2) respectively. (Note: *rPVI-C* and *nPVI-V* are adopted in this paper to represent consonantal *rPVI* and vocalic *nPVI*.)

$$rPVI = \sum_{k=1}^{m-1} |d_k - d_{k+1}| \cdot \frac{1}{m-1} \quad (1)$$

$$nPVI = 100 \cdot \left(\sum_{k=1}^{m-1} \left| \frac{d_k - d_{k+1}}{(d_k + d_{k+1})/2} \right| \right) \cdot \frac{1}{m-1} \quad (2)$$

where *m* is the number of intervocalic or vocalic intervals in a sentence, and *d* is the duration of the *k*th interval.

With the results of this investigation we endeavour to answer the following questions:

- Do Chinese speakers exhibit different *nPVI-V* and *rPVI-C* from German native speakers? If yes, what factors might account for the differences?
- Can the pairwise variability indices produce comparable values from different investigations? Can these indices fully reflect the perceptual impression of rhythm?

2.1. Subjects

We recruited 18 native Chinese speakers, including 10 males and 8 females, who come from different parts of China, but all of them speak standard Chinese. At the time of speech data collection they had been living in Germany for one month, and they were just enrolled in the German language course for the DSH exam (the German language university entrance exam for foreign students). Their ages ranged from 22 to 28. All of them had learned German for one to one and a half years, and the length of their formal German instructions had been around 1,200 hours. These participants could be classified as having a low intermediate level, they formed a homogeneous group in terms of age, L1 background, motivation, proficiency of the German language, and the length of residence in Germany. Their German teachers found that their German speech was highly syllable-based, which deviated from the stress-timed native German speech, we thus conducted a durational investigation into their L2 speech to test whether *PVI* measures can reflect the deviated rhythm perceived. In order to provide a reference for comparison, we included six German speakers, one was male and five were female speakers. They were between 22-30 years old and were ordinary German native speakers.

2.2. Speech data collection

In order to have certain control of the speech data, reading tasks were used for analysis. The subjects were instructed to read 50 Phondat sentences in German. For the current study only ten read sentences were selected and analyzed, because they include different sentence types and the vowel and consonant percentages vary from sentence to sentence. It is better to concentrate on a small amount of data since the accuracy of annotation is essential for the measurement, which requires much carefulness and patience. Before the recording began, the subjects were given as much time as they needed to read the text to become familiarized with it. Each subject was individually recorded at 16-bit resolution with a sampling rate of 44.1 kHz by a German phonetics expert, who controlled the quality of their production.

2.3. Data analysis

The sentences were first automatically labeled by a trained aligner, and then manually corrected by the first author assisted by a German phonetics expert on Praat [3]. Sentences were first annotated at the phoneme level on the basis of both audio and visual information, and the phonemes were then grouped into vocalic and consonantal intervals. We followed the same criteria described by Grabe and Low [9] in determining the location of vowel-consonant and consonant-vowel boundaries:

- *Vocalic intervals* were characterized by vowel formants, which could contain a monophthong, a diphthong, or more vowels if the formants continue.
- *Intervocalic intervals* were defined as stretch of signals between vocalic intervals, which could include one or more consonants.

Annotation of vowel boundaries were conducted according to the generally accepted criteria [15]. Consonants such as stops, fricatives, affricates and nasals were clearly identifiable from the changes in spectrogram and formant structures. The approach to glides was also based on acoustic criteria, like that in [9]. If a clear change could be observed in the formant structure or in the amplitude as a prevocalic glide, it was excluded from vocalic portions. Otherwise, glides (especially postvocalic glides) were included in the vocalic portion. If there was a gap that was not part of the sound, it was marked as breath, and this breath gap was subtracted from the calculation of the intervals. Any two intervocalic (or vocalic) intervals split by this gap were combined into the same intervocalic (or vocalic) interval. Since we employed sentences as reading material, we computed the pairwise variability in sentences other than in a passage of speech in [9]. This procedure allows us to compare whether there are any differences among different kinds of sentences.

3. Results

The comparison results on *nPVI-V* and *rPVI-C* measures, and speaking rate are presented in the following.

3.1. Pairwise variability indices

Figure 1 demonstrates the data of the six German native speakers (de) shown as small triangles and 18 Chinese speakers (cn) indicated with small squares. *nPVI-V* values are plotted on the horizontal axis against *rPVI-C* values on the vertical axis. The index values of each speaker are the average of ten sentences.

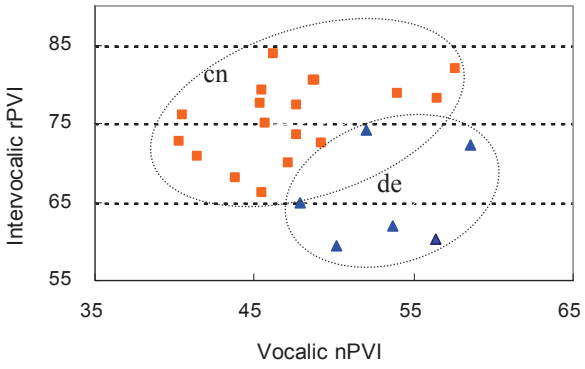

Figure 1: *Vocalic nPVI-V against intervocalic rPVI-C.*

A two-sample independent t-test shows the differences between the Chinese and the German speakers in both *rPVI-C* (t=-3.93, p=0.001) and *nPVI-V* (t=2.515, p=0.020) are significant ($p<0.05$). The Chinese speakers have a higher *rPVI-C* and a lower *nPVI-V* than the German native speakers.

3.2. Speaking rate

It is clear that the Chinese speakers spoke at a slower rate and made more pauses than the native German speakers. Without consideration of pauses or silences, the average speaking rate calculated in phonological syllables per second (syl/s) of the native German speakers and Chinese speakers are 5.95 and 3.90

respectively. A significant negative correlation (r=-0.85) between speaking rate and *rPVI-C* is found for the German speakers, but no such correlation (r=-0.17) can be found for the Chinese speakers.

Table 1: Speaking rate and correlation with *rPVI-C*

	German speakers	Chinese speakers
speaking rate (syl/s)	5.95	3.90
standard deviation	0.42	0.26
correlation with *rPVI-C*	-0.85	-0.17

Since the Chinese speakers inserted many epenthesis vowels, they produced much more additional syllables [7]. Speaking rate calculated on the basis of phonetically uttered syllables resulted in a higher rate of 5.27 syl/s (5.27>3.90), which is also negatively correlated with *rPVI-C* (r=-0.567, p=0.014).

4. Discussion

The *PVI* results obtained in this investigation can partly reflect the rhythmic deviance of L2 speech, but may not fully reflect the perceptual impression of speech rhythm.

4.1. Evaluation of *PVI*

The outcome where the Chinese speakers have a higher *rPVI-C* mirrors the result of the previous investigation [6, 10], where the Chinese speakers produced a higher standard deviation of consonantal intervals (ΔC). Since speaking rate is negatively correlated with ΔC in the German language [5], a slower speaking rate results in a higher ΔC, and also produces a higher *rPVI-C*. Moreover, the Chinese speakers can hardly reduce nonstressed vowels, and their *nPVI-V* should be much lower than the German native speakers, which is also indicated in the results. These findings support the results in previous studies [9, 8, 2]. Generally speaking, a higher *rPVI-C* and a lower *nPVI-V* can partly reflect the syllable-timed characteristic of L2 German speech by Chinese speakers.

4.2. Influencing factors

However, there are many factors which can influence the measures of *nPVI-V*, examples in this investigation will be illustrated in the following.

4.2.1. Syllable combinations

The *nPVI-V* scores are found to be influenced not only by the structure of the syllables but also by their combinations in our data. This observation supports previous findings [2, 14] that metric scores can be affected by the choice of material. If one pair of syllables exhibits quite different structures or displays quite different stress patterns, their *nPVI-V* values can be higher than other pairs. More various pairs in one sentence can result in a higher *nPVI-V*. Therefore, the mean *nPVI-V* scores in our investigation are quite different from sentence to sentence, which range from 41.98 to 74.18 for the German speakers, and from 37.06 to 55.50 for the Chinese speakers. However, *nPVI-V* values based on sentences are highly correlated between the German speakers and the Chinese speakers with r=0.67 ($p<0.05$), which explains that *nPVI-V* is partly subject to the syllable combinations in the sentence. For example, in *Wie hast du das gemacht? (How did you do that?)*, schwa in prefix /g@/ between /das/ and /maxt/ makes *nPVI-V* larger for both German and Chinese speakers.

4.2.2. Successive vowels

Successive vowels do not influence *%V*, but can influence *nPVI-V*. The conventional approach in both Ramus [17] and Grabe & Low [9] is to include adjacent heterosyllabic vowels in the same vocalic interval, which makes *nPVI-V* quite different for different sentences. Successive vowels may and may not be separated by a glottalized period.

If glottalization is found between successive vowels, these intervals were treated as silent pauses. We followed the approach in [19], the glottalized part marked between the solid lines in Figure 2 was omitted in the calculation, and the vocalic intervals before and after the glottalization were summed.

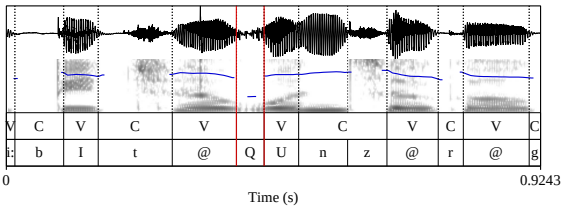

Figure 2: *Waveform, spectrogram and SAMPA annotation of "bitte unsere (please our)" with glottalization between successive vowels by a Chinese speaker.*

Another speaker produced the same phrase without glottalization, as it is shown in Figure 3.

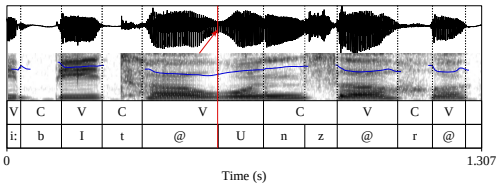

Figure 3: *Waveform, spectrogram and SAMPA annotation of "bitte unsere (please our)" without glottalization between successive vowels by a Chinese speaker.*

To put /@/ and /U/ in one vocalic interval enlarges the *nPVI-V* value greatly for the Chinese speakers. However, both a decrease in pitch and amplitude in the glottalization in Figure 2, and a decrease in the amplitude as pointed out by the arrow in Figure 3 without glottalization can be clearly perceived as a reset in prosody. It is obvious that in the above two figures the duration values of the five vowels are comparable. However, to group these two successive vowels into one vowel interval enlarges *nPVI-V*, which cannot reflect the perceptual impression of the syllable-based rhythm of Chinese speakers faithfully.

4.2.3. Syllabic consonants

Another factor which influences *nPVI-V* values is the annotation of fully reduced vowels in German. One obvious instance is that many word-final syllables in infinite verbs with *-en* are usually pronounced with syllabic consonants. For example, in

Figure 4, schwa @ in word-final with *-en* is reduced, and consonant *s* and syllabic consonant *=n* are combined without any vocalic interval between them.

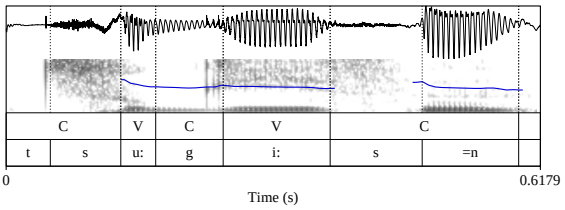

Figure 4: *Waveform, spectrogram and annotation of "zu gießen (to water)" with a syllabic consonant (=n) by a German speaker.*

If a short schwa @ is annotated, the *nPVI-V* can be greater than that with a syllabic consonant. However, a very short weak @ might not be quite different from that with a syllabic consonant perceptually, but the *nPVI-V* values may be quite different.

4.3. Measurements beyond duration

We have observed that various syllable combinations and different annotation approaches of vocalic intervals may lead to various *nPVI-V* scores, which implies that the measures of vocalic and intervocalic intervals may not fully reflect the perception of rhythm. This finding further supports the idea that rhythm metrics such as *PVI* can provide measures of speech timing and variability, but they cannot convey an overall rhythmic impression [2]. It is generally believed that rhythm is the recurring timing patterns of fundamental frequency, syllabic duration, syllabic energy, and spectral dynamics [12]. By comparing the syllable-timed L2 German speech with the stress-timed native German speech, it suggests that not only timing but also fundamental frequency and energy contribute to the rhythmic pattern over time [12]. Cumming [4] also demonstrated that f0 and duration are interdependent in the perception of rhythmic groups in speech and sentence rhythmicity.

German has full as well as spectrally reduced and shortened vowels, and the consequence is a high level of variability in vowel durations. Chinese does not have vowel reduction, and the level of vocalic variability is significantly lower. German employs sentence intonation to express intonational meanings; Chinese uses lexical tones to distinguish words. The difference between a stress-timed German speech by a native speaker and a syllable-timed German speech by a Chinese speaker can be observed in the following two figures, which are vividly displayed with ProZed [11].

In these figures, the pitch contour of the sentence is clearly demonstrated in a continuous dotted line; each circle corresponds to one vocalic or consonantal interval with the vocalic interval marked with corresponding vowels. The level on the vertical y-axis of the circle represents the pitch and the diameter represents the duration of the interval. The unit of pitch has already been normalized to the logarithmic scale $\log_2$(Hz/median), so that speakers of different fundamental frequencies can be comparably displayed on this scale. It is obvious that the vowels have more variability for the German speaker than the Chinese speaker. In Figure 5 the vowels /*u:*/ in **du** and /@/ in ***ge****macht* are very short in duration, while /*a*/ in *ge****macht*** is much longer of the German speaker. In Figure 6, except for a very short /@/ in ***ge****macht*, the variations of the other vowels (including the epenthesis /@/ after /t/ in *hast****e***) are not so much as those in Figure 5. Not only duration variations but also pitch and energy changes are different. All these prosodic parameters work together to organize speech into rhythmic chunks, which impresses us with different rhythms.

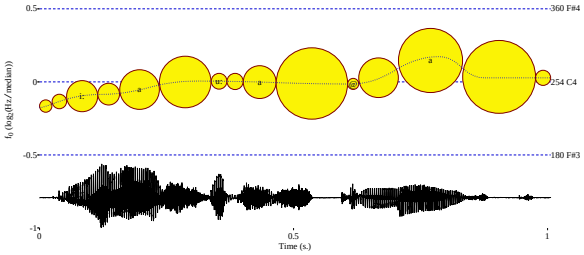

Figure 5: *Prosody display of "Wie hast du das gemacht? (How did you do that?)" produced by a German speaker.*

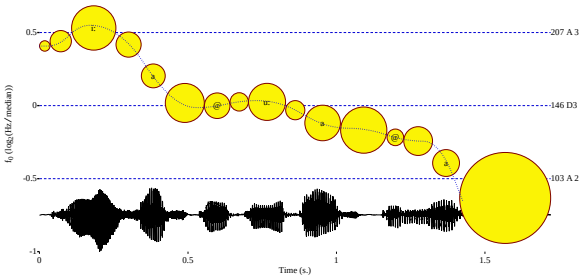

Figure 6: *Prosody display of "Wie hast du das gemacht? (How did you do that?)" produced by a Chinese speaker*

5. Conclusion

This paper analyzes L2 German speech with pairwise variability indices and demonstrates that the syllable-timed L2 German speech by Chinese speakers is characterized by a lower *nPVI-V* and a higher *rPVI-C*. However, due to many influencing factors, a comparable *nPVI-V* can hardly be expected from different investigations. We further suggest that other prosodic parameters, such as F0 and energy, can work together with duration to contribute to the acoustic analysis of rhythmicity, which can better reflect the perceptual impressions of speech rhythm. This study also suggests that in the future we should focus more on grouping patterns of prominence with more prosodic parameters than duration to investigate speech rhythm, and it would be more reasonable to link measurements of acoustic parameters in rhythm production with listeners' rhythm perception in the investigation of rhythm, as it is suggested by many researchers in [4, 12].

Abstract

Building on Erickson et al. [9], the current electromagnetic-articulography (EMA) experiment proposes that the amount of jaw displacement—or mandible movement—may reflect the metrical organization of English sentences. The experiment also supports F1 as a reliable acoustic correlate of jaw displacement, hence metrical organization. On the other hand, the study also demonstrates that F0 does not have a similar relationship to mandible movement.

Index Terms: metrical organization, jaw movement, EMA, F1, F0

1. Introduction

Work in Metrical Phonology [1] (*et seq.*) posits that our speech exhibits patterns of organization that are akin to the metrical organization of poetry [2], [3]. Metrical structure consists of rhythmic categories, within which strong-weak patterns are assigned. Different theories propose different levels of rhythmic categories, but they generally include such units as syllable, (prosodic) word, minor phrase, major phrase (and utterance), as in Figure 2 [4], [5], [6:384]. Each syllable, based on its metrical constituency, is assigned a level of stress or prominence relative to other syllables in the utterance [4], [5], and overall prominence may be represented as a number of grid marks [7]. The acoustic prominence of each unit is often described in terms such as quality, duration, loudness, and pitch [8].

Recent X-ray Microbeam and electromagnetic-articulography (EMA) studies, inspired by Fujimura [10]-[12], with four American English speakers [9], suggest that an articulatory correlate of syllable stress in English is the amount of jaw (mandible) displacement. As a speaker opens and closes the mouth to produce each syllable, the jaw moves. It opens more for low vowels than high vowels *ceteris paribus* [13], [14]; if all the vowels in an utterance are the same, the pattern of jaw opening should mirror syllable stress levels and correspond to the metrical structure of the speaker's utterance. The greater the jaw displacement, the higher the level of syllable stress. Also, the first resonant formant of the vowel (F1) exhibits a significant correlation with jaw displacement and metrical structure, suggesting that F1 is an important acoustic correlate of English metrical structure. Figures 1 and 2, based on [9], illustrate the pattern of jaw displacement for three American English speakers uttering: "[Yes, I saw] five bright highlights [in the] sky [to]night". The greater the jaw displacement, the greater the syllable stress (syllable "magnitude" according to [10]), and this magnitude is displayed vertically in bars, making it easier to visualize how jaw displacement mirrors the metrical structure of the utterance, shown in Figure 2. F1 values are not reproduced here, but they present essentially the same pattern as jaw displacement [9]. For these three speakers, nuclear stress—the most prominent stress in a sentence [15]—is on "high" of "highlights". For the fourth speaker (not shown here), nuclear stress is on "five"; this difference of nuclear stress placement is also observed in our current experiment, as discussed in the Results section.

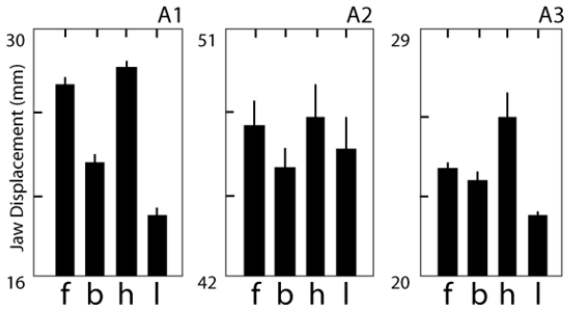

Figure 1: *Bar graphs showing the amount of jaw displacement (mm) for 3 American English speakers, for the sentence "[Yes, I saw] 5 bright highlights [in the sky tonight]." Error bars indicate standard error of the mean. Ordinate scaling is by speaker, to better display individual jaw displacement patterns.*

Major Phrase			x	
Minor Phrase	x		x	
Word	x	x	x	
Syllable	x	x	x	x
Stress level	3	2	4	1
	five	bright	high	lights

Figure 2: *Metrical structure of the utterance in Figure 1.*

One question addressed in this paper is how robust is the correlation between metrical prominence and jaw opening and between F1 and maximum jaw displacement. Additionally, do these patterns generalize beyond the single sentence tested in [9]? Is metrical prominence the only factor that affects jaw movement patterns? Does this correlation generalize to other vowels or do specific consonantal or vocalic gestures affect jaw displacement patterns? In addition, we examined F0 in

order to see what role it plays in implementing metrical stress patterns in American English.

2. Method

To address these questions, we report on jaw displacement patterns and corresponding acoustic measurements of data recorded by 3D-EMA (Carstens AG500 Electromagnetic Articulograph) at the Japan Advanced Institute for Science and Technology (JAIST, Ishikawa Prefecture, Japan) for three English sentences, as produced by two speakers of American English, one male (Speaker 1, fourth author), and one female, (Speaker 2, third author, an English-Spanish bilingual). Custom software (mview, Haskins Laboratories) was used to analyze the articulatory data. The lowest vertical position (maximum displacement) of the jaw with respect to the bite plane was located for each syllable of each utterance using a velocity-based criterion. For a more detailed description of EMA, including placement of sensors and recording procedures, see [9]. The sentences were all presumed to have the same metrical pattern; in the first and second sentences, the vowel of interest is /a/ and in the third, /e/, all followed by the palatal glide. The sentences are shown below, with the target words in the midsentence underlined.

(1) [Yes, I saw] five bright highlights [in the sky tonight].

(2) [Yes, I saw] nine nice bike fights [on the dyke tonight].

(3) [Yes, I saw] eight great playmates [in the bay today].

Sentence (1) is the same as reported in [9]; Sentence (2) contains the same diphthong /aɹ/ but different words, and Sentence (3) contains the diphthong /eɹ/. The participants practiced the sentences with pictures illustrating a scenario to match each sentence. For data recording, each sentence was presented (without parentheses or underlining) six times in random order using a PowerPoint display. The underlined syllables in each sentence were analyzed for jaw displacement, F1, and peak F0. Acoustic measurements were made using Praat [16]. Maximum F0 was measured in Hz for the steady state portion of the vowel, before the transition to the glide, and F1 was measured at that same point in time. F1 measurements in [9] were taken at the time of maximum jaw displacement. However, sometimes maximum jaw displacement occurred before the onset of voicing, so that F1 was not measurable. Measuring F1 at the time of maximum F0 has its own drawbacks, in that physiologically, lowering jaw would result in low F0 since the larynx gets lowered as well. However, this measuring method is at least consistent and obvious across all the tokens recorded.

3. Results and Discussion

Figure 3 shows a sample jaw tracing of Sentence (1) "[Yes, I saw] five bright highlights [in the sky tonight]." for the male speaker. Notice in the bottom panel of Figure 3 that the jaw opens and closes for each of these four syllables, and even though the vowel plus glide is always /aɹ/, the amount of jaw opening varies systematically.

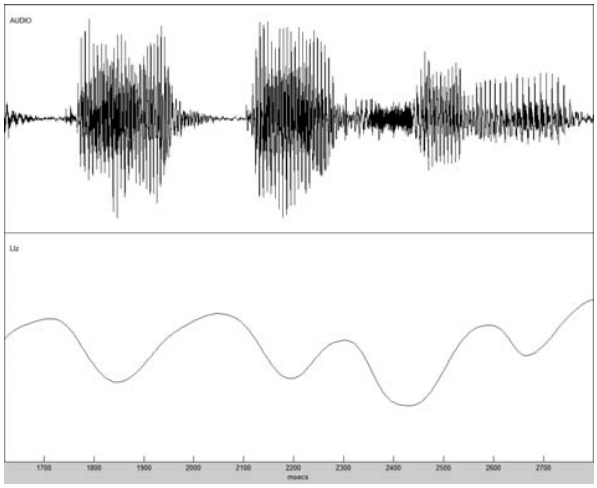

Figure 3: *Acoustic waveform (top) and jaw displacement tracing in mm (bottom) for Speaker 1 saying: "[Yes, I saw] 5 bright highlights [in the sky tonight.]"*

The patterns of jaw displacement averaged over 6 repetitions for Speakers 1 and 2 are displayed in Figure 4 such that the taller the bar, the larger the jaw displacement/syllable stress. Speaker 2 (at right in Figure 4) shows patterns similar to those reported for three of the four speakers in [9] (see Figure 1), supporting our hypothesis that metrical structure is reflected in jaw displacement patterns.

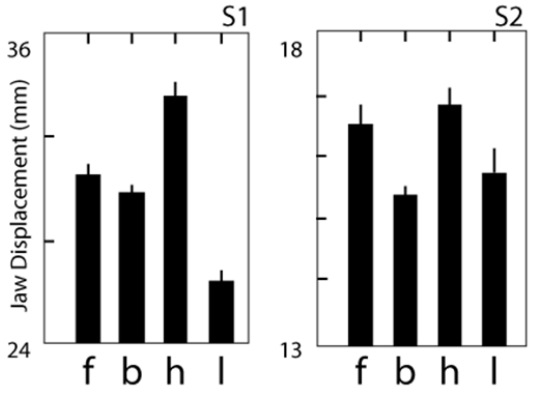

Figure 4: *Speaker 1 (L) & Speaker 2 (R) "[Yes, I saw] 5 bright highlights [in the sky tonight]" (Sentence 1).*

Figure 5 shows jaw displacement measures for Sentence (2) "[Yes, I saw] nine nice bike fights [on the dyke tonight]." Both speakers produce patterns similar to those for sentence (1), except that "nine" (the first syllable of this phrase) receives the nuclear stress. The pattern of jaw displacement for these speakers, especially for Speaker 1, is similar to that reported for the fourth speaker in [9] for "[Yes, I saw] five bright highlights [in the sky tonight]", putting nuclear stress on "five".

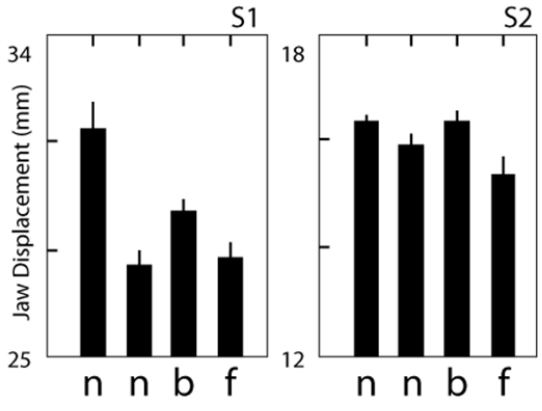

Figure 5: *Speaker 1 (L) & Speaker 2 (R) "[Yes, I saw] 9 nice bike fights [on the dyke tonight.]" (Sentence 2).*

Major Phrase	x			
Minor Phrase	x		x	
Word	x	x	x	x
Syllable	x	x	x	x
Stress level	4	2	3	2
(Yes, I saw)	nine	nice	bike	fights

Figure 6: Metrical structure of Sentence 2.

It is interesting that each speaker seems to show the jaw displacement pattern previously reported for Sentence 1, even though the words in the sentence have changed; i.e., the way they implement the metrical patterns of utterances is consistent across different sentences.

Figure 7 shows jaw displacement for a sentence with seemingly the same stress patterns, but the diphthong is /eɹ/: "[Yes, I saw] eight great playmates [in the bay today.]"

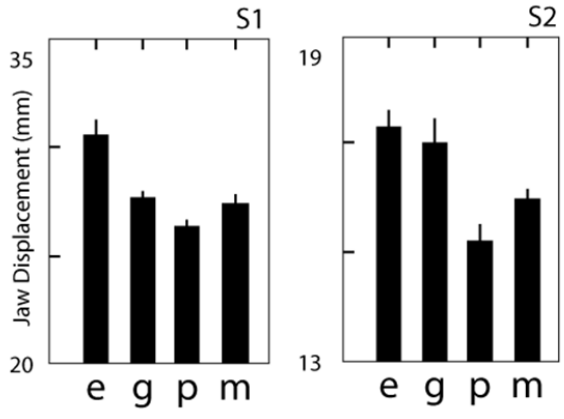

Figure 7: *Speaker 1 (L) & Speaker 2 (R). "[Yes, I saw] 8 great playmates [in the bay today]." (Sentence 3).*

Speakers 1 and 2 both show stronger jaw displacement for "eight" compared with "great", but "mates" is stronger than "play". Thus, the first phrase, "eight great", is similar to the first phrase of "nine nice bike fights" but the second phrase, "play mates", is different. It appears that the speakers treated "play mates" as a two-word phrase rather than a compound; i.e., as in the classic "bla'ckboa,rd" vs. "bla,ck boa'rd" minimal pair, where the second element in a phrasal compound receives more prominence. Thus, this sentence may have a different metrical structure than the previous two sentences.

Major Phrase	x			
Minor Phrase	x			x
Word	x	x	x	x
Syllable	x	x	x	x
Stress level	4	2	2	3
(Yes, I saw)	eight	great	play	mates

Figure 8: *Metrical structure for Sentence 3.*

What are the acoustic consequences of a speaker using the jaw to articulate the metrical structure of an utterance? Figure 9 below is a scatter plot of jaw displacement and F1 for each target word in the three sentences, produced by Speaker 1, grouped by the hypothesized stress levels.

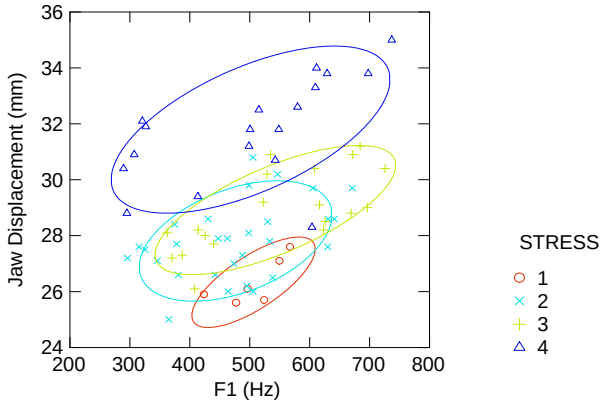

Figure 9: *Jaw Displacement and F1 (Speaker 1) as a function of stress level.*

Note that for Speaker 1, the greater the syllable stress, the larger the jaw displacement, and within each stress group, there is a significant correlation between jaw displacement and F1 for the three highest stress levels; the correlation is also high for the lowest stress group, but did not reach significance due to small N (See Table 1 for statistical results).

Table 1. *Pearson Correlation Analysis of Jaw Displacement with F1, within stress levels.*

stress level	*r*	Bartlett Chi-square statistic	df	*p*	N
1	0.737	2.743	1	0.098	6
2	0.433	5.512	1	0.019	29
3	0.694	10.823	1	0.001	19
4	0.600	6.923	1	0.009	18

Figure 10 shows a scatter plot of jaw displacement and peak F0 for each target word in the three sentences, produced by Speaker 1, grouped by the hypothesized stress levels.

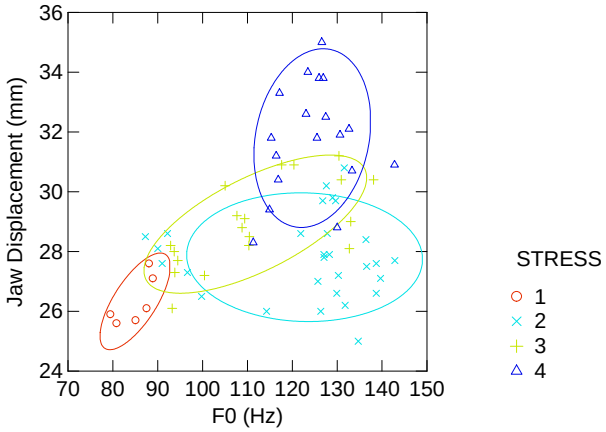

Figure 10: *Jaw Displacement and F0 (Speaker 1) as a function of stress level.*

The scatter plot does not show a consistent distribution of F0 according to the stress groups, thus suggesting that F0 is not a good indicator of stress. Stress level 2 shows a bimodal distribution, which indicates that metrical prominence cannot be the only factor that determines F0. For instance, sentence-final lowering may be responsible for the left cluster of stress level 2 [19]. In addition, F0 overlaps with a cluster of stress levels 2 and 4; and those of stress level 3 are a subset of stress level 2. From our data, it appears that F0 is not a reliable acoustic measure of metrical prominence.

For Speaker 2, we see that patterns of jaw displacement by F1 and jaw displacement by F0, when grouped by stress level, are somewhat similar to those of Speaker 1. Speaker 2's grouped stress data for jaw displacement by F1 show that the greater the stress, the larger the amount of jaw displacement (except for stress level 1); however, there is no correlation between jaw displacement and F1 within each level, as we saw for Speaker 1. Additionally, Speaker 2 does not exhibit any consistent distribution of jaw displacement by F0 according to stress groups, failing to confirm F0 as a reliable measure of metrical prominence for English sentences. The data scatter for Speaker 2 appears somewhat messy and not as clear as that seen for Speaker 1, which may reflect Speaker 2's bilingualism. The effect of bilingualism on the articulation of metrical stress is an interesting area for future exploration.

4. Conclusions

This is a preliminary report on an initial research study to investigate articulatory correlates of metrical structure in American English. Clearly, more speakers are needed, as well as more sentences. Further research, including constructing syllable triangles and boundaries according to the C/D model [10], [11], [20] will provide additional information on syllable magnitudes and differences in boundary strengths. Given that rhythm is often perceived as a pattern of "beats", the "beats" of jaw opening/closing may well be related to the rhythm/metrical structure of spoken language. Obviously, the listener does not hear jaw movement, but the resulting changes in formant frequencies, particularly in F1, may cue the listener to these "jaw beats". In our analysis of the data, peak F0 patterns fail to distinguish metrical stress levels. The results of this exploratory articulatory study reinforce the observation that metrical structure may best be reflected in jaw displacement patterns [9].

In closing, we address an issue that was raised by a reviewer -- that both of our subjects are authors. Trained speakers, including phoneticians and professional speakers, are probably able to consciously control the "rhythm" (metrical organization) of their utterances; however, it is unlikely that even these speakers can manipulate their jaw displacement patterns, since these are probably "hard-wired" from infancy [21]. Research is needed to explore this issue.

This process of deriving speech organization from mandible movement raises many questions for future investigation and provides a possible method for exploring metrical structure of language in general as well as specific languages, as demonstrated here for American English. It is hoped that this approach may offer a means to mesh the phonological abstractness of language with the phonetic instantiation of speech, resulting in new views and insights.

5. Acknowledgements

The impetus for this approach to the phonology-phonetics interface of language and its metrical structure comes from the insights of Osamu Fujimura and his life-long research in articulation, especially his theoretical framework of the C/D Model.

Male and female speech: a study of mean f_0, f_0 range, phonation type and speech rate in Parisian French and American English speakers

Erwan Pépiot [1]

[1] Department of Anglophone Studies, University Paris 8, France

erwan.pepiot@free.fr

Abstract

Many studies have been conducted on acoustic differences between female and male speech. However, they have generally been led on speakers of only one language, and have focused on a single acoustic parameter. The present study is an acoustic analysis of dissyllabic words or pseudo-words produced by 10 Northeastern American English speakers (5 females, 5 males) and 10 Parisian French speakers (5 females, 5 males). Several prosodic parameters were measured: mean f_0, f_0 range, phonation type (through H1-H2 intensity differences) and words' duration. Significant cross-gender differences were obtained for each tested parameter. Moreover, cross-language variations were observed for f_0 range, and H1-H2 differences. These results suggest that cross-gender acoustic differences are partly language-dependent and could be socially constructed.

Index Terms: speech and gender, fundamental frequency, phonation type, speech rate, cross-gender acoustic differences, cross-language variations, Parisian French, American English.

1. Introduction

Numerous studies on acoustic differences between female and male speech have been conducted. Among the different acoustic parameters, mean fundamental frequency is commonly considered the major cross-gender difference. It would be around 120 Hz for men and 200 Hz for women [1] [2], hence a higher pitch in female speech. These values slightly vary through age [3] and are broadly lower for smokers [4]. Mean f_0 is also known to be a decisive clue in speaker's gender identification from speech [5] [6] [7].

Several authors have brought to light that vowel formants tend to be located at higher frequencies in female speakers [8] [9] [10] [11]. The scope of this cross-gender difference strongly varies from one study to another, from one formant to another, and seems to depend on vowel type. The spectral characteristics of consonants also differ as a function of speaker's gender [12] [13] [14]: once again, resonant frequencies tend to be higher in female speech.

Aside from mean f_0, other suprasegmental parameters could be gender-dependent. Some studies suggest that f_0 range would be larger for female speakers [1] [15]. Nonetheless, there is no strict consensus on this point [16]: the acoustic unit used to measure f_0 range appears to be determining. When calculated in hertz, f_0 range is almost unequivocally larger in female speech, but it is unclear whether this difference exists when it is calculated in semitones [17] [18]. This can be accounted for by human perception of pitch [16]: female speakers, who typically have a higher mean f_0 than males, have to use a larger raw range (i.e. in hertz) to reach the same perceived pitch variation (i.e. in semitones).

Phonation type also seems to depend on speaker's gender. Female voices are often considered more breathy (i.e. having a greater *glottal open quotient –GOQ*) than male voices [19] [20] [21]. Male voices, at least in American English speakers, are typically more creaky (i.e. having a very low GOQ) than female ones [22]. However, these results slightly vary from one study to another, and depend on the acoustic parameter used to estimate phonation type. Intensity difference between H1 and H2 could be the most reliable measurement [23], if used properly [24].

Potential male-female differences in speech rate have also been investigated. In a broad study led on 600 American English speakers, Byrd [25] found that mean utterance duration was 6.2 % lower in male speakers, thus indicating a faster speech rate than female speakers. Similar tendencies were found in more recent studies [26] [27]. However, several authors found no significant cross-gender differences on this parameter [28] [29].

Some of these cross-gender acoustic variations can mainly be accounted for by anatomical and physiological differences that arise during puberty. First of all, vocal folds become longer and thicker in male speakers [30], which would account for their lower mean f_0. A second relevant anatomical parameter is vocal tract length, which corresponds to the distance from the vocal folds to the lips: all things being equal, the longer the vocal tract, the lower resonant frequencies [31]. The average length of the adult male vocal tract is about 17 to 18 cm, while the average female vocal tract is 14.5 cm long [16]. It would explain, at least partially, why consonant noise and vowel formants frequencies are generally higher in female speakers.

Most of the previously mentioned studies were conducted on English speakers. Interesting facts arise when one considers other languages' data. For instance, a study reported that in Chinese Wu dialect, mean F0 was almost equivalent for male and female speakers [32]. Furthermore, if one compares various acoustic studies about vowel formant frequencies conducted on different languages [33, 34], one can notice that cross-gender differences vary from one language to another: for example, female-male differences are relatively small in Danish but appear to be much greater in Russian.

How to account for such cross-language differences? Physiological and anatomical cross-gender differences are very unlikely to explain then, and one must consider the possibility of socially constructed behaviors. Nonetheless, we have to take into account that the comparisons made by Johnson [33, 34] were based on several studies led by different authors, at different times and using different methods. Therefore, we must be very careful when interpreting such results, which need to be confirmed.

Given such facts, it seems relevant to conduct a cross-language study on acoustic differences between female and male speech. Moreover, we can notice that most studies in this field focus on a single acoustic parameter, although a multiparametric analysis would probably be much more productive. The present study is an acoustic analysis conducted jointly on Parisian French and Northeastern American English female and male speakers. It focuses on the

following prosodic parameters: mean f_0, f_0 range, phonation type and speech rate. The general hypothesis is that cross-gender acoustic differences are partly language-dependent.

2. Material and method

2.1. Linguistic material

French and English linguistic material was required for this study. Dissyllabic words and pseudo-words were used, so that many phoneme combinations could be tested. Their selection was based on two main criteria: make the two corpora as similar as possible, and limit the number of combinations by choosing only the most relevant phonemes while holding the last CV sequence constant: /pi/ was chosen as it can appear in word final position in both languages. Twenty-seven (C)VCV words or pseudo-words were finally chosen for each language:

- /C (plosive) – V – p – i / combinations: /tipi/, /tapi/, /tupi/, /dipi/, /dapi/, /dupi/, /kipi/, /kapi/, /kupi/, /gipi/, /gapi/, /gupi/ for the French corpus, /ˈti:pi/ , /ˈtæpi/, /ˈtu:pi/, /ˈdi:pi/, /ˈdæpi/, /ˈdu:pi/, /ˈki:pi/, /ˈkæpi/, /ˈku:pi/, /ˈgi:pi/, /ˈgæpi/, /ˈgu:pi/ for the English corpus.
- /C (fricative) – V – p – i / combinations: /sipi/, /sapi/, /supi/, /zipi/, /zapi/, /zupi/, /ʃipi/, /ʃapi/, /ʃupi/, /ʒipi/, /ʒapi/, /ʒupi/ for the French corpus, /ˈsi:pi/, /ˈsæpi/, /ˈsu:pi/, /ˈzi:pi/, /ˈzæpi/, /ˈzu:pi/, /ˈʃi:pi/, /ˈʃæpi/, /ˈʃu:pi/, /ˈʒi:pi/, /ˈʒæpi/, /ˈʒu:pi/ for the English corpus.
- /V – p – i / combinations: /ipi/, /api/, /upi/ for the French corpus, /ˈi:pi/, /ˈæpi/, /ˈu:pi/ for the English corpus.

English words were read by American speakers while French words were read by French speakers. There is no phonological lexical stress in French [35], but within the frame sentence used for the recordings (see 2.3) French speakers naturally produced an emphatic stress on the first syllable of each experimental word.

2.2. Speakers

Twenty monolingual speakers were recorded. Ten of them were French native speakers (5 women, 5 men) and ten others were American English native speakers (5 women and 5 men). The 10 American speakers all came from the same northeastern area of the United States (Pennsylvania, Massachusetts, New York State, or southern Vermont). The 10 French speakers all came from Paris area (Ile-de-France). Speakers were aged from 20 to 40 (SD=6.5 years). Mean age was 28.2 for US speakers (29.4 for females, 27 for males) and 26.6 for French speakers (27.2 for females, 26 for males). All speakers were non-smokers and had reported no speech disorder. Each of them received a USB memory stick for their participation in the study and was informed that the data from the recordings would be treated with confidentiality.

2.3. Recording procedure

Recordings took place in a quiet room, using a digital recorder *Edirol R09-HR* by *Roland*. English speakers read the English corpus aloud and French speakers the French one. Words were presented to the participants in an orthographical transcription. In order to make prosodic parameters consistent, words were placed into a frame sentence: "He said '*WORD'* twice" for the English corpus and "Il a dit '*MOT'* deux fois" for the French one. Speakers were asked to say each sentence twice, at a normal speech rate.

2.4. Acoustic analysis

Data analysis was conducted with *Praat* software. After having extracted the words from the frame sentence, their duration (in milliseconds) and mean f_0 (in Hertz) were obtained by creating a Pitch file for each word, and performing *Get total duration* and *Get mean* commands. This operation was automated by a Praat script.

F_0 range is the difference between the highest and the lowest f_0 frequency reached within a given linguistic unit (here, a dissyllabic word). It was collected manually through the *Pitch info* window: these data were taken in hertz as well as in semitones, which is a much more adequate scale [16].

In order to estimate phonation type, intensity differences between H1 and H2 were measured. The relative strength of H1 is correlated with glottal open quotient (GOQ): the stronger H1 is, the higher the GOQ [19, 23]. Nevertheless, H1-H2 can only be measured on open vowels: F1 would otherwise distort the results [19]. Thus, vowel [a] for French speakers and vowel [æ] for English speakers were the only ones taken into account.

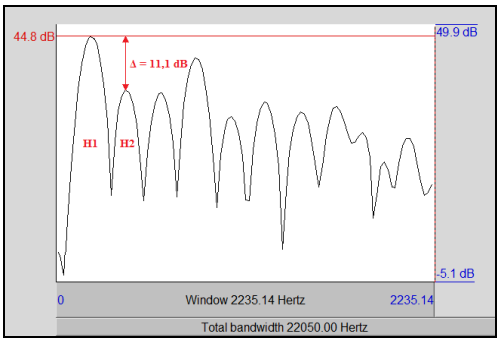

Figure 1. *Measurement of H1-H2 intensity differences on vowel [æ] extracted from word [æpi] produced by an American Female speaker.*

A 5 period selection was made on a central portion of each vowel. As shown in Figure 1, the corresponding spectrum was displayed and the difference between H1 and H2 intensity (in dB) was then calculated manually.

3. Results

3.1. Mean f_0

Mean f_0 (Hz) for French and American English speakers as a function of speaker's gender is presented in Table 1, below.

Table 1. *Mean f_0 (Hz) measured on the 27 (C)VCV words for female (n=5) and male (n=5) French speakers and female (n=5) and male (n=5) American English speakers. Standard deviation among the 135 measurements (27 words * 5 speakers) is also mentioned for the four groups.*

	French Speakers		**American speakers**	
	Females	**Males**	**Females**	**Males**
Mean f_0 (Hz) - all words	**234**	**133**	**210**	**119**
SD	*18*	*12*	*27*	*19*

Unsurprisingly, mean f_0 appeared to be much higher for female speakers in both languages. The scope of this cross-gender difference is perfectly similar from one language to another: in both cases, females' mean f_0 is 76 % higher than males'. Moreover, we can notice that mean f_0 for both genders is slightly lower in American English speakers.

In order to test if these tendencies were significant, several statistical tests were conducted. First of all, a one factor ANOVA ("speaker's gender") was led on French speakers' data. The test revealed a very strong and significant effect of this factor: $F_{(1,268)}$=3064.26 ; p<.0001. A similar statistical test was performed on American English speakers' data. Once again, the speaker's gender appeared to have a very significant effect on mean f_0: $F_{(1,268)}$=1045.21 ; p<.0001. These results confirm that mean f0 was significantly higher for female speakers in both languages.

3.2. F_0 range

F_0 range for French and American English speakers as a function of speaker's gender is presented in Table 2. It was calculated both in Hertz and in semitones.

Table 2. *F_0 range (Hz and st) measured on the 27 (C)VCV words for female (n=5) and male (n=5) French speakers and female (n=5) and male (n=5) American English speakers. Standard deviation among the 135 measurements (27 words * 5 speakers) is also mentioned for the four groups.*

	French Speakers		**American speakers**	
	Females	**Males**	**Females**	**Males**
Mean f_0 range in Hertz - all words	**90**	**41**	**74**	**40**
SD	*22*	*11*	*19*	*15*
Mean f_0 range in semitones - all words	**6.76**	**5.35**	**5.87**	**5.95**
SD	*1.81*	*1.37*	*1.45*	*1.78*

When calculated in Hertz, f_0 range was much larger for female speakers in both languages. It was 120 % wider for females in French speakers, and 85 % wider for females in American English speakers. When the data are converted into semitones, a scale that shows the perceived pitch variation, the cross-gender difference completely disappears in American English speakers. On the other hand, f_0 range remains substantially higher for females in French speakers (+ 26 %).

One factor ANOVAs ("speaker's gender") were conducted on French speakers' data. When f_0 range was calculated in Hertz, a very strong and significant effect of this factor was found: $F_{(1,268)}$=549.19 ; p<.0001. When the data were given in semitones, the analysis also reveals a strong and significant effect of the speaker's gender: $F_{(1,268)}$=51.71 ; p<.0001. Therefore, in French speakers, mean f_0 range appeared to be significantly wider for females, even when it was expressed in semitones.

Similar statistical analyses were made on American English speakers' data. When f_0 range was expressed in Hertz, the test indicated a significant effect of speaker's gender: $F_{(1,268)}$=266.23 ; p<.0001. On the other hand, when the data were expressed in semitones, no significant effect of this factor was found: $F_{(1,268)}$=.14 ; p=.71. These results confirm that f_0 range was wider in female than in male American English speakers when expressed in hertz. However, contrary to French speakers, f_0 range was no longer wider in female speakers when it was converted into semitones.

3.3. Phonation type

Mean intensity difference (dB) between the first (H1) and the second harmonic (H2) for French and American English speakers as a function of speaker's gender is presented in Table 3. It was measured on open vowels, giving a total of 9 measurements for each speaker (9 words contained vowel [a] in the French corpus while 9 words contained vowel [æ] in the English corpus).

Table 3. *H1-H2 mean difference (dB) measured on the 9 open vowels of each corpus, for female (n=5) and male (n=5) French speakers and female (n=5) and male (n=5) American English speakers. Standard deviation among the 45 measurements (9 words * 5 speakers) is also mentioned for the four groups.*

	French Speakers		**American speakers**	
	Females	**Males**	**Females**	**Males**
Mean H1-H2 difference (dB) in open vowels	**3.8**	**-1.4**	**4.0**	**-2.9**
SD	*2.5*	*1.3*	*2.6*	*2.2*

H1-H2 intensity difference appeared to be greater in female speakers. It was true in both languages. This cross-gender difference reaches 5.2 dB in French speakers and 6.9 dB in American English speakers. This cross-language variation is mainly due to American English male speakers, who had a particularly weak H1.

A one factor ANOVA ("speaker's gender") was performed on French speakers' data. The analysis revealed a significant effect of this factor over H1-H2 intensity difference: $F_{(1,88)}$=157.22 ; p<.0001. The same statistical test was conducted on American English speakers' data. Similarly to French speakers, this test indicated that there was a significant effect of speaker's gender: $F_{(1,88)}$=180.04 ; p<.0001. These results confirmed that in both languages H1-H2 difference was higher in female speakers, which suggests that females' phonation type tends to be more breathy than males'.

In order to test if cross-language variations were significant, other statistical tests were conducted. Females' data from both languages were gathered and a one factor ANOVA ("speaker's language) was performed. The analysis showed no significant effect of this factor: $F_{(1,88)}$=.11 ; p=.74. A similar test was conducted on males' data. This time, a significant effect of speaker's language was found: $F_{(1,88)}$=13.55 ; p=.0004. This analysis confirmed that American male speakers had a significantly lower H1-H2 intensity difference than French male speakers, which suggests they used a creakier phonation type.

3.4. Speech rate

Mean word duration (ms) for French and American English speakers as a function of speaker's gender is presented in Table 4, below.

Table 4. *Mean word duration (ms) measured on the 27 (C)VCV words for female (n=5) and male (n=5) French speakers and female (n=5) and male (n=5) American English speakers. Standard deviation among the 135 measurements (27 words * 5 speakers) is also mentioned for the four groups.*

	French Speakers		**American speakers**	
	Females	**Males**	**Females**	**Males**
Mean word duration (ms)	**510**	**445**	**555**	**441**
SD	*90*	*58*	*77*	*54*

Results show that mean word duration was higher for female speakers in both languages. Cross-gender difference is wider in American English speakers (+26 %) than in French speakers (+15 %). This variation can be accounted for by the difference between French and American Female speakers: the words produced by the latter appeared to be longer than those produced by the former (+9 %).

A one factor ANOVA ("speaker's gender") was conducted on French speakers' data. This test indicated that there is a significant effect of this factor on words' mean duration: $F_{(1,268)}$=48.94 ; p<.0001. The same analysis conducted on American English speakers' data reveals a strong and significant effect of speaker's gender: $F_{(1,268)}$=200.28 ; p<.0001. These results confirm that speech rate was significantly higher for male speakers in both languages.

4. Discussion - conclusions

This cross-language acoustic analysis has given several remarkable results. Mean fundamental frequency, measured on dissyllabic words, was significantly higher for women in both languages, which broadly confirms results obtained in previous studies [1] [2]. Moreover, even though mean f_0 was slightly lower for both genders in American English speakers, the scope of the female-male difference was very similar in the two languages. This suggests that cross-gender differences in mean f_0 are relatively consistent across languages, apart from a few known exceptions, such as Chinese Wu dialect, in which male speakers tend to use an exceptionally high f_0 [32].

Regarding f_0 range, measurements have highlighted an interesting cross-language variation. When data were taken in hertz, f_0 range appeared to be significantly wider for female speakers in both languages, which supports results from previous studies [1] [15]. This cross-gender difference can be accounted for by the fact that female speakers, who generally have a higher mean f_0, have to use a larger f_0 range than males (in hertz) to achieve the same perceived result in terms of pitch variation.

Indeed, when f_0 range was calculated in semitones, a scale expressing perceived pitch variation, there was no more cross-gender difference in American English speakers. However, f_0 range was still significantly larger for French female speakers compared to their male counterparts. These results clearly support a former perceptual study from Pépiot [5] that showed a tendency for French listeners to associate flat f_0 with male voices, whereas no such effect was found in American English listeners.

H1-H2 intensity measurements in open vowels gave precious indications about speakers' phonation type. In both languages, significant cross-gender differences were found. H1's relative intensity appeared to be significantly greater in female than in male speakers, which suggests they tend to speak with a greater GOQ, hence a more breathy phonation type. Moreover, American English male speakers had a significantly lower H1-H2 than French male speakers, with strongly negative values. This indicates a very low GOQ, hence a creakier voice. Such results support the claim that female speakers' breathy voice quality would have a physiological origin [16], whereas male speakers' use of creaky voice would rather be socio-phonetic and language-dependant [22].

Concerning temporal measurements, dissyllabic words' global duration was found to be significantly greater for female speakers in both languages. These data are quite similar to former results obtained by Byrd [25] and Whiteside [27]. Cross-gender difference was slightly wider in American English speakers. Nonetheless, these results may suggest that the lower speech rate in female speakers, at least in a reading task, could be fairly consistent across languages.

Overall, the present study has brought to light several cross-gender differences, but also some cross-language variation between Parisian French speakers and Northeastern American English speakers. This tends to support the general hypothesis which claimed that cross-gender acoustic differences could be partly language-dependent. Furthermore, some of the female-male differences found in this acoustic analysis, such as differences in speech rate, are unlikely to be explained by anatomical and physiological factors. A large part of cross-gender variation is likely to be accounted for by gender social construction. Therefore, these data may be of interest for improving vocal rehabilitation of transgender people [36]. They could also be useful in speech recognition and automatic gender identification from speech.

Nevertheless, such results have to be interpreted with caution. Only 5 men and 5 women were recorded for each language. Despite the restrictive selection criteria and the small intra-gender variation, it seems quite difficult to generalize the results to the whole Parisian French and American English speaker populations. Furthermore, it is known that speech task influences several acoustic parameters, such as speech rate and phonation type [37]. These corpora were made of read dissyllabic words: it is unclear whether similar results would be obtained with spontaneous speech.

5. Acknowledgements

I would like to thank the 20 speakers who agreed to participate in the recordings. I am also grateful to the *EA1569* laboratory of University Paris 8, which provided financial support for this study. Finally, many thanks to Isabelle Coydon, from NYU Paris, who was of great help for finding the American English speakers.

Perceived Prominence Reflected by Imitations of Words with and without F0 Continuity

Abstract

This paper continues our work on the perception of prominence as a function of *F0* continuity. In an earlier study the first author had shown that *F0* intervals occurring at lexically stressed syllables – and measured using the amplitude of Fujisaki model accent commands – strongly contribute to the perceived prominence of that syllable. More recent work explored how *F0* continuity influenced prominence ratings of single word utterances. The outcome indicated that listeners made use of the physically available *F0* information and therefore words containing gaps in the contour were perceived as less prominent. It was also shown that subjects were able to interpolate missing parts as long as the *F0* peak was still present. The current study explores whether subjects compensate the lack of prominence in words containing *F0* gaps by asking them to produce a word with the same accent strength as that of a spoken word stimulus, the spoken word being either the same or different from the one they are asked to utter. We evaluated word durations, *F0* intervals and intensities of the responses as correlates of prominence and found that listeners indeed seem to adjust depending on the kind of stimulus they have heard.

Index Terms: prominence, perception, Fujisaki model, *F0*

1. Introduction

The information structure of an utterance is reflected in the relative saliency of its lexical constituents. At the acoustic level we observe that accented syllables serve as anchoring points of this structure. They are emphasized or toned down by phonetic means. The perceptual correlate of this process is the so-called prominence [1]. Various segmental and supra-segmental factors have been shown to affect prominence, cf. [1][2][3], such as F0 excursions, segment durations, intensity as well as vowel type and syllable coda structure. In an earlier study [4], the first author and his co-worker investigated the relationship between perceived syllable prominence and the *F0* contour in terms of the parameters of the Fujisaki model [5]. The model was used to parameterize a subcorpus of the Bonn Prosodic Database [6]. Analysis showed that prominences labeled on a scale from 0-31 strongly correlated with the excursion of *F0* movements, but only when it was anchored to accented syllables. This indicates that the prominence judgment is partly guided by linguistic considerations. Evidence in support of this assumption has been presented for many languages, including German ([7],[8], [9]), which is the language of the present study.

While we are well aware that other factors such as syllable duration [4] influence prominence perception, we concentrate in the current work on the contribution of *F0*. As mentioned above the Fujisaki model decomposes natural *F0* contours with a defined value for each speech frame, irrespective of segmental structure. This entails that it smoothly interpolates or extrapolates *F0* gaps owing to unvoiced sounds. However, from a communicative point of view, the implicit claim of using the same underlying prosodic gesture for voiced and unvoiced sound sections is that listeners are *also* able to interpolate or extrapolate *F0* gaps. Recent evidence from a tonal scaling study [10] seemed inconsistent with this assumption.

Subjects were presented with short resynthesized utterances and asked to rate the tonal height of accent-related *F0* rises. The rises led to a peak that was either present or absent due to an unvoiced stop consonant. Tonal height ratings were made and analyzed relative to reference utterances in which the *F0* rise was replaced by a flat *F0* stretch, yielding a constant tonal height. The findings of [10] suggested that the subjective continuity of pitch contours in speech is due to the fact that the auditory system simply ignores rather than fills *F0* gaps.

In [11] we therefore examined the implications of these findings for the perception of word prominence. We investigated how gaps in the *F0* contour due to unvoiced consonants affect prominence perception, given that such gaps can either be filled or blinded out by listeners. For this purpose we created a stimulus set of real disyllabic words which differed in the quantity of the vowel of the accented syllable nucleus and the types of subsequent intervocalic consonant(s). Participants rated pairs of these stimuli in a 2AFC discrimination task for accent strength, that is, they decided which word in a pair sounded more strongly accented. Results included, inter alia, that stimuli with unvoiced gaps in the *F0* contour are indeed perceived as less prominent. The prominence reduction was smaller for monotonous stimuli than for stimuli with *F0* excursions across the accented syllable. Moreover, in combination with *F0* excursions, it also mattered whether *F0* had to be interpolated or extrapolated, and whether or not the gap included a fricative sound. The results supported both the filling-in and blinding-out of *F0* gaps, which fits in well with earlier experiments on the production and perception of pitch.

The current experiment examines whether speakers compensate for the inherent difference in prominence when they produce words with or without continuous *F0* contours. To this end we asked participants of a production experiment to reply to an acoustic stimulus of an isolated word and speak either the same or a different word with the same accent strength. Our hypothesis are: (1) if speakers indeed compensate for missing F0 parts and their prominence contribution when they reproduce a given accent strength, then they will realize higher *F0* targets in low-sonority than in high-sonority words in which *F0* is more/ all F0 is present; (2) replicating our previous findings, acoustic stimuli in which *F0* is either continuous *or* can be interpolated or filled-in will make speakers produce higher *F0* targets.

2. Stimuli and Experiment Design

The acoustic stimuli were taken from the set employed in [11]. They are shown in Table 1 with their critical segments set in bold in the SAMPA column. As can be seen, the critical segment extends from the beginning of the open vowel to the end of the intervocalic consonant(s).

Table 1. *Five target words, SAMPA transcription, English translation, type and mean energy of the critical segment.*

Word	SAMPA	English	critical segment	mean energy (dB)
Rahmen	[R**a:m**@n]	frame	long vowel (LV), voiced (vcd) nasal	74.23
Rasen	[R**a:z**@n]	lawn	LV, vcd fricative	72.10
Raten	[R**a:t**@n]	guess	LV,voiceless (vcl) plosive	68.10
Ras(s)ten	[R**ast**@n]	rest	short vowel (SV), vcl fricative+plosive	66.19
Ratten	[R**at:**@n]	rats	SV, long vcl plosive	50.68

For acoustic uniformity, the stimuli had been created using the *MBROLA* concatenative speech synthesizer driving the German male voice *de8* [12]. The base stimulus had a monotonous *F0* at 100Hz. The long vowel [a:] was adjusted to 244ms and the central consonant portion to 126ms. In the short-vowel words the V/C portions were 142ms and 228ms. These critical segment durations and the word durations, respectively, were kept constant for all stimuli, in order to avoid that durational differences influenced the prominence judgments.

Using the *FujiParaEditor* [13] and Praat PSOLA resynthesis [14] we created further stimuli by adding *F0* peak contours to the monotonous stimuli. The contour basis was laid by a phrase component, constant for all stimuli. One accent component with duration of 200ms was superimposed on the base contour. Unlike in [11] we decided to employ only medial-peak stimuli in the current study. Their *F0* maxima were aligned close to the accented-vowel offset in the long-vowel words and in the following coda in the short-vowel words, in line with previous findings [15] and observations in citations forms.

Figure 1 displays the stimuli Rahmen, Raten and Ras(s)ten with *Aa*=0.6, *Aa* being the amplitude of the underlying Fujisaki model accent command which corresponds to the interval of the *F0* excursion associated with each word (see box-shaped accent command at the bottom of Figure 1. The F0-peak range was varied in three steps, represented by three different accent command amplitudes (*Aa*): 0.4 (interval of approximately 3 semitones), 0.6 (about 3 semitones higher) and 0.8 (about 6 semitones higher). Hence, including the monotonous condition, we generated four different acoustic versions of every word and hence a total of 100 acoustic stimulus/text pairs.

The experiment was conducted using WikiSpeech [16], a framework developed at Ludwig-Maximilian-University Munich for web-based perceptual testing and speech data collection. Participants were asked to enroll on the WikiSpeech-Website and accept the download of the Speech Recorder audio recording tool. When participants executed the program on their computers, the task was explained to them on the start-up screen. Every trial consisted of the automatic playback of the acoustic stimulus, that is, one of the synthetic stimuli, followed by the display of the word to be produced written as text. A traffic light indicated when to speak. The duration of the recording slot was fixed at five seconds. After having recorded the subject's response to the given synthetic stimulus, the experiment immediately continued with the next stimulus. Each of the acoustic words was either paired with its text equivalent or that of one of the other target words. Subjects were asked to pronounce the text word with the same accent strength as the acoustic stimulus.

Prior to the experiment the subjects listened to two examples in which of an acoustic stimulus was followed by the reply of a dummy subject. Subsequently a training session started which four pairs of the same or different words had to reproduced by the subjects with the same accent strength.

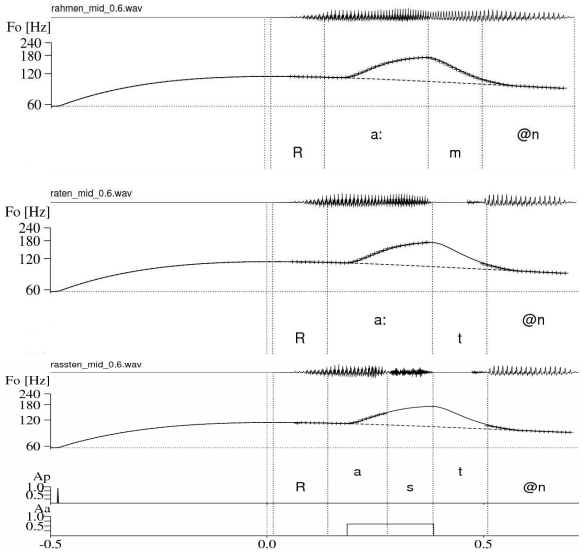

Figure 1. Examples of stimulus words Rahmen, Raten and Ras(s)ten with Aa=0.6. Panels display waveform (top), F0 contour (+++extracted, —Fujisaki model-based, middle), and underlying phrase/accent commands (bottom).

3. Acoustic Analysis of Stimuli

We recorded 19 native speakers of German (10 females, 9 males, 22-46 years old), most of them students at Beuth University Berlin or Kiel University. Since the experiment was web-based, we had no control over the recording equipment and environments. Although we had requested the use of headsets, many participants apparently used built-in microphones picking up environmental noise. Thus, the quality of recordings varied considerably with a wide range of gain settings, background noise and audible audio compression effects. But as long as the recording quality was sufficient to reliably extract prosodic parameters, and F0 in particular, we included data which would not have qualified for other acoustic analyses.

We first checked the audio files for the correct intended word, then admitted data sets with more than 70% correct word replies to further analysis, excluding, of course, all erroneous tokens within these sets. As a consequence, two participants were entirely excluded (1 female, 1 male), leaving a total of 17 data sets or 1,700 recordings.

Of the remaining sets 1,561 contained the correct word (92%). Only three of the subjects were a 100% successful. Errors chiefly concerned the words [Rast@n] and [Rat@n]. This was because, [Rast@n] (*"to rest"*) and [Ra:st@n] (past tense of *"to speed"*) have the same spelling <Rasten> in German. Since we had anticipated this interference we had spelled [Rast@n] in the non-standard way 'Rassten' to indicate the short vowel. However, the presence of 'Rasen' (infinitive

of "to speed", in addition to *"lawn"*) in the data set possibly triggered errors, especially when a long-vowel word had to be reacted to. Eleven of the participants produced [Rast@n] wrongly, in a total of 79 trials. [Rat@n] exhibited 38 two-way confusions with [Ra:t@n]. In most cases the vowel quantity of the acoustic stimulus matched the one produced erroneously. In contrast, participants reacted to the words [Ra:m@n] and [Ra:z@n] without difficulties. A few cases of errors also concerned empty audio files (9), stuttered words (8) or repetition of the acoustic stimulus word (5) when this was not requested.

After having selected the analyzable sets, their recordings were down-sampled to 16 kHz, and the first 0.85 seconds removed as they often contained audible traces of the acoustic stimulus. These traces disturbed the subsequently conducted forced alignment with the WEVOSYS LINGWAVES aligner [17]. Automatic phone segmentations were checked and corrected manually in the *PRAAT* TextGrid Editor [14].

We calculated word, syllable and phone durations in *PRAAT* based on the segmentations. *F0* values were extracted at intervals of 10 ms with *F0* floors and ceilings for male (50-300Hz) and female participants (120-400Hz). All *F0* contours were then subjected to Fujisaki model parameter extraction [18]. Results were checked and if necessary corrected in the *FujiParaEditor* [19]. In this way, we obtained a smooth, interpolated model *F0* contour even when the natural *F0* contour was interrupted by unvoiced segments. Hence the accent command amplitude *Aa* is a measure of the underlying *F0* gesture magnitude.

Intensity contours were extracted in *PRAAT* with default settings, and mean intensities in dB, as well as maxima employing parabolic interpolation were determined for each phone.

In order to analyze our data with respect to the research question, it was sufficient use only the following four Fujisaki model parameters as dependent variables: *Aa* (accent command amplitude, as a measure of magnitude of *F0* excursion at the accented syllable), *Fb* (base frequency of the *F0* pattern), *Ap* (phrase command magnitude, a measure of the magnitude of *F0* reset before phrase onset), and *T1rel* (the timing of the accent command onset relative to the onset of [a:] or [a:] in the first, accented syllable). Each word exhibited one phrase and one accent command, like the acoustic stimuli in Figure 1. *F0* con-tours of several reactions to monotonous stimuli were absolutely flat, so that neither a phrase nor an accent command was extracted.

The four dependent variables provided by the Fujisaki model were complemented by five dependent derived from the segmentation and measurement procedures conducted with PRAAT. These additional five dependent variables were *duration syllable 1*, *duration syllable 2*, as well as *vowel duration*, *mean vowel intensity*, and *maximum vowel intensity*. The latter three concerned the accented vowel [a:] or [a].

It should be stressed prior to the results presentation that we did not aim to perceptually evaluate whether participants had actually succeeded in producing words of equal prominence, but explore the patterns in their reactions to the acoustic stimuli depending on the magnitude of *F0* excursion and type of word. Our only assumption is that subjects reacted to the stimuli as requested and aimed at producing equal prominences.

4. Results of Analysis

Our 4+5=9 dependent variables were analyzed statistically with a three-way multivariate ANOVA based on the fixed factors *Word Heard*, *Word Realized*, and *F0 Range Heard*. The latter factor included the four *Aa* levels of the acoustic stimuli, i.e. 0.0 (monotonous), as well as 0.4, 0.6, and 0.8 (henceforth "*F0* peak conditions"). The other two factors had five levels each, corresponding to the disyllabic target words Rahmen, Rasen, Raten, Ras(s)ten (henceforth Rasten), and Ratten.

All three fixed factors had significant effects on many dependent variables. Our results section can only summarize a subset of these findings; and since the monotonous conditions differ considerably from the *F0* peak conditions, we will deal with the two conditions separately, starting with the *F0* peak conditions.

The most important finding in the *F0* peak conditions was that the *Aa* levels in the speakers' productions were highly significantly affected by *F0 Range Heard* ($F[3,1296]= 7.582$, $p<0.001$). More specifically, the *Aa* levels produced by the participants clearly mirrored those of our acoustic stimuli, independently of the target word (cf. Figure 2, center). The *Aa* level 0.4 was on average even exactly reproduced, whereas the higher *Aa* levels 0.6 and 0.8 of the acoustic stimuli were slightly underestimated and on average produced as 0.5 and 0.6.

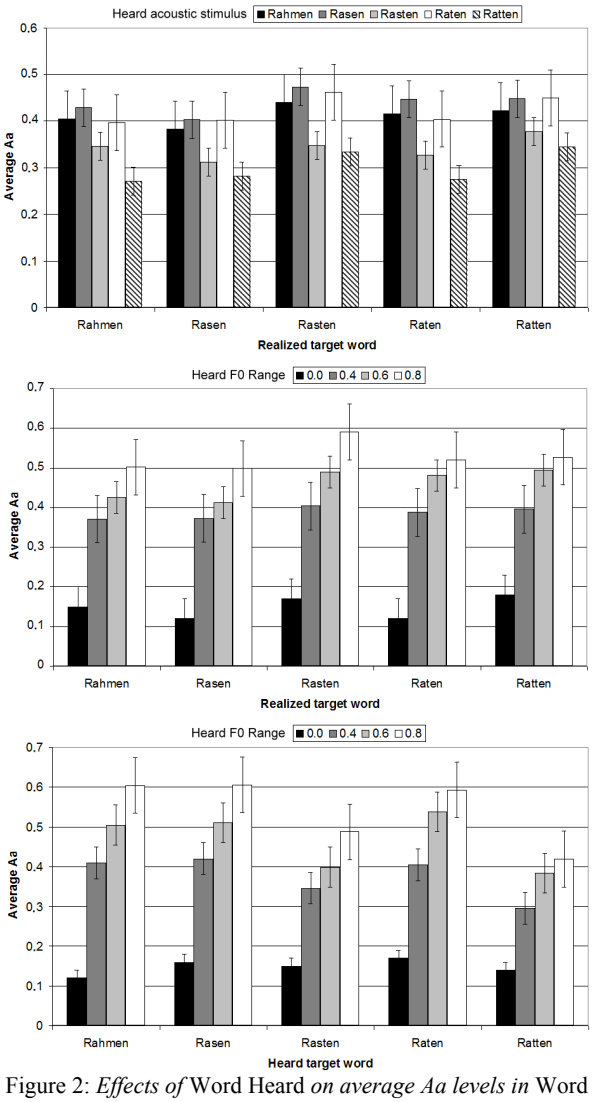

Figure 2: *Effects of* Word Heard *on average Aa levels in* Word Realized *(top), as well as combined effects of* F0 Range Heard *and* Word Realized *(center) or* Word Heard *(bottom) on the produced average Aa levels.*

Next to this general parallelism between heard and actually produced *Aa* levels, the *Aa* levels in the speakers' productions showed target word-specific differences. This is reflected in the MANOVA in a significant interaction between *Word Heard*

and *F0 Range Heard* (F[12,1296]=3.813, p<0.001). However, there was also a separate significant main effect of *Word Heard* (F[4,1296]= 35.522, p<0.001). Breaking down this main effect in terms of multiple post-hoc comparisons with Sidak correction revealed that our speakers produced higher *Aa* levels across all target words when the *F0* peaks they heard came from the more sonorous stimuli Rahmen, Rasen, and Raten rather than from the less sonorous stimuli Rasten and Ratten. The *Aa* level difference was on average 0.1 (p<0.001 in all cases, 278 ≤ n ≤ 286, cf. Figure 2, bottom). Moreover, the latter two words Rasten and Ratten yielded an additional weak *Aa* difference (p<0.05) with the Rasten stimuli triggering significantly higher *A*a level productions (of about 0.05) than the Ratten stimuli.

Exactly the opposite pattern led to a separate significant main effect of *Word Realized* (F[4,1296]= 6.829, p<0.001). We analyzed this effect by means of multiple post-hoc comparisons with Sidak correction (p<0.05 in all cases, 224 ≤ n ≤ 305, cf. Figure 2, top) and found that the *F0* peaks in the less sonorous target words Rasten and Ratten were produced with an *Aa* on average about 0.7 points higher than the more sonorous target words Rahmen, Rasen, and Raten (p<0.05 in all cases, cf. Figure 2, top and center). So, while successive desonorization and/or devoicing caused a reduction of the *F0* range at the level of perception, it triggered an extension of the *F0* range at the level of production. It is not a usual finding in the area of segment-related microprosodic perturbations that production and perception findings go in opposite directions. The present outcome suggests the existence of a compensatory strategy in *F0* production.

The speakers' productions after monotonous stimuli differed considerably from those after the *F0* peak stimuli. The nature of these differences suggests that the speakers used a stylized, singing speech mode when producing target words after monotonous stimuli. For example, *Fb* (i.e. the base *F0*) was significantly higher and *Ap* significantly smaller after monotonous than after all other stimuli, which is among others reflected in a main effect of *F0 Range Heard* (F[3,1296]= 20.752, p<0.001; F[12,1296]= 103.065, p<0.001). Furthermore, we found with respect to *F0 Range Heard* that target word productions after monotonous stimuli were softer in terms of a lower *maximum vowel intensity* (F[3,1296]= 2.253, p<0.05) and longer due to increased durations in both the first and especially the second syllable (*duration syllable 1*: F[3,1296]= 2.169, p<0.05; *duration syllable 2*: F[3,1296]= 5.095, p<0.001).

Besides these major findings, *Word Heard* resulted in an interesting further effect, which could be characterized as "transfer" or "echo effect" of the acoustic stimuli on the produced target words. For example, after hearing the short-vowel stimuli Rasten and Ratten, speakers produced their target words with shorter first syllables and vowels, independently of the target word or the quantity of its accented vowel (F[4,1296]= 10.965, p<0.001; F[4,1296]= 17.097, p<0.001). So, even Rahmen was produced with shorter first syllables and vowels when preceded by a stimulus like Rasten or Ratten. Finally, a significant main effect of *Word Realized* on *T1rel* (F[3,1296]= 5.309, p<0.001) replicated known effects of syllable structure and/or consonant type on *F0* peak timing [20], for example, in the form of an earlier timing relative to the vowel onset with increasing desonorization of the produced target words.

Last but not least, we have no indications from randomly composed sub-samples for speaker- or gender-specific effects on the crucial *Aa* variable. However, other duration and intensity variables show differences, pointing to individual F0-peak timings (cf. [24]), speaking rates or loudness levels, the latter of which could also be due to the different recording equipments.

5. Discussion and Conclusions

This paper presented results from an imitation study comparing reactions to word stimuli with either the same or a different word. Effects of *F0* on prominence perception are usually investigated with continuously voiced speech material. But what happens in more natural speech conditions, i.e. when parts of prominence-related *F0* movements are missing due to interruptions by voiceless sound segments? Do speakers and/or listeners compensate for the missing *F0* sections? The answers to these questions provided by the present findings are consistent with our hypotheses (1) and (2).

That is, in accord with previous findings on English [10], our speakers' responses to the stimuli suggest that *F0* gaps are ignored rather than filled so that word intonations in which the peak maximum and/or adjacent high *F0* section are missing sounded lower and were hence imitated with lower *Aa* on the same or other words. As in our previous study, voiceless fricatives, here the Rasten/Ratten distinction, seem to be an exception. Speakers produced higher *Aa* as a reaction to Rasten stimuli than to Ratten stimuli, which suggests that they also heard more of the prominence-related *F0* peak in the Rasten stimuli, although the *F0* gap was physically equally long as in Ratten. That is, it seems that voiceless fricatives lend themselves better to a perceptual fill-in of *F0* gaps. This matches well with the notion of "segmental intonation", developed with reference to *F0* adjusted fricative productions by the third author [21].

However, even though *F0* sections masked by voiceless segments can be restored by listeners under certain circumstances, our present findings also suggest the existence of a compensatory mechanism. Speakers did not use the same *Aa* level across all target words when they imitated the prominence level of a given stimulus. Rather, they adjusted the *Aa* level of the realized target word such that they used higher *Aa* levels for words with *F0* interruptions, hence compensating for their inherently lower prominence. As far as we know, such a compensatory mechanism is observed for the first time here, although it is known for a long time that microprosodic variation is compensated for in speech production and/or perception. For example, listeners compensate for intrinsic *F0* variation [22] or intrinsic duration variation [23]. Such compensatory mechanisms are typically only partial; and a comparison between the *Aa* levels in perception and production/imitation suggests that the same also applies to our findings.

Finally, given the general parallelism between heard and realized *Aa* levels, the clear distinction between short and long vowels, the observed "transfer/echo effect" (short/long vowels in the stimuli resulted in generally shorter/longer syllable productions), and the replication of known interactions between syllable structure and F0 peak timing, we can be confident that our speakers generated valid data and did a good job in reproducing the prosodic prominence patterns of acoustic stimuli on the same of different target words. Nevertheless, follow-up studies should aim at replicating the present findings with a larger number of speakers. and probably without the monotonous *F0* stimuli, as it is unclear how their very special character biased the prominence imitations in the *F0* peak stimulus conditions. Future work should also take up the observed "echo effects", which could point to phonetic accommodation or the way in which acoustic properties are mapped onto perceptual measures, which is another promising field for imitation tasks.

The Structure of Japanese Phrase in Accordance with Speaking Modes

Toshiyuki Sadanobu

Graduate School of Intercultural Studies, Kobe University

sadanobu@kobe-u.ac.jp

Abstract

While English is often spoken in an increment of clause (i.e. subject and predicate), Japanese of a smaller phrase called "bunsetsu" (e.g. noun phrase and case particle). Previous studies on Japanese language, however, have traditionally been focusing on clause structure, and little attention has been paid on the structure of "bunsetsu" (non-predicate one, especially). This paper describes the basic structure of non-predicate "bunsetsu" from grammatical point of view, and elucidates that the structure of non-predicate "bunsetsu" varies in accordance with four speaking modes ((i) Sentence mode A; (ii) Sentence mode B; (iii) "Bunsetsu" mode; and (iv) Character mode), which are identified on the criteria of compatibility among seven phenomena attested in Japanese speech. To be more concrete, this paper shows that it is only the mode (iii) that enables copula, "bunsetsu"-final particle ("Kantoujoshi" in Japanese), final leaping, and combination of breaking and prolongation in non-predicate "bunsetsu").

Index Terms: intonation unit, speaking mode, Japanese

1. Introduction

While English speech often employs the clause (subject + predicate) as a unit, ([1][2]), Japanese speech often employs the phrase ("bunsetsu") as a unit ([3][4][5]). However, Japanese language studies through now have concentrated on structural analysis of the sentence, with few exceptions ([5][6]) almost never looking at the structure of the phrase (particularly the non-predicate phrase). By focusing on the relation between phenomena, this paper groups speech modes (speech consciousness) into four main types ((i) sentence mode a, (ii) sentence mode b, (iii) phrase mode, (iv) character mode), and shows that the structure of a non-predicate phrase varies by speaking modes.

Section 2 will introduce the phenomena discussed in this paper. Section 3 will show how they can be grouped into four categories connected with four speaking modes ((i) Sentence mode A; (ii) Sentence mode B; (iii) Bunsetsu mode; and (iv) Character mode) based on the relation between these phenomena, and describe that the structure of non-predicate phrase can be complex only on Bunsetsu mode. Lastly, Section 4 will summarize this paper's findings.

2. Seven phenomena

This paper observes seven types of phenomena in total. A brief introduction to each is provided below

2.1. Disappearance of lexical accent (DA)

While traditionally it has been thought that in Japanese intonation does not break down the form of lexical accent ([7]), in actual everyday communication it is not uncommon for intonation alone to be reflected in tone, with lexical accent drowned out ([8]).

For example, in the database of conversations between a mother and her child commonly known as "Emi-chan Data," ([9]), the entire sentence of the joking threat "Emi no otete tabechau zoo" ("I'm going to eat your hand!") is spoken in a gently rising tone, ignoring lexical accent on all words and phrases (no. 14, side B, approx. 49: 32).

In this paper, we will call this phenomenon in which tone reflects only one intonation and lexical accent is not reflected "disappearance of lexical accent" (DA).

2.2. Preposed predicate phrase (PPP)

As seen in the example "Chan to kare ni itta yo" ("I already told him"), in a Japanese sentence the predicate phrase (in this example, "itta yo") is positioned at the very end. However, this order of occurrence of phrases is not strictly unchanging, and in some cases the predicate phrase may appear in a position more to the front of the sentence, as in "Itta yo, chan to kare ni." Furthermore, in some cases the predicate phrase may appear in positions other than the end of the sentence with modifiers, as in "Chan to itta yo, kare ni" or "Kare ni itta yo, chan to." In this paper, we will call this phenomenon, including all of these cases, "preposed predicate phrase" (PPP).

This paper will not pursue the issue of whether the predicate phrase actively is placed in the front in all cases referred to as PPP or whether some cases should properly be described as "rear placement" (late appearance) of other phrases. Instead, it will refer to every such case uniformly as PPP.

2.3. Occurrence of copula (OC)

In the example "Nihon no shuto wa Tokyo da" ("The capital of Japan is Tokyo"), the copula (in this example, "da") occurs at the end of the predicate phrase. Traditionally, the copula has been known to appear at the end of other phrases as well ([7]). As one specific example, in "Shikamo da" ("And that too") the copula (in this example, "da") occurs at the end of the adverbial phrase "shikamo," which is not a predicate phrase.

As used in this paper, "occurrence of copula" (hereafter OC) will refer only to cases in which a copula occurs at the end of a phrase other than a predicate phrase. It will not include cases when a copula occurs at the end of a predicate phrase.

Besides "da", there is another copula "desu", which often appears at the end of non-predicate phrase as well as "da". Moreover, it is possible to combine these two copulas through the past particle "ta" to construct a complex form "da-tta-desu."

Aside from "da" and "desu," other copula widely seen to occur at the end of non-predicate phrases include "ja," as well as "ssu," "zamasu," "degozaru" and "deojaru" etc. As

well as in predicate phrases, form of copula in non-predicate phrases varies in accordance with the speaker's types ([8][9]). For example, a speaker of "old man" type utters "ja" instead of "da", and "desu-ja" instead of "desu". And instead of "desu", athletic speaker utters "ssu", upper-class matron speaker utters "zamasu", samurai/ninja utters "degozaru", and Heian noble man utters "deojaru."

2.4. Occurrence of interjectory particle (OI)

Some final particles appearing at the end of a predicate phrase (i.e., those other than particles such as "zo," "ze," or "wa") traditionally are known also to appear at the end of phrases other than predicate phrases, as interjectory particles ([7]). While some advocate eliminating the distinction between final particles and interjectory particles ([10]), in this paper we will maintain the distinction between the two, referring to the phenomenon of an interjectory particle ("ne" in the following examples) appearing at the end of a phrase other than a predicate phrase ("shikamo") as in the example "Shikamo ne" as "occurrence of interjectory particle" (hereafter OI).

In addition to "ne," widely seen interjectory particles likely to occur in this way include "na," "yo," and "sa," as well as "no(o)" as spoken by elderly people and "nya(a)" as spoken by "cat-like" people.

In some cases both a copula and an interjectory particle may appear together at the end of a non-predicate phrase. In such a case, as seen in the example "shikamo da ne" the copula ("da" in this example) is positioned first, with the interjectory particle ("ne" in this example) coming later.

2.5. Final leaping of intonation (FLI)

The phenomenon in which, for example, the phrase "kare ga," generally pronounced with a High-Low-Low tone (hereafter HLL), is instead pronounced with a HLH or the phrase "sore ga," generally pronounced with a LHH tone is instead pronounced with a LH-Ultra High, pronouncing the final component (in these examples, "ga") with a higher intonation as if it is leaping from the phrase, including cases in which this is followed by a return to a lower intonation ("kare ga(a) [HLHL], "sore ga(a)" [LH-Ultra High-L]), has been known for some time and is referred to by various names. In this paper we will refer to it simply as "final leaping of intonation" (FLI), separating this into "returned final leaping of intonation" (returned FLI) and "unreturned final leaping of intonation" (unreturned FLI) as necessary.

While returned FLI has a negative image as childish, unintelligent way of speaking among young people, in fact this intonation is observed broadly in the speech of young and old, male and female, with the exception of some high-ranking characters. Unless repeated frequently and consecutively, this intonation does not actually give such a bad impression.

Although it is difficult for a predicate phrase or final phrase to appear in the case of a returned FLI, this is merely a general tendency. In strong expressions such as "Hara ga tatsuu!" ("It makes me angry!"), "Koitsuu!" ("You!"), "Mo, otosan-ttaraa!" ("Oh, you, father!"), "Itsumo so nan da karaa!" ("It's always that way!"), "Wakatta yoo!" ("I get it!"), or "Kaeshite yoo!" ("Give it back!"), returned final leaping intonation may occur with a predicate phrase or final phrase ([12]).

2.6. Combination of breaking and prolongation (CBP)

Japanese permits various types of halting of speech. For example when saying the title "Dokurokamen" hesitatingly in a form such as "Saikin terebi de hayatteru anime arimasu yo ne. Eeto, _____ deshita-kke" ("There's a popular animated series on TV lately. What's it called, _____?"), it would be natural to say "Do, Dokurokamen" (breaking off and then repeating from the start), "Do, kurokamen" (breaking off and then continuing), "DooDokurokamen" (extending the first sound and then repeating from the start), or "Dookuro kamen" (extending and then continuing). At the same time, a certain connection can be seen between halting and feeling (i.e., hesitation or surprise), as in the way the only halting used to express surprise is "Do-, Dokuro Kamen" (breaking off and then repeating from the start) ([6]).

As used here, "combination of breaking and prolongation" (hereafter CBP) refers to a complex kind of halting in which, as in the examples "koozookaikaku, uuno" ("structural reforms" in genitive case) or "koozookaikakuo, oo," ("structural reform" in accusative case) after once halting pronunciation at the end of a word ("koozookaikaku") or phrase ("koozookaikakuo") ("koozookaikaku,""kozokaikakuo,") the final vowel sound ("u" or "o") is extended. This type of halting is used in official situations by adult characters who have authority (while taking care to be noncommittal). It is not used by children speakers.

2.7. High pitch accent on first mora (HF)

When, for example, reading the alphabet one letter at a time as it is pronounced in Japanese, every letter is pronounced with a high pitch accent on first mora, from "Ee" ("A") (HL) through "daburuyuu" ("W") (HLLL), "ekkusu" ("X") (HLLL), "wai" ("Y") (HL), and "zetto" ("Z") (HLL). Similarly, when reading the Kanji characters in the name "Koobe Daigaku" ("Kobe University") one at a time as "koo," "be," "dai," "gaku," again each character is pronounced with a high pitch accent on first mora: "koo" (HL), "be" (H), "dai" (HL), and "gaku" (HL). This phenomenon will be referred to as "high pitch accent on first mora" (hereafter HF). In general, when adding honorifics such as "-san," "-chan," and "-kun" to people's names the pitch of the immediately preceding mora is continued unchanged, as in "Tanaka-san," "Tanaka-chan," or "Tanaka-kun" (LHH-HH) or "Shimizu-san," "Shimizu-chan," or "Shimizu-kun" (HLL-LL). However, in all cases when there is a high pitch accent on the first mora, as in "Ka-san," " Gi-chan," "Go-kun," "Shu-san," "Jo-chan," "So-kun," "Pe-san," or "Ra-chan," "-san," "-chan," and "-kun" are pronounced with a low pitch (HLL). Furthermore, when pronouncing a foreign name such as Xiaoming Chang in a way patterned on the tone of its original language (Chinese), such as "Chen Shaomin"(LHHLLH), "-san" appended at the end has a low pitch as well. These cases too are due to the phenomenon of reading with a high pitch accent on the first mora. When saying, for example, "'Sada' to iu ji wa ko kakimasu" ("The character 'sada' is written this way") as well, the accent is high on the first mora, and this too is due to the phenomenon of reading with a high pitch accent on the first mora.

3. Relation between these phenomena

Observation of whether the seven types of phenomena introduced above are likely to co-occur shows that while three types of phenomena are unlikely to co-occur with others, four types may co-occur with and affect on each other. That is, three types of phenomena may be considered each to result from peculiar speech modes of the speaker, while four may be considered to result from a common speech mode.

3.1. Peculiarity of DA

Among these seven types of phenomena, DA does not co-occur with the other phenomena. No copula or interjectory particle is added, for example by saying in a gently rising tone without lexical accent something such as "??Emi no o-tete da ne tabechau zoo" ("I'm going to eat your hand!"). (Hereinafter, double question marks "??" at the start of the sentence indicate that the sentence is an unnatural expression.)

3.2. Peculiarity of PPP

The PPP also does not co-occur with the other phenomena. For example, the sentence "Itta yo, chan to kare ni" is not spoken in a gently rising tone without lexical accent or spoken with a copula or interjectory particle added ("??Itta yo, chan to da ne, kare ni saa.")

3.3. Peculiarity of HF

HF does not co-occur with other phoneme phenomena (i.e., DA or FLI). The possibility of its co-occurrence with non-phoneme phenomena (i.e., PPP, OC, OI, or CBP) relates to the details of what is described as "speakership" [13] in this paper.

If the speaker is an "animator" merely reading something given to him or her, he or she may pronounce each character individually with a high pitch accent on the first mora—that is, HF may co-occur—in a sentence with a PPP ("Itta yo, chan to kare ni"), a phrase in which a copula or interjectory particle occurs ("Shikamo da ne"), or a phrase in which CBP occurs ("kozo kaikaku, u-wo"). However, if the speaker is the "author" choosing his or her own words, then co-occurrence with these phenomena is not possible.

3.4. Interrelation between other phenomena

Unlike the above three types of phenomena, the remaining four types may co-occur and affect each other in complex ways. I shall begin to show this by describing the relationship between OC and OI.

OC tends to make OI easier. To be more concrete, "zo" and "ze" tend to be natural at the end of non-predicate phrase only with copula. For example, "shikamo da zo" and "shikamo da ze" are natural unlike "??shikamo zo" and "??shikamo ze". (We might be able to say that "shikamo da zo" and "shikamo da ze" are sentences to some degree. However this does not mean that they are not phrases at all. One reason for this is that "ze" and "zo" in "shikamo da zo" and "shikamo da ze" bear a prosodic restriction which are not found for them in the end of predicate phrase. That is to say, "ze" and "zo" in "shikamo da zo" and "shikamo da ze" are necessarily pronounced in rising intonation but never in "FLI".) The variety of interjectory particles at the end of non-predicate phrase still increases when we add the past particle "ta" to the copula, as in "tookyoo kara da-tta kashira" and "(tashika) tookyoo kara da-tta wa" (cf. "?? tookyoo kara kashira" "?? tookyoo kara wa"). And "wa" at the end of non-predicate phrase is uttered in rising intonation. Another example of increase of naturalness by additing "ta" is some unnatural phrases with the particle "ka" at the end of non-predicate phrase: "?tookyoo kara ka" (cf. "doko kara ka") vs. "tookyoo kara da-tta ka"

OI can make non-predicate phrases more natural, as in "soreo desune" (cf. "??soreo desu"). More striking is the case with the complex copula "da-ttadesu", as in "kare to da-tta desu kane" (cf. "??kare to da-tta desu"). However this effect of interjectory particles can be seen only when OC realizes.

We can see still more relationship between the four phenomena. This will be discussed in practical terms below, looking chiefly at the phenomenon of FLI. First we will look at the relationship between FLI, OC, and OI.

When no copula or interjectory particle appears at the end of a phrase, both returned FLI ("kare ga" ("he . . ."), "dakara" ("because . . ."); HLH) and unreturned FLI ("kare ga(a)," "dakara(a); HLHL) are possible.

When a copula but no interjectory particle appears at the end of a phrase, while returned FLI is not possible unreturned FLI may occur for a particle ("kare ga da"; HLHL). After all, unlike the way the copula of a predicate phrase may have a high tone (the "da" in "Tokyo da" is High, while the "desu" in "Tokyo desu" is High-Low), the copula of a non-predicate phrase always is low and is not subject to FLI. This is similar to the way a quotation marker "to" spoken to oneself as a separator when composing a sentence, as in "'Bunsetsu matsubi ni' to, 'kopyura ga' to, 'arawareru ga' to, . . ." ("'at the end of a phrase,' and . . . 'a copula,' and . . . 'appears, but, . . . ").

When no copula but only an interjectory particle appears at the end of a phrase, both unreturned FLI ("da kedo ne" ["that's true, but"; HLLH) and returned FLI ("da kedo ne(e)"; HLLHL) are possible.

When both a copula and an interjectory particle appear at the end of a phrase, FLI may occur for the part immediately preceding the copula or for the interjectory particle immediately following it. That is, it may occur up to two times in a single phrase ("kare ga da ne(e)"; HLHLHL). While only unreturned FLI may occur for the part immediately preceding the copula ("??kare ga(a) da ne(e)"; HLH(L)LHL), both returned FLI and unreturned FLI are possible for an interjectory particle.

Next, let's look at the relationship between combination of brealing and prolongation and continuation and the other phenomena. Since as described above in Section 2.6 CBP and continuation is used in official situations by adult characters who have authority, when considering the possibility of co-occurrence with this halting we must look only at copula such as "desu" and "da" and interjectory particles such as "ne" and "na." However, it is hard to judge whether "ee"and "aa"in "sore o da ne, ee"and "sore o desu na, aa" are part of this halting or are merely the fillers "ee"and "aa," or if there may be instances of both cases. That is, the possibility of co-occurrence of CBP and OC or OI is unclear.

However, it is clear that co-occurrence of CBP and FLI is possible, and what's more these two phenomena affect each other as shown below.

When CBP occurs at the end of a noun (“koozookaikaku, uuno”), both returned and unreturned FLI are possible for the end of the phrase (“koozookaikaku, uuno”; LHHHHLLL, L-H; “koozookaikaku, uuno(o)”; LHHHHLLL, L-HL). The extended part in CBP is simply a continuation of the immediately preceding sound, so that if the immediately preceding sound is high (“kaikaku”; LHHH), the extended part also will be high (“kaikaku, uuno(o)”; LHHH, H-Ultra High(-L)).

When CBP occurs at the end of a phrase (“koozookaikaku no, oo”), while again both returned and unreturned FLI are possible (“koozookaikaku no(o), oo; LHHHHLLLH(L), L-), the extended part is not subject to the FLI, so that no matter how high the tone of the immediately preceding sound the extended part always will be low.

3.5. Four types of speech consciousness

We have grouped the seven types of phenomena into four categories based on the possibility of co-occurrence between phenomena. These four categories can be understood as differences in speaking mode.

First of all, HF can be considered a phenomenon that occurs when the speaker is pronouncing characters as a list of characters without being conscious of their meaning.

Also, DA can be considered a phenomenon that occurs at the sentence level when the speaker is conscious of the entire sentence, since a single intonation is expressed for the entire sentence. The speaker is conscious of a strong feeling connected to this intonation (i.e., a joking threat if the intonation is gently rising).

PPP also can be considered a phenomenon that occurs at the sentence level when the speaker is conscious of the entire sentence, since it manipulates the order of phrases within the sentence. However, in the case of preposed predicate the speaker is not conscious of a particularly strong feeling.

The four phenomena of OC, OI, FLI, and CBP occur when the speaker is conscious of the smaller units of individual phrases rather than the entire sentence. For this reason all the more, they may co-occur and affect each other.

4. Conclusion

By looking at seven phenomena in spoken Japanese, focusing on the relations between phenomena, this paper grouped the speaker’s speaking mode into four categories. These four categories are (i) when the speaker is conscious of the sentence as a whole and is conscious of a strong feeling connected to a specific intonation, (ii) when the speaker is conscious of the sentence as a whole but is not conscious of such a strong feeling, (iii) when the speaker’s consciousness is at the phrase level, and (iv) when the speaker is conscious only of the characters, without being conscious of their meanings.

While past studies of grammar and prosody have concentrated their conditions on category (ii), in fact there are various other types of speech consciousness, and the form of speech varies with these types. In particular, if we admit that Japanese speech often takes place in units of phrases, then perhaps we should turn our observation to category (iii) as well.

This paper has made it clear that it is only in category (iii) that a copula, interjectory particle, FLI, or CBP may occur within a phrase, and in doing so it has showed that in this sense the structure of a phrase varies with the speech consciousness of the speaker. We also have observed the complexity of the relationship between the four phenomena in the case of category (iii). In order to unravel this complexity, there probably is a need to further deepen our understanding of the structure of the phrase in the future.

Stability in perceiving non-native segmental length contrasts

Yuki Asano

Department of Linguistics, University of Konstanz, Konstanz, Germany

yuki.asano@uni-konstanz.de

Abstract

Previous studies have demonstrated that listeners show high sensitivity in discriminating non-native segmental length contrasts thanks to auditory memory [1, 2]. We tested the limits of discriminating Japanese consonantal length contrasts with three groups of listeners (German learners of Japanese, German non-learners and Japanese natives) under increasing task demands. We increased memory load through a longer inter-stimulus interval (= ISI) (2500ms vs. 300ms) and added psycho-phonetic complexity (trials with task-irrelevant pitch falls that occurred simultaneously with the consonant vs. with monotonous pitch).

Results showed very good discrimination in all groups when the task demands were the lowest. With increasing task demands, only the non-natives' discrimination abilities decreased: non-learners were strongly affected by both ISI and pitch, while learners only by pitch. The psycho-phonetic complexity of the stimuli had a stronger impact on performance than the increased memory load.

Our findings suggest that L2 learners can establish novel phonological representations, but the ability to use them can be applied only under favourable listening conditions with no distracting acoustic information. The non-native listeners' reduced sensitivity under increasing task demands appears to be the reason why even advanced learners still face difficulties in natural learning situations.

Index Terms: task demands, discrimination, non-native length contrast, Japanese, German, geminate

1. Introduction

The discrimination of non-native length contrasts is expected to be difficult for L2 listeners when such contrasts do not exist in an L2 lexicon (theoretical supports for segmental contrasts see e.g. [3, 4]). Indeed, better performances have been oft found in L1 listeners rather than in L2 listeners [5, 1, 6]. At the same time however, despite this prediction, even non-native listeners have occasionally been reported to discriminate non-native prosodic contrasts fairly better than expected, given the lacking L2 phonological category in a listeners' L1. Hayes and Masuda [1] and Wilson *et. al* [2] report that even non-learners who have no consonantal length contrasts in their L1 could discriminate them without any exposure to the L2, by simply relying on auditory memory [7] and absolute durations [8, 2]. We postulate that these findings do not contradict each other, but do relate to task demands.

Under challenging situations, speech perception becomes more demanding. This is because the listener's cognitive load, operationalized as attention control (efficient attention shift among foregrounding and backgrounding of task-relevant and -irrelevant information [9]) and memory load becomes higher in such situations (e.g. [10, 11]). That appears to be all the more true when it comes to L2 perception. Previous studies show that the difficulty of listening to speech in noise or with greater talker variability is more exacerbated in L2 perception when compared to L1 perception [12, 13, 14, 15]. Given that the cognitive resources in L2 speech processing are fewer due to reduced L2 proficiency in comparison to native speakers [12], L2 perception is expected to be more "vulnerable" under such demanding listening conditions.

Werker and Logan [16] for instance show a performance decrease in the L2 listeners' discrimination of non-native segmental contrasts once an ISI becomes longer. ISI is known to increase task demands affecting the memory load (the longer the higher) and involving different levels of speech processing (the longer the more higher phonological perception) [17, 18, 19, 7, 20, 16]. Their findings suggest that L2 listeners had difficulties in discriminating non-native segmental contrasts once memory load increased and the processing tapped into the phonological one. We will investigate non-native listeners' limitations in discriminating non-native segmental *length* contrasts (and not segmental contrasts) under increasing task demands by increasing ISI [16] and by adding another dimension of task demands, psycho-phonetic complexity relating to attention control.

A discrimination task is a suitable method to investigate said issue, because it appears to require low task demands under a certain condition (see the aforementioned fairly good non-native performance) and it is therefore easy to enhance task demands in other conditions. In the current study, we conducted a speeded same-different-task to discriminate consonantal length contrasts testing Japanese natives, German learners and non-learners. Consonantal length is lexically contrastive in Japanese, but not in German. We expect therefore that the discrimination of consonantal length contrasts will be exacerbated to a greater extent only for German learners and even more for German non-learners under increasing task demands. Increasing task demands in our study are defined along two dimensions: attention control through psycho-phonetic complexity of the stimuli (e.g. [9, 21]) and memory load (e.g. [22]), the capacity to hold memory for a limited period of time.

psycho-phonetic complexity was increased by adding a task-irrelevant pitch movement. We built two stimuli conditions, one with pitch falls that occurred simultaneously with the consonant and the other with flat (namely monotonous) pitch. Attention control in the former condition is expected to be higher, because ignoring the task-irrelevant pitch movement is required in this condition. In case listeners cannot ignore it, they need to process both pitch and length simultaneously in the consonantal length contrast. In the flat pitch condition, listeners have one prosodic cue less to process (only duration). In case of an unsuccessful attention control, the trials with a falling pitch are expected to become psycho-phonetically more complex and more difficult for the discrimination of consonantal length contrasts than those with a flat pitch.

Previous studies consistently report that the complexity of speech perception in a bad speech quality or in unfavourable circumstances (e.g. in noise) impairs successful speech perception [10, 11, 23] and that is more the case for L2 perception [12, 13, 14]. It may be assumed that L2 listeners' are less successful in ignoring or shutting down the task-irrelevant information, e.g. noise in background. In our study we therefore hypothesize that the psycho-phonetic complexity of the stimuli constitutes is an impediment to a greater extent for L2 listeners than for L1 listeners, because the former are less likely to ignore the task-irrelevant pitch movement. Moreover, this additional falling pitch movement mirrors the phonetic form of a Japanese lexical falling pitch accent. The study will therefore contribute to understanding the L2 perception of a language with lexical tone or pitch accent.

The other dimension, memory load, was manipulated by increasing the duration of ISI (in one condition 300ms and in another condition 2500ms). In order to eliminate the risk of backward masking, ISI should be longer than 250ms [17, 24, 25]. Around 250ms after the offset of a sound, information is recognized at the sensory level, but is not yet identified or categorized [26]. The discrimination ability increases rapidly between 100 and 500ms and falls gradually as the ISI increases further [17, 7, 20]. The decrease after 500ms may be interpreted as the effect of gradually decaying auditory information in short-term memory. In order to test the acoustic comparison of successive stimuli without risking a backwards masking effect, we decided to use 300ms in one condition (slightly longer than 250ms) to ensure the acoustic trace was available. Then, it is claimed that this uncategorized acoustic information is maintained for a while (approximately 2000ms) in the precategorical acoustic storage [26] or in the short-term phonological storage as an auditory image [27, 28]. To keep our experiment to a duration that would not cause the participants to diminish their concentration or motivation, but at the same time to make sure that the the processing taps into the categorical level after 2000ms [27, 28, 26], we decided to use 2500ms as the long ISI.

At the segmental level, numerous studies have investigated the effect of the durations of ISIs on the discrimination of non-native *segmental* contrasts. With a short ISI with which researchers hypothesize that the lexical knowledge or phonological category is not consulted, no difference between L1 and L2 listeners was found. When the ISI became long, however, the L1 listeners' performance surpassed the L2 listeners' one. No study has been carried out so far that explores the discrimination of non-native *segmental length* contrasts by varying ISIs. We assume that segmental length contrasts are perceived relatively in a larger unit in relation to the adjacent words than segmental contrasts. Therefore, it might be more difficult to discriminate two stimuli with a segmental length contrast by directly relying only on auditory memory.

2. Experiment

2.1. Methods

2.1.1. Participants

Twenty-four native Japanese participants (henceforth= JNs, 10 male, 20-31 years), 24 native German who were not learning Japanese (= non-learners, henceforth= GNs, 8 male, 19-30 years) and 48 German learners of Japanese (henceforth= GLs, 30 male, 20-34 years) took part for a small fee. They were unaware of the purpose of the experiment. None of the learners had prior training in Japanese phonology.

2.1.2. Materials

We used disyllabic triplets that differed segmentally only in the length of the first vowel or in the length of the second consonant (e.g., [pɯnɯ],[pɯːnɯ], [pɯnːɯ]). Twenty-one triplets were evaluated in a pretest with Japanese and German native listeners (different from those of the main experiment) to select only stimuli that did not activate a word via phonological analogy. Participants were presented with one stimulus at a time and were required to write down the first word coming to their mind. We analysed the responses of 24 Japanese natives and 24 German natives separately. From there, six non-word triplets with the lowest association strength in both groups were selected (word association rate between 29.8 % and 45.3%, mean = 34.5%, while the one of all 21 triplets ranged between 29.8% and 100.0%, mean = 52.3%). The selected stimuli differed in manner of articulation and voicing of the medial consonant (= phon), *punu, gunu, gupu, gubu, zusu, sufu*. The materials were recorded by a female speaker of Japanese in two pitch conditions; high flat pitch and falling pitch (with a pitch fall during the medial consonant pitch tracks, see Figure 1). Each stimulus was recorded six times in order to have different tokens of the same type (N = 216). To ensure the same pitch between the two stimuli presented together (= A and X), the pitch was manipulated by using a method which is based on the representation of F_0 contours with B-splines [29] and on a smooth warping of the time axis allowing us to move selected time boundaries to desired positions (see [30]). More specifically 6 tokens of each triplets of a given phon (thus N = 18 for each phon) realized in the same pitch pattern were aligned on the average pitch across tokens (in the flat pitch: average = 1.3 semitones, range = 1.0 – 1.6 semitones; in the falling pitch: average = 13.0 semitones, range = 10.5 –16.4 semitones). Finally, a female native speaker of Japanese and a male native speaker of German selected the most naturally sounding tokens as experimental items (for each phon, N = 3 for the stimuli with a long vowel or a long consonant, N = 4 for the stimuli with short vowels and consonants). There was no disagreement on the decisions.

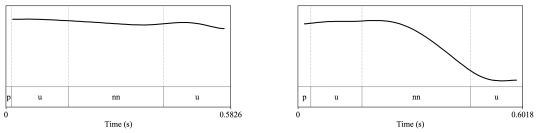

Figure 1: *Pitch track of geminate stimuli in the flat and falling pitch condition. F_0 range is shown between 100 and 350 Hz.*

To verify the durational differences of the selected stimuli, mean durations from the three different tokens of the respective long and short consonants and vowels were analyzed. A linear mixed effects regression model with the critical vowel or consonant *duration* as dependent measure and *pitch* (flat vs. falling), *segmental condition* (short vs. long vowel or consonant) as fixed factors and *phon* as a random factor including random slopes for the fixed factors [31, 32] showed a significant interaction for vowel contrasts ($p < 0.01$), but not for consonantal contrasts ($p > 0.1$). Then we analyzed the durations in the flat and falling pitch conditions separately for vocalic contrasts. Results of paired t-tests showed that, on average, long vowels in the flat pitch condition were 3.3 times longer than short vowels ($t(5) = 20.0$, $p < 0.001$) and those in the falling pitch condition were 3.0 times longer ($t(5) = 28.1$, $p < 0.001$). For consonant contrasts, we analyzed the durations in the flat

and falling pitch conditions together. Results of paired t-tests showed that geminates were on average 3.2 times longer than singleton consonants in the flat pitch condition ($t(10) = 25$, $p < 0.001$). These duration measurements ensured that the acoustic criteria for the length distinction in vowels and consonants were met (ratio for Japanese vowels was approximately 3.2:1, [33] and for consonants 3.2:1 [34, 35]).

To compare the spectral quality for long and short vowels /u:/ and /u/, the first and second formants at the midpoint of the vowel were automatically extracted. A linear mixed effects regression model with *formant* as dependent measure and *pitch* (flat vs. falling), *formant condition* (F1 vs. F2) as fixed factors and *phon* as a random factor including random slopes for the fixed factors [31, 32] showed that an interaction approached significance ($p = 0.07$). Results of paired t-tests separately in the two pitch conditions showed no difference in F1 nor in F2 (p-values were overall > 0.15). On average, F1 was 501.3 Hz for long vowels and 484.8 Hz for short vowels in the flat pitch condition and 467.9 Hz for long vowels and 429.9 Hz for short vowels in the falling pitch condition. F2 was 1499.0 Hz for long vowels and 1530.8 Hz for short vowels in the flat pitch condition and 1510.0 Hz for long vowels and 1495.9 Hz for short vowels in the falling pitch condition.

2.1.3. Procedures

A speeded AX-task was used to test the subjects' sensitivity for consonantal length contrasts. One base list was assembled by presenting all possible pairings of the stimuli (N = 84). The short ISI was 300ms lSI (session 1) and the long one 2500ms lSI (session 2). In both sessions, the intertrial-interval was 1000ms. Each trial began with a beep of 44100 Hz (500ms). No feedback was provided during the experiment. Each session began with 10 training trials using the phones that were not used as the experimental ones (*guna* and *puna*) followed by a pause before the experimental session started. The test lasted approximately 20 minutes. The order of presentation was automatically randomized using *Presentation* (Neurobehavioral Systems).

2.2. Results

2.2.1. Sensitivity to contrast: d' scores analyses

Participants' sensitivity to the contrasts was calculated using d' [36]. We calculated d' scores for each participant for each of the consonantal and vocalic length contrasts, flat and falling pitch as well as short and long ISI. We normalized them by subtracting those for vocalic length contrasts (as baseline) from those for consonantal length contrasts (note that there were no differences in the d' scores for vocalic length contrasts across *language groups*, overall $p > 0.2$). The value of 0 in the plot means that the d' for consonantal and vocalic length contrasts were almost the same. A linear mixed effects regression model with *d' scores* as dependent measure and *language groups*, *pitch* (flat vs. falling), *ISI* (short vs. long) as fixed factors and *participants* as a random factor including random slopes for the fixed factors [31, 32] showed a significant three-way interaction ($p < 0.003$). To investigate the nature of this interaction, the data were split by *pitch*. In the flat pitch condition, an interaction was found between *language group* and *ISI* (GNs' d' scores decreased in the long ISI condition, but the d' scores of the other two groups did not, $p < 0.03$). JNs' and GLs' d' scores did not differ from each other. In the falling pitch condition, a main effect of *language groups* was found (the JNs' d' scores higher than the GLs' ones, $p < 0.01$, the GLs' ones higher than the GNs' ones, $p< 0.01$); see Figure 2. In order to compare the d' scores between the two plots, we analyzed the d' scores for both pitch conditions in each *language groups*. JNs' d' scores were not affected by *pitch* or *ISI* (overall $p > 0.7$). In the GLs' data, the effect of *pitch* approached significance (flat $>$ falling, $p = 0.09$). The GNs' data showed a significant interaction between *pitch* and *ISI* (d' scores only in the flat pitch condition decreased in the long ISI condition, $p < 0.03$).

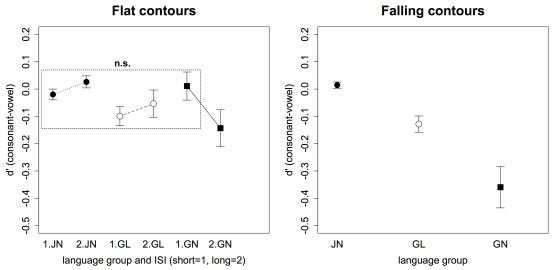

Figure 2: *Results of the normalized d' scores*

2.2.2. Processing difficulty: reaction time analyses

The reaction time (RT) analyses were performed to investigate task difficulty for the discrimination of *length conditions* (vowel vs. consonant) [37, 38]. We only analysed RTs in trials with different pairs. To account for participant-specific RT-differences, we normalized the raw RT data in the following way: We discarded RTs longer than 2000ms and aggregated the data for each *participant*, *pitch*, *length condition* and *ISI*. Then, the averaged RTs for vocalic length contrasts were subtracted from those for consonantal length contrasts.

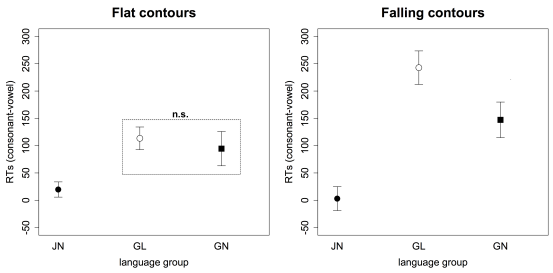

Figure 3: *Results of the normalized RTs*

In the following, we will describe the results of a linear mixed effects regression model with normalized *RTs* as dependent variable, *language groups*, *pitch* and *ISI* as fixed factors and *participants* as a random factor including random slopes for the fixed factors. Results showed a main effect of *language groups* (JNs faster than other two groups, $p < 0.001$) and an interaction between them (only GLs slower in the falling condition than JNs and GNs were, $p < 0.03$); see Figure 3. In order to compare the data between the two plots in Figure 3, we further analysed the RTs in both two pitch conditions in each *language groups* separately (*pitch* as a fixed factor and *participants* as a random factor including random slopes for the fixed factor). The analysis revealed that the JNs' and GNs' RTs in the two pitch conditions did not differ ($p > 0.9$, $p > 0.2$ respectably), while those of GLs did ($p < 0.001$).

3. Discussion

To investigate the (in)stability of the discrimination of non-native prosodic contrasts, we conducted discrimination tasks with various conditions that may impair the processing.

We found a consistent effect of pitch on the discrimination of consonantal length contrasts in the d' score analyses: the discrimination of consonantal length contrasts presented in falling pitch was more difficult for learners than in flat pitch and this especially for non-learners. The findings consistently confirm that the psycho-phonetic complexity affected only the non-natives' discrimination ability, indicating the non-natives' decreasing attention control along the increasing psycho-phonetic complexity. Additionally, the difference between the learners' and the non-learners' d' scores suggests a positive L2 learning effect in establishing higher attention control and in obtaining a more stable L2 processing of non-native prosodic contrasts.

The RT analyses also showed longer RTs in the learners' group when the pitch was falling. Contrary to the results of the d' scores, the non-learners' RTs did not change in both pitch conditions, suggesting that the psycho-phonetic complexity did not impact on a *perceivable* task difficulty for non-learners just as for native listeners. In this way, however, the learners' performance regarding the RTs became worse than the non-learners' one in the falling pitch condition. Such a similar tendency was also found in Altmann *et al.* [5] that investigated the non-native (= German) discrimination ability of Italian consonantal length contrasts. They found higher d' scores for learners than non-learners, but no significant difference between the learners' and non-learners' RTs. We postulate that learners and non-learners applied different strategies for the task. When the stimuli became psycho-phonetically more complex, the direct auditory comparison of the stimuli became more difficult. Therefore listeners started to rely on phonological knowledge. Such learners' indecisiveness demonstrates that the learners already had a degree of access to a newly forming category and thus needed to decide between two possible mapping representations. Non-learners on the contrary, required a shorter time for the decision without the "selection" processing. Another possible interpretation would be the following: this difference between the learners and non-learners was found to be independent from the two ISI conditions, suggesting a direct co-activation or mapping of phonological representations from acoustic speech signals [39]. Here again, since learners established L2 phonological representations, they needed more time to select one between the L1 and the L2 phonological representations, but non-learners did not. We assume that this difference was found only in the increasing psycho-phonetic complexity, because this temporal effect of the selection was relatively small. In future experiments further attention needs to be paid to the underlying mechanisms for non-learners and learners in future experiments.

As for the other dimension of increasing task demands, memory load, native-like good performance by learners and even non-learners was observed only in the condition with the lowest task demands (short ISI and flat pitch). In the long ISI condition, however, the non-learners' d' scores decreased. Such decrease is the evidence that they had difficulties in discriminating non-native consonantal length contrasts, when the memory load increased and once the processing tapped into the phonological one. Learners were not affected by the increasing memory load just as Japanese natives were not. This effect of memory load was found in a so to say "greenhouse condition" for the consonantal length contrasts, when it was not disturbed with another prosodic cue, pitch, but the processing only dealt with length contrast without any effects of pitch. Once pitch came into play, the effect vanished. Recall that the d' scores in the falling pitch condition were generally lower than those in the flat pitch condition in both the learners' and the non-learners' group, while those of native listeners did not change between the two pitch conditions. Therefore, the reason for not finding the temporal decrease in the falling pitch condition may be explained with a floor effect.

Taken together, the effect of psycho-phonetic complexity was stronger than the one of memory load. Both learners and non-learners were distracted by the stimuli with greater psycho-phonetic complexity, because their attention control became lower. As learners become more familiar with the situation, attention demands were eased and automatic processes developed [21]. Therefore, our finding suggests that learners, who even established the phonological representations of non-native consonantal length contrasts still were not successful in automatising the L2 speech processing fully.

The task demands controlled in our study may be translated into various distracting factors in our natural speech perception. Therefore, the performance decreases found in our study suggest the instability of the L2 perception under various task demands in our daily life. Moreover, the performance decrease due to the psycho-phonetic complexity suggests that the Japanese lexical pitch movement (e.g. a falling lexical pitch accent or an initial low [40]) makes the perception of non-native consonantal length contrasts more difficult.

4. Conclusions

We examined the discrimination of non-native consonantal length contrasts under increasing task demands. Even non-learners without any exposure to the L2 could discriminate them in the lowest task demands, simply by comparing two stimuli at the auditory level. However, such a reliance on the auditory comparison could not last long. Once the ISI became longer and memory load became higher, so that the auditory information began to be processed phonologically, their discrimination ability decreased and differed from the one by learners or native listeners. The learners' performance did not differ from the native listeners' one. This result suggests that the exposure to the L2 helped them to establish the phonological representations of non-native consonantal length contrasts. However, even learners who were not distracted by the increasing memory load could not overcome the performance decrease due to the increasing psycho-phonetic complexity of the stimuli. It was difficult for both learners and non-learners to ignore the task-irrelevant pitch and to focus on their attention only to the task-relevant information. The finding indicates the difficulty to automatise the L2 processing even after establishing or being exposed to the L2 categories. To summarize, the non-natives' performance was native-like good only under favourable listening conditions with no distracting acoustic information and with lower memory load.

In our natural listening situations, there are numerous distracting factors that might impair L2 perception. The overall decreases indicate why L2 perception remains difficult in the daily-life situations, despite the still successful exercise in L2 class room situations.

Abstract

The aim of this study was to investigate the relationship between compensatory shortening and coarticulation in German tense and lax vowels and to determine whether this relationship was influenced by prosodic accentuation. While previous studies focussed on temporal vowel reduction due to compensatory shortening, and often found conflicting results, our study extends previous results by including a formant analysis of spatial reduction in two types of compensatory shortening. Specifically, we tested for polysyllabic shortening (monosyllabic vs. disyllabic words) and incremental coda shortening (words with final singletons vs. final clusters). Speakers produced minimal pairs differing in vowel tensity in accented and deaccented contexts for both shortening conditions. Vowel duration was influenced primarily by vowel tensity as well as by accentual lengthening for tense but not lax vowels. While vowel duration was not affected by compensatory shortening, formant analyses revealed an effect of coda cluster for tense vowels as well as clear effects of accentuation and vowel tensity. There was no effect of polysyllabic shortening on formants.

Further to previous studies on compensatory shortening, these results reveal that compensatory shortening is not limited to temporal reduction, but can have an impact on vowel quality as well.

Index Terms: coarticulation, speech timing, compensatory shortening, accentual lengthening, target undershoot, sound change

1. Introduction

This study investigated the effects of two types of compensatory shortening on the acoustic duration and formant values of vowels in rhythmically strong syllables. Our general goal within a larger series of experiments is to better understand the relationship between prosodic weakening, coarticulation and sound change.

The first type of compensatory shortening we investigated, polysyllabic shortening, refers to the compression of a vowel spoken in a polysyllabic compared with a monosyllabic word. Thus, the vowel in English *sleep* is longer than the same vowel in English *sleepy* [1]. Polysyllabic shortening has been well-documented in Germanic languages such as English [1, 2, 3, 4, 5, 6], Dutch [7] and Swedish [8, 9, 10, 11, 12], although [13] found no evidence of polysyllabic shortening in a study of read speech in English.

The second type of compensatory shortening we investigated, incremental coda shortening, refers to the compression of a vowel spoken before a consonant cluster compared with a consonant singleton. [14] found acoustic shortening of vowels before consonant clusters in their study of three speakers of English, and [15] replicated these effects for obstruent clusters (but not for sonorant clusters in syllable-final position). A recent study on German by [16] found no results of incremental coda shortening in production, but they did find that listeners expected shorter vowel durations before complex clusters in a perception experiment.

Prior research has largely failed to establish the effect of accentuation on compensatory shortening (see [17]), in that studies have mostly examined stressed syllables or accented words only. In German, as in other Germanic languages, a word is accented when a pitch accent is associated with the rhythmically strongest syllable [18]. In addition to the f0 changes caused by a pitch accent and any adjacent boundary tones, pitch accented syllables in many Germanic languages are also hyperarticulated and produced with greater duration [19].

Thus, this study aimed to investigate vowel reduction and the extent to which compensatory shortening interacts with prosodic accentuation and vowel tensity. Based on previous studies, we had three main hypotheses for the durational analysis as well as analogous hypotheses for the formant analysis. Firstly, we expected acoustic vowel shortening and thus also vowel undershoot before coda clusters compared with coda singletons [14, 15] as well as in disyllabic compared with monosyllabic words [11, 20]. Secondly, we expected compensatory shortening and undershoot induced by this shortening to be more marked in accented than in deaccented contexts [4, 17, 21, 22]. Thirdly, we expected more shortening and hence more shortening-induced undershoot of tense than of lax vowels [4, 23, 24].

2. Method

2.1. Participants

Twenty-nine L1 speakers of Standard German (11 male, 18 female) were recorded at a sampling rate of 44 100 Hz in a sound-attenuated booth. Speakers had no known speech or language impairments and were paid for their participation.

2.2. Stimuli

We chose a tense-lax target vowel pair believed to vary mostly in quantity and only minimally in quality in order to study the effects of compensatory shortening. In German, tense vowels are phonologically long, while lax vowels are phonologically short, for example /ˈbiːtn̩/ (to offer) vs. /ˈbɪtn̩/ (to request). The German vowel that differs least in quality between its tense and lax versions is the open central /a/, which varies mainly in vowel height (F1), for example a lower F1 for lax *Kamm* /kam/ (comb) and a higher F1 for tense *kam* /kaːm/ (came) [23, 24]. [23, p341] claim that even the durational contrast is minimised in prosodically weak contexts. Our stimuli were real German words with

lax /a/ and tense /aː/. We restricted the target vowels to one consonantal context in order to avoid varying effects of CVC coarticulation. The target words were embedded in phrase-medial position in the carrier sentence *Anna hatte [target word] verstanden* (Anna understood [target word]) in order to avoid utterance or phrase-final lengthening.

	Cluster Shortening		
Lax Vowels	/zak/	/zakt/	/zaktə/
Tense Vowels	/zaːk/	/zaːkt/	/zaːktə/
		Polysyllabic Shortening	

Table 1: The 6 target words, spoken in both accented (A) and deaccented (U) contexts (= 12 target words).

A minimal pair paradigm was created using one consonantal context adjusted for Syllabicity (monosyllabic vs. disyllabic), Coda (final singleton vs. final cluster), Accentuation (accented vs. deaccented) and Vowel Tensity (tense vs. lax). The monosyllabic level of the Syllabicity condition overlapped with the cluster level of the Coda condition (see Table 1), leading to a total of 12 target items. Each speaker produced 10 repetitions of each item, leading to a total of 120 utterance tokens for each speaker (29 subjects x 120 utterances = 3 480 utterances). Filler words and sentences were also included to disguise the object of the experiment.

2.3. Procedure

The stimuli were presented and recorded in randomised order using SpeechRecorder software [25]. Participants were first presented with a question designed to elicit a narrow focus on the target word for the accented context and a broad focus for the deaccented context: either *WAS hatte Anna verstanden?* (WHAT did Anna understand?) or *WER hatte [target word] verstanden?* (WHO understood [target word]?). The target sentence was then presented with the accented word in capital letters. The experimenter asked subjects to repeat the sentence if they made a mistake (either segmentally or suprasegmentally).

Three subjects were eliminated from further analysis as they were unable to elicit the correct accentuation patterns of the stimuli. The remaining 26 speakers (9 males, 17 females; mean age 24 years) were included in the analysis.

The entire corpus was automatically segmented and labelled using the Munich Automatic Segmentation System [26] and corrected manually. During this procedure several rare cases of incorrect accentuation were discovered and removed from the database.

2.4. Analysis

For the durational analysis, the dependent variable was normalised vowel duration. We normalised the vowel durations by dividing the duration of each target vowel by the duration of each /a/ in the utterance-final word *verstanden* in order to control for changes in speech tempo throughout the experiment. *Verstanden* was chosen as it was considered least likely to be affected by the varying accentuation pattern, which was confirmed by a visual analysis of the data. The normalised vowel duration was then averaged per speaker and per condition.

For the formant analysis, the dependent variable was maximum F1 measured in Hz from the central third of the vowel. We calculated formants with a frame shift of 5 ms and a window length of 12.5 ms for female speakers and 20 ms for male speakers using Emu [27]. Formant errors were hand-corrected in Emu when necessary.

Both dependent variables were tested individually alongside within-subjects factors Vowel Tensity, Accentuation and Syllabicity (for the polysyllabic shortening analyses) or Coda (for the cluster shortening analyses) and random factor Speaker in a repeated measures ANOVA design using the `ez` package in `R` [28, 29].

3. Results

3.1. Cluster Shortening

For the cluster shortening condition, we compared the monosyllables with and without final clusters (the stimuli coloured light grey in Table 1). Disyllabic stimuli were excluded from analysis.

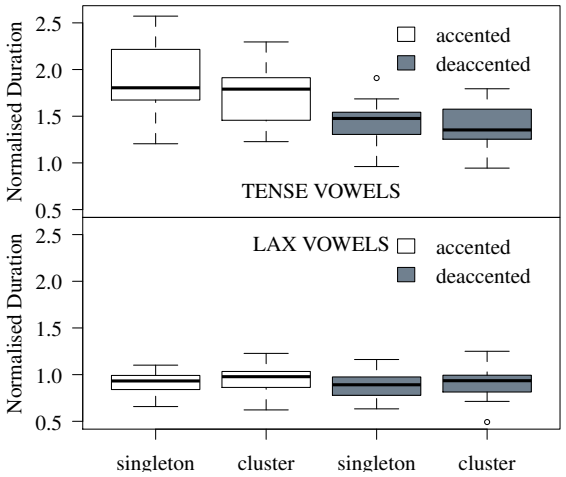

Figure 1: Effects of incremental coda shortening, accentuation and vowel tensity on normalised vowel duration

The durational analysis revealed main effects of both Vowel Tensity ($F[1, 25] = 278.7; p < .001$) (top vs. bottom of Figure 1) and Accentuation ($F[1, 25] = 54.6; p < .001$) (white vs. grey in Figure 1), but there was no effect of Coda on the normalised vowel duration. We found significant interactions between Vowel Tensity and Coda ($F[1, 25] = 6.3; p < .05$) and Vowel Tensity and Accentuation ($F[1, 25] = 82.2; p < .001$). Post-hoc Bonferroni-corrected t-tests revealed accentual lengthening of tense ($p < .001$) but not lax vowels. The post-hoc tests did not reveal the reason for the interaction between Vowel Tensity and Coda, but Figure 1 shows a slight tendency toward compensatory shortening of tense vowels which cannot be seen for lax vowels.

The formant analysis revealed main effects of Vowel Tensity ($F[1, 25] = 105.7; p < .001$) (black vs. grey in Figure 2), Accentuation ($F[1, 25] = 102.8; p < .001$) (solid vs. dashed in Figure 2) and Coda ($F[1, 25] = 5.8; p < .05$) on the maximum F1, with a significant interaction between Vowel Tensity and Coda ($F[1, 25] = 8.5; p < .01$) . Pairwise post-hoc comparisons for the Vowel Tensity vs. Coda interaction indicated that the effect of Coda on F1 is restricted to tense vowels only, although the effect is weak (see Figure 3).

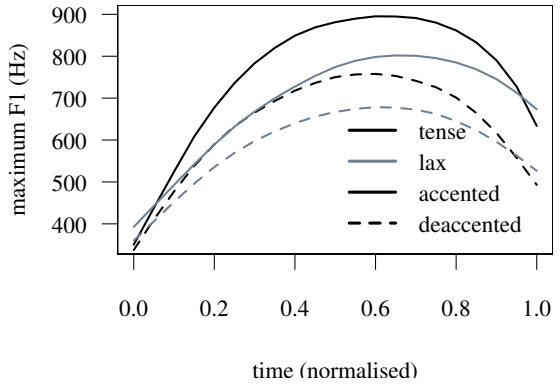

Figure 2: F1 trajectories (linear time-normalised) for the cluster shortening experiment as a function of vowel tensity and accentuation

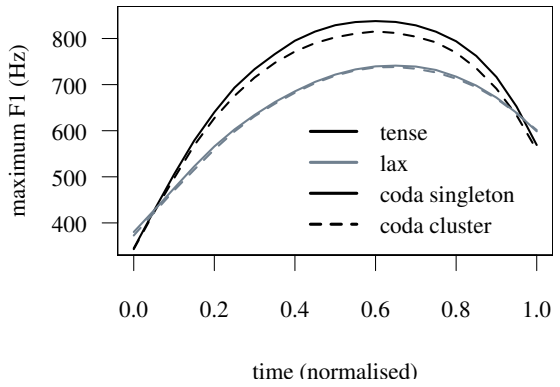

Figure 3: F1 trajectories (linear time-normalised) for the cluster shortening experiment as a function of vowel tensity and coda condition

3.2. Polysyllabic Shortening

For the polysyllabic shortening condition, we excluded all monosyllabic words with final singleton from the analysis and compared the monosyllabic and disyllabic words with clusters at the end of the first syllable (the stimuli coloured dark grey in Table 1).

While we found main effects of both Vowel Tensity ($F[1, 25] = 33.2; p < .001$) (top vs. bottom of Figure 4) and Accentuation ($F[1, 25] = 401.9; p < .001$) (white vs. grey in Figure 4), there was no effect of Syllabicity on the normalised vowel duration. We also found a significant interaction between Vowel Tensity and Accentuation ($F[1, 25] = 31.6; p < .001$). Post-hoc Bonferroni-corrected t-tests revealed a significant effect of accentual lengthening on tense vowels ($p < .001$), but not on lax vowels.

The F1 analysis found main effects of Vowel Tensity ($F[1, 25] = 100; p < .001$) (black vs. grey in Figure 5) and Accentuation ($F[1, 25] = 103.7; p < .001$) (solid vs. dashed in Figure 5), but not of Syllabicity. There was a significant interaction between Vowel Tensity and Accentuation ($F[1, 25] = 9.3; p < .01$). In view of Figure 5, this interaction is likely due to a slightly larger difference between tense and lax vowels in accented contexts than in deaccented contexts (see Figure 5).

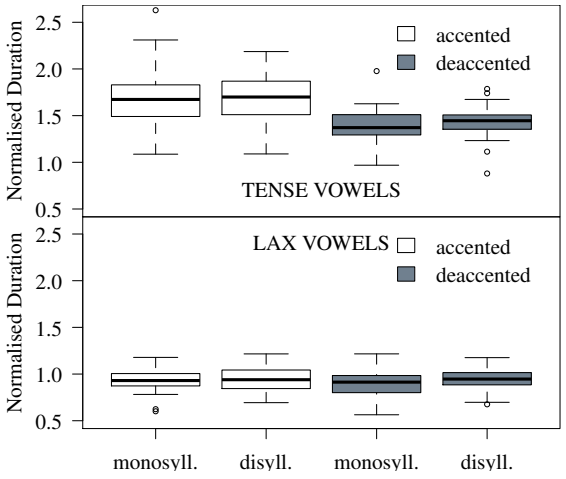

Figure 4: Effects of polysyllabic shortening, accentuation and vowel tensity on normalised vowel duration

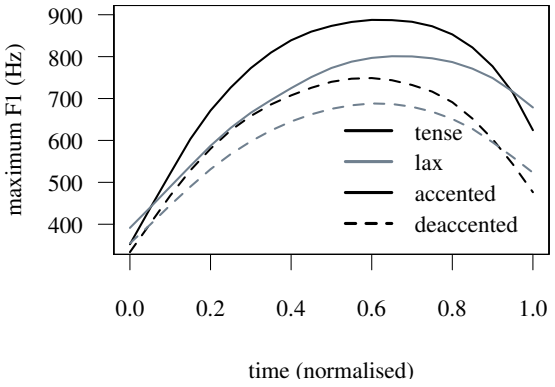

Figure 5: F1 trajectories (linear time-normalised) for the polysyllabic shortening experiment as a function of vowel tensity and accentuation

4. Discussion

We expected compensatory shortening and target undershoot of vowels before coda clusters (incremental coda shortening) and in disyllabic words (polysyllabic shortening), and for these effects to be more marked in accented than in deaccented words. In addition, we expected tense vowels to undergo more compensatory shortening and shortening-induced vowel reduction than lax vowels.

4.1. Vowel Tensity

We confirmed that the tense-lax distinction (at least of low vowels) is defined by both vowel quantity and quality in German.

The quantity distinction was maintained even in deaccented contexts, and there was accentual lengthening of tense but not lax vowels. In terms of quality, we found lower first formants in lax than in tense vowels and in deaccented tense vowels than in accented tense vowels (black vs. grey in Figures 2, 3 & 5), contrary to [24, p14]'s conclusion that "tense and lax low vowels [i.e. /a, aː/] in [Standard] German differ consistently only in duration, but not in formant structure". A clear distinction in F1 between tense and lax low vowels may be necessary because the

durational distinction between tense and lax vowels lessens (but is not neutralised) in deaccented contexts (see Figures 1 and 4; see also [23, 24]).

4.2. Accentuation

We found clear effects of accentual lengthening of tense but not lax vowels. In line with [30], who found larger jaw movements in stressed than in unstressed syllables, there was a significant effect of accentuation on the F1 of both tense and lax vowels, and this effect was slightly stronger for tense vowels (see also [23]). As a result, there is less difference in duration between tense and lax /aː/ and /a/ in deaccented contexts. In Figures 2 and 5, a large amount of overlap between tense and lax vowels is visible: /a/ has a higher first formant (indicating greater jaw opening and greater tensity) in the accented condition than /aː/ in the deaccented condition.

4.3. Cluster Shortening

Contrary to our hypothesis and some previous studies [14, 15], we found no effect of complex coda on the duration of the target vowel. Our findings thus match those of [16] and are compatible with the c-centre hypothesis [31], which predicts incremental onset shortening but not incremental coda shortening.

The conflicting results of incremental coda shortening emphasise the need to investigate whether shortening in fact induces other types of reduction. Indeed, we did find significant spatial reduction of F1 in tense vowels before complex clusters. That is, incremental coda shortening (at least in German) appears to induce F1 undershoot of primary-stressed tense vowels, even if there is no durational shortening. This provides support for our hypothesis that there is greater undershoot before clusters than before singletons, thus leading to a smaller difference between tense and lax vowels before coda clusters (see Figure 3).

There is no evidence for our hypothesis that undershoot is greater in accented than in deaccented contexts: that is, the degree of separation in F1 between tense and lax vowels before singletons or clusters is largely unaffected by accentuation. Thus, while accentuation does influence vowel quality and quantity, it does not interact with incremental coda shortening.

4.4. Polysyllabic Shortening

In this study, we found no effect of polysyllabic shortening on vowel duration. This result is contrary to the main body of research on polysyllabic shortening, but in line with [13], who found no polysyllabic shortening in connected speech. However, their study differed from others in that it was based on syllable shortening in stress groups rather than in polysyllabic words. In addition, they counted syllables with secondary stress as stressed syllables.

According to [4]'s incompressibility theory, "a vowel that is shortened by one rule becomes less compressible to additional shortening influences" [4, p1103]. As a result, one might argue that there was no polysyllabic shortening of the target vowel because both the monosyllabic and the disyllabic condition contained a final coda cluster, which can induce incremental coda shortening. However, as there was no effect of incremental coda shortening on vowel duration, it is unlikely that the final coda cluster prevented shortening of the target vowel in the disyllable compared with the monosyllable.

In addition, there was no effect of polysyllabic shortening on the first formant, which is known to be correlated with jaw opening. There is no evidence from our results that polysyllabic shortening induces greater durational compression in accented contexts than in deaccented contexts and in tense vowels than in lax vowels. As a result, there is no evidence from this study that polysyllabic shortening induces any type of vowel reduction, neither temporal nor spatial.

4.5. Implications for Sound Change

The results of this study show slightly less durational contrast between tense and lax vowels in deaccented contexts (white vs. grey in Figures 1 and 4) and a slight decrease in the quality contrast before coda clusters (see Figure 3). In general, there is a great amount of overlap in the first formant of accented lax vowels and deaccented tense vowels (see Figures 2 and 5).

If tense and lax vowels are more difficult to distinguish before clusters based on their vowel quality, this might be the reason the durational contrast between tense and lax vowels was maintained in our analysis of acoustic shortening before coda clusters. Alternatively, the tense-lax contrast may be diminishing in German [32], and this might be a context in which listeners could misperceive the vowel, leading to a mini sound change [33].

4.6. Outlook

In view of the above, there may be a greater risk of confusing /aː/ and /a/ before clusters, not because of acoustic shortening, but because of F1 undershoot. In order to determine how listeners parse this undershoot, we are now running perception experiments in which a synthetic vowel continuum is created and spliced into two contexts: /zaːk/-/zak/ and /zaːkt/-/zakt/. For the target vowel, we chose an ambiguous vowel duration (the mean of tense and lax tokens of a speaker) and varied only the height of the first formant. If listeners attribute vowel undershoot before coda clusters to compensatory shortening, we would expect a higher F1 at the category boundary for the continuum ending in coda cluster than the one ending in coda singleton. Alternatively, if listeners incorrectly attribute vowel undershoot before coda clusters to (lax) vowel quality, i.e. they are not aware of the effects of compensatory shortening on vowel quality, we would expect the continuum before coda singleton and the continuum before coda clusters to have the same category boundary.

5. Conclusions

This study examined the relationship between vowel tensity, accentuation and compensatory shortening and in particular how these factors affect vowel quantity and quality. At least for the vowel pair we tested, vowel tensity in German is clearly marked by both duration and quality. In addition, accentuation affects both duration and quality, but not equally for tense and lax vowels. This asymmetry leads to considerable overlap between tense and lax vowels. We found no effects of compensatory shortening on duration, but we did find F1 undershoot before coda clusters. Thus, the quality contrast is diminished before clusters. A perception experiment is being carried out to determine whether or not listeners correctly attribute cluster-induced vowel undershoot to its source. If not, this context could be a source of sound change.

The form and use of uptalk in Southern Californian English

Abstract

This study examines the phonetics, phonology and pragmatic function of uptalk, utterance-final rising pitch movements, as used in Southern Californian English. Twelve female and eleven male speakers were recorded in a variety of tasks. Instances of uptalk were coded for discourse function (statement, question, confirmation request, floor holding) based on context. The excursion of the pitch rise and the distance of the rise start from the onset of the utterance's last stressed vowel were also measured. Confirmation requests and floor holding showed variable realization. Questions, on the other hand, showed a rise that typically started within the stressed vowel and had a large pitch excursion, while uptalk "proper", i.e. uptalk used with statements, exhibited both a smaller pitch excursion and a later rise that often started after vowel offset. This pattern suggests that statements have a L* L-H% melody while questions have L* H-H%. Gender differences were also found: female speakers used uptalk more often than males, and showed greater pitch excursion and later alignment, all else being equal. Other social parameters, however, such as social class and linguistic background, did not affect the use of uptalk.

Index Terms: intonation, HRT, uptalk, English, sociolinguistics, gender

1. Introduction

Rising melodies used with statements, commonly referred to as *uptalk* or *high rise terminals* are common in many varieties of English. Here we use the term *uptalk* which better reflects the Southern Californian patterns that are the focus of our investigation. Research on uptalk in some varieties is quite extensive, but has often been impressionistic [1]. The varieties that have been most investigated include those spoken in Australia and New Zealand as well as UK varieties from Glasgow and Belfast [1]–[5] (and references therein).

These studies document that different tunes are used for uptalk across varieties. Thus, [1] report that Australian uptalk is realized as either L* H-H% or H* H-H%. For Glasgow, L*H H-L% is proposed for the "rise-plateau-slump" type of uptalk, with suspension of the rule that in other English varieties upsteps a L% after a H- phrase accent [2]. In [1], New Zealand uptalk is analyzed as reflecting two main patterns, LH* H-H% and L* H-H% (based on [3]), but a newer study suggests that New Zealand English may exhibit change in progress with respect to uptalk [4].

In addition to differences in form, uptalk across varieties of English is used for different purposes. Thus, [1] report that in Australian English upstep is used both with questions and declarative statements; upstepped statements are particularly frequent when the speaker wishes to hold the floor. This leads [1] to suggest that the intonational difference between statements and questions and that between statements and continuation is neutralized in Australian English. New Zealand English also uses uptalk for both statements and questions but the tunes used for each function are becoming increasingly distinct [4]. Research on Glasgow and Belfast English, e.g., [2] and [5], focused on form rather than function, but recent research suggests that uptalk, in Belfast at least, may have its origins in list intonation [6].

One of the varieties that is stereotypically known as exhibiting use of uptalk is Californian English, particularly the varieties spoken in the south (henceforth *SoCal*). The use of uptalk in SoCal is often referred to as "valley girl speak" and is often assumed to be a feature of younger females only, though no studies exist, to our knowledge, confirming or refuting this general lay perception.

Here we present data from SoCal English which show that the use of uptalk is widespread in this variety and exhibits gender-related variation. We further show that SoCal uptalk tunes are different from those reported for other varieties of English, and that speakers retain systematic differences between uptalk used in statements and other types of uptalk, such as pitch rises used with questions. Differences apply both to the tunes employed and to the scaling of the rise.

2. Methods

2.1. Speakers

Twenty-three speakers were recorded for the study, eleven male and twelve female. They were all native speakers of SoCal English, from San Diego (N = 7), Orange (N = 6), Los Angeles (N = 8), and Riverside (N = 2) counties. Fifteen were monolingual, while the other eight reported being bilingual in English and one of the following languages: Vietnamese (N = 3), Japanese (N = 1), Armenian (N = 1), Assyrian (N = 1), Spanish (N = 1), and Cantonese (N = 1). The speakers' ethnic backgrounds varied: twelve self-identified as Asian, six as Hispanic and five as White.

The MacArthur Scale of Subjective Social Status (cf. [7], [8]) was used to determine the speakers' socioeconomic status or *SEC*, a rather fluid concept in California. Participants found the use of the scale easy and intuitive. They were classed into three groups based on their responses: lower (rungs 1-4, N = 4), middle (rungs 5-7, N = 13) and upper (rungs 7-10, N = 6).

2.2. Materials, Tasks and Procedures

Recordings took place in the recording studio of the UCSD Phonetics Lab, using an AD converter at 48 KHz and 16-bit quantization. Four types of data were collected from each speaker: (a) map task; (b1) reading of the transcript of a popular sitcom scene; (b2) retelling of the sitcom scene; (c) controlled materials consisting of isolated questions and statements. For the first 17 participants, tasks were presented in the following order: (c), (b), (a). (For task (b), the retelling of the clip always followed the reading of the transcript.) To control for possible order effects, the order of tasks was

counterbalanced for the other recordings and each participant was randomly assigned to one of three possible orders (Latin square design): abc, bca, or cab. However, given that the data consist largely of spontaneous speech it is unlikely that order could have severely biased speaker productions with respect to uptalk.

For the map task, maps with local (or local sounding) landmarks were designed as illustrated in Figure 1. In the map task, the participants acted as leaders with the follower being either the first author or an undergraduate research assistant (both females and native SoCal speakers). For task (b1), a scene from either *Scrubs* or *How I met your mother* was used; the show chosen was the one the participant was less familiar with. Lack of familiarity was sought so that speakers would not imitate the actors' accents. The scene was muted and participants were given a transcript of the dialogue while they watched the clip. When they were ready, they chose which character they were most comfortable reading from, and participated in reading aloud the transcript in a dialogue with the experimenter. In task (b2), participants had to retell the same scene in their own words. For task (c), the participants read aloud a list of 49 sentences. These were statements and questions constructed for the study. In these sentences, the number of syllables and position of stress was controlled in order to examine the realization of specific tonal events; see (1) for an illustration. Here we report on the results from tasks (a) and (b2).

b. *Did Annabelle and Melinda eat the lime?*

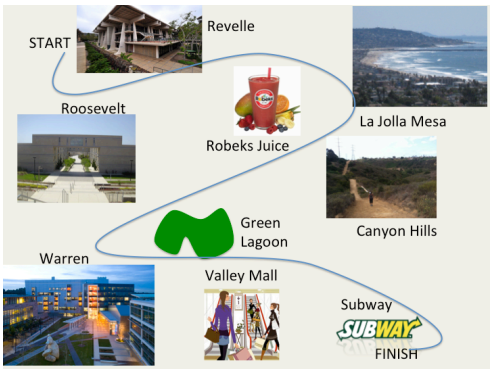

Figure 1: *The Instruction Giver's map used in the map task.*

2.3. Analysis and Measurements

The analysis involved both a categorization of each instance of uptalk in terms of its discourse function and acoustic measurements with respect to the alignment and scaling of the pitch rise associated with each uptalk token.

Specifically, instances of uptalk were classed in one of four discourse functions: question, statement, holding the floor, and confirmation request. A token was considered to be a question when it was syntactically marked as such, for example by showing inversion. Confirmation requests were indirect questions: they were not syntactically questions, but the context and interlocutor response indicated that the speaker was indirectly asking if their interlocutor was paying attention, agreed or understood. Holding the floor was defined as an utterance indicating that the speaker did not intend to cede the floor, in that s/he continued talking with either a minimal or no pause and was not interrupted by their interlocutor. All other instances of uptalk were identified as statements. These were regular declaratives for which no other discourse function was apparent from context; e.g., such utterances did not elicit information from the interlocutor. For cases in which the discourse context was ambiguous, a forced choice was made by the first author who is a native speaker of the dialect.

In addition, the scaling and alignment of the rise was annotated using the facilities of Praat [9]. The beginning of the rise was manually located as the point at which an upward trend was apparent in which successive F0 values differed by more than 5 Hz (this was done to exclude microprosodic variation); see Figure 2 for an illustration. Scaling was measured in Hz and defined as the difference between the F0 at the beginning of the rise and the highest F0 point at its end. After the F0 information was extracted, values in Hz were converted to ERB in order to better compare male and female voices. The alignment of the F0 rise was defined as the distance of the point annotated as the start of the rise from the onset of the last stressed vowel in the utterance. This measurement was based on the assumption (supported by the data) that the last content word is typically the one carrying the nuclear pitch accent.

3. Results

Results presented here are related to the function, scaling and alignment of rises and to differences in gender. We note that ethnicity, SEC status and bilingualism did not affect the use of uptalk; thus they will not be discussed further. All significance testing was determined using linear mixed-effects models with Speaker as a random intercept. P-values are given with respect to model comparisons and are reported with the χ^2 statistic, which compares the (reduced) model without the fixed effect and the (full) model with the fixed effect.

3.1. Discourse Functions and Distribution of Uptalk

The best-fit model for comparing uptalk against other utterances in the corpus included discourse function, task type, gender and an interaction between gender and discourse function as fixed effects. Uptalk was more frequent in the map task than in clip retell: 34% of the utterances in the map task ended in uptalk as opposed to only 20% of utterances in clip retell [$\chi^2(1) = 37.4$, $p < 0.001$]. Uptalk was also used more frequently, approximately twice as often, by female than male speakers: uptalk comprised 42% of the female speakers' utterances vs. 20% of the male speakers' utterances [$\chi^2(1) = 14.1$, $p < 0.001$].

Gender also interacted with discourse function [$\chi^2(3) = 16.9$, $p < 0.001$]. First, no gender or discourse differences were found for uptalk in questions and confirmation requests in the corpus: uptalk was used for both types of utterances in 100% of the tokens independently of speaker gender. Statements and floor holding, on the other hand, showed different frequencies for uptalk, with floor holding being signaled by uptalk significantly more frequently than statements: 45% of floor holding ended in uptalk vs. 16% of statements [$\chi^2(3) = 244.7$, $p < 0.001$]. However, while females and males used uptalk with statements equally frequently, females used uptalk to hold the floor significantly more frequently than males; indeed females used uptalk more than twice as much as males for floor holding. This is illustrated in Figure 3.

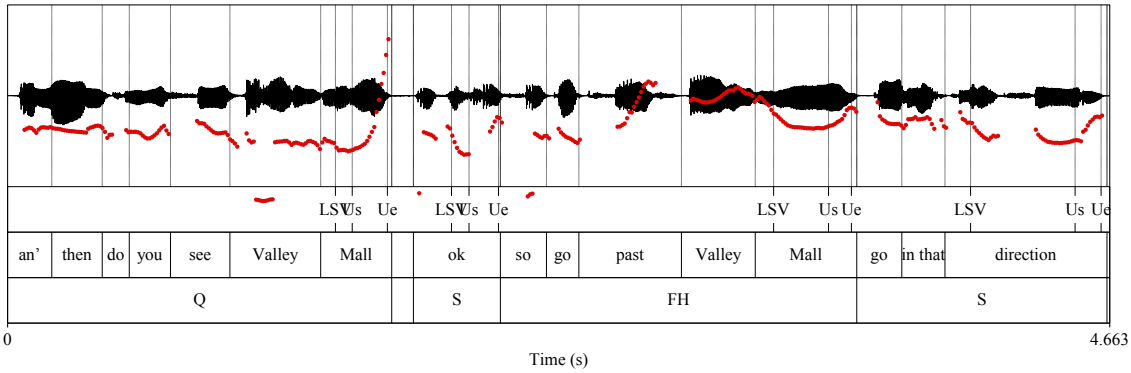

Figure 2: *Example of data annotation from the map task. LSV = last stressed vowel; Us = start of uptalk rise; Ue = end of uptalk rise; Q = question; S = statement; FH = floor holding. The follower's response ("yes, I do") which followed the question in this example has been removed for clarity.*

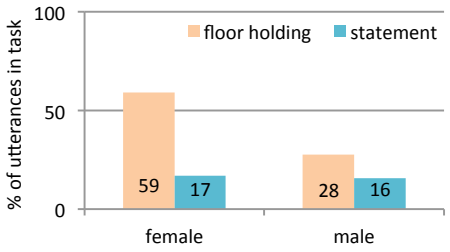

Figure 3: *Proportion of uptalk used by discourse function and gender.*

3.2. Alignment of Uptalk Rise

The best-fit model for the alignment of the uptalk rise included discourse function and gender as fixed effects. In this model, only two levels of discourse function were included, statement and question. Floor holding and confirmation requests were omitted from the model as their alignment was too variable.

The results from statements and questions showed a consistent difference between the onset of the rise in statements vs. questions, with the former having significantly later alignment than the latter [$\chi^2(1) = 19.3$, $p < 0.001$]. Specifically, the rise in the questions included the last stressed vowel (which is presumed to carry the nuclear pitch accent) while in statements the rise started after this vowel. The difference in the alignment of the rise in statements and questions is illustrated in Figure 4, which also shows the effect of gender on alignment. Specifically, uptalk produced by female speakers showed later alignment than uptalk produced by male speakers both for statements and questions [$\chi^2(1) = 5.6$, $p = 0.02$]. The differences were quite substantial, particularly for the questions: male speakers started the rise just before the last stressed vowel on average, while the rise for the female speakers started within this vowel.

3.3. Scaling of the Uptalk Rise

The best-fit model for the scaling of the rise included discourse function [$\chi^2(3) = 19.4$, $p < 0.001$], gender [$\chi^2(1) = 27.01$, $p < 0.001$] and task type [$\chi^2(1) = 20.03$, $p < 0.001$] as fixed effects. The major difference in pitch excursion with respect to discourse function was between statements and the other functions, with statements showing approximately half the pitch rise than questions, confirmation requests and floor holding (see Figure 5). Differences between these last three discourse functions were also statistically significant but minimal in actual terms [questions, confirmation requests > floor holding].

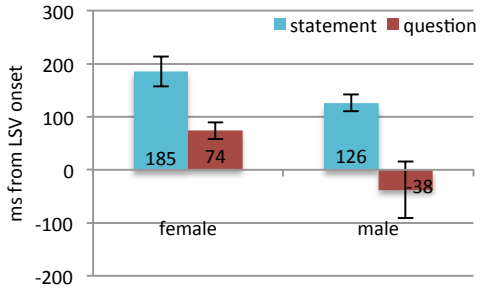

Figure 4: *Mean rise alignment (with standard error bars) per type of discourse function and gender. Negative values represent a rise beginning before the onset of the last stressed vowel (LSV).*

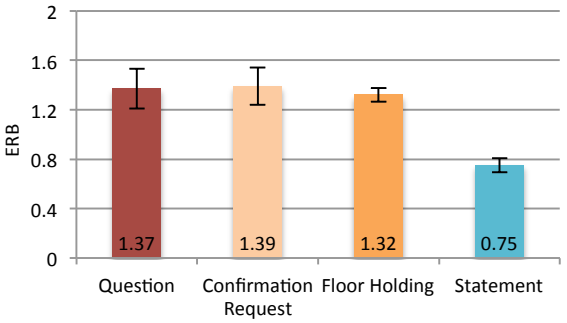

Figure 5: *Mean scaling of rises (with standard error bars) per discourse function.*

In addition, the data showed that female speakers had generally greater pitch excursions than males (see Figure 6a), presumably a reflection of gender differences in the use of the

frequency and effort codes [10]. Further, pitch excursions associated with uptalk were significantly larger in the map task than in clip retell (see Figure 6b). Neither result interacted with discourse function, however, suggesting these are independent effects and not the result of, e.g., female talkers asking more questions, or speakers in general making more confirmation requests in the map task than in clip retell.

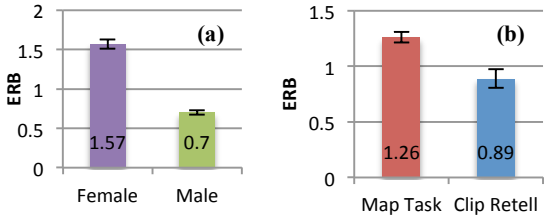

Figure 6: *On the left, mean scaling of uptalk (with standard error bars) by gender; on the right, mean scaling of uptalk (with standard error bars) by type of task.*

4. Discussion and Conclusions

Given the above results, we propose that the melody *typically* used with questions in SoCal English is L* H-H% and that used with statements is L* L-H%. The difference in phonological composition accounts both for the difference in alignment reported above but also for the difference in the scaling of the pitch rise: L-H% results in a lower rise than H-H%. Questions, as noted, can show a rise on the stressed syllable, a contour that could be interpreted as the reflex of a bitonal LH accent. However, the auditory impression is that of a low pitch accent, while the use of either L*H or LH* in questions is pragmatically doubtful (cf. [11] on the pragmatics of L*H when followed by a rise). Independently of the representation adopted for the question tune, the fact remains that questions and statements are not relying on the same melody as is often assumed; to put it differently, SoCal statements with uptalk do not sound like questions.

Our results further show that SoCal English makes a distinction between uptalked statements and questions even when the same melody is used (as happens occasionally). In particular, although the distinction is typically realized as a choice of tune, as noted above, it can also be signaled by just differences in the pitch scaling of the final rise (cf. the question and statements in Figure 2). The difference in pitch rise scaling is particularly evident when the tune used is H* H-H%, a variant that was attested but was not as frequent in our data as the L* accent variants. If such differences in the scaling of the rise turn out to be used by listeners to interpret the pragmatic intent of an utterance, this would suggest the need to incorporate scaling contrasts beyond H vs. L in phonological representations of intonation.

The two main melodies L* H-H% and L* L-H% are also used for floor holding and confirmation requests except that these two functions do not have as consistent a connection with a specific melody. In the case of confirmation requests this could be due to their dual role as questions and statements: speakers are making a statement but simultaneously requesting that their interlocutor confirm that what is said is understood or accepted. Thus, speakers use L* H-H%, L* L-H% or H* H-H% in these instances. Regarding floor holding, one of the most noticeable features was the use of high plateaux, rather than rises per se. Plateaux are particularly prevalent when speakers are listing items or instructions in the map task (cf. [12] on the intonation of lists). Plateaux are possible realizations of high tones [13] and thus they can perhaps create the impression of a rise; however, in our data they were clearly different from uptalk "proper" both acoustically and impressionistically and thus best represented phonologically as L* H-L% where the L% is upstepped.

The patterns described above document the use of tunes that are different from those described for other varieties of English that use uptalk. In particular, the prevalence of L* is not reported for other varieties of English (but see [4] on New Zealand English). As noted, for example, Australian English uses mostly a H* accent and it is precisely this use that has given rise to the term *High Rising Terminal*. Thus, the present study underlies the importance of including dialectal variation in the investigation of intonation and gives support to the claim that such variation exists even within dialectal areas often described as uniform, like the USA West [14].

Regarding the demographic factors in our study, we note that there are consistent differences between genders, with females using uptalk twice as often as males. This difference is presumably what has given rise to the stereotype that uptalk is used by females only; among women uptalk is sufficiently frequent to be identified as a distinctive characteristic of their way of speaking. Contrary to the popular stereotype, no gender differences in the use of uptalk were observed for statements: approximately 16% of statements ended in uptalk in the speech of both men and women in our sample. However, differences are evident in the use of uptalk for floor holding: in this use, uptalk is twice as frequent in the data from female speakers (a result that in itself suggests that the similar frequency of uptalk with statements cannot be attributed to the fact that our male speakers interacted with female researchers). At present we do not have a good explanation for this but offer some suggestions. One possibility is that women wish to hold the floor longer and use uptalk as a device to indicate this intent. This explanation however does not quite tally with existing research suggesting that women do not take longer turns than men ([15] and references therein). Another possibility is that women wish to indicate their intent to hold the floor because they are generally interrupted more often than men [15]. Again, this is not entirely satisfactory as our data were based on monologues (clip retell) and a cooperative task in which the interlocutor was always female. Thus, this aspect of the data clearly requires further investigation. At the same time, we do find that gendered use of uptalk did not interact with task. From this we can infer that the gender effect is not due, e.g., to women asking more questions, but rather to their general preference for certain uses of uptalk.

Unlike gender, which was a clear determiner of the frequency, function and form of uptalk, we did not find differences relating to ethnicity, SEC status or the language background of our speakers. Although it is possible that such differences could emerge with a larger sample, the ubiquitous use of uptalk in our corpus rather suggests that uptalk is sufficiently widespread in SoCal to transcend social barriers. In turn this tallies with the speakers' attitude to uptalk: for SoCal speakers it is not a feature that attracts attention.

5. Acknowledgements

We thank our participants, our research assistants Annabelle Cadang and Andy Hsiu for help with constructing and labeling the corpus, and the members of the UCSD Phonetics Lab for valuable feedback on this project.

Rhythmic structure of utterances in native and non-native Polish

Agnieszka Wagner

Institute of Linguistics, Adam Mickiewicz University in Poznan, Poland

wagner@amu.edu.pl

Abstract

This paper presents results of an ongoing study concerning speech rhythm in native and non-native Polish. The goal of the analyses described in the paper was to characterize rhythmically Polish utterances realized by native and non-native speakers with German and Korean accent. The analyses are limited to the domain of duration, but in the future other prosodic parameters will also be investigated. In the current study, different rhythm metrics (%V, ΔV, ΔC, PVIs and Varcos) were applied to provide quantitative description of temporal patterning in native and non-native Polish. Following the assumption that perceived speech rhythm is the effect of meter and grouping which are closely related to prominence and phrasing, durational marking of various levels of prominence and prosodic edges was also analyzed between the three accents (native Polish and German- and Korean-accented Polish). The analyses aimed also at rhythmic classification of Polish – for that purpose the results of quantitative description with rhythm metrics and phonotactic properties of the speech material used in the current study were compared with the data for other languages presented in the literature.

Index Terms: speech rhythm, rhythm metrics, prominence, phrasing, native and non-native Polish

1. Introduction

Speech rhythm can be defined as a systematic temporal organization of prominent and less prominent speech units. In linguistics and phonetics, the notion of speech rhythm is traditionally related to the notion of *isochrony* [1, 2]. Isochrony underlies *rhythm class hypothesis* according to which every language represents a specific rhythm class, i.e. syllable-timed (Spanish, Italian), stress-timed (English, German) or mora-timed (Japanese), on the basis of its temporal organization of syllables. The lack of experimental evidence for stress-, syllable- and mora-based isochrony caused that in rhythm research the focus moved from duration measurements of syllables and feet to investigation of phonetic and phonological factors which affect the timing of syllables and feet, most importantly degree of vowel reduction in unstressed syllables, and phonotactic complexity of syllables. As a results rhythm has been redefined as the perceptual effect of interaction of a number of components: phonetic and phonological on the one hand, and segmental and prosodic on the other [3].

1.1. Rhythm metrics

The differences in vowel reduction, stress-based lengthening and syllable complexity between stress- and syllable-timed languages became the basis of *rhythm metrics* – formulas that measure durational variability in consonantal (C) and vocalic (V) intervals (or syllables). The most widely used metrics include %V-ΔC [4], PVIs [5] and Varcos [6]. Languages with the stress-timed rhythm are expected to exhibit higher nPVI and lower %V and higher consonantal rPVI and ΔC that result from vowel reduction and quite complex syllable structure respectively. Syllable-timed languages generally do not have spectrally reduced and shortened vowels and most syllables have a simple CV structure. Consequently, these languages are expected to exhibit higher %V and lower values of nPVI and the consonantal metrics. There is a growing body of evidence from experimental studies showing that rhythm metrics are not perfect. First of all, they are sensitive to differences in text materials, speech elicitation methods, measurements and changes in speech rate [7, 8]. This sensitivity explains why rhythm metrics take different values in different studies. Second major problem is that metrics reduce rhythm to *timing*, whereas apart from duration, perceived speech rhythm is also the product of properties such as melodic (F0) change and, to a lesser extent, intensity and vowel quality. As a result, different metric scores do not necessarily reflect perceptually different rhythms [9]. Perceived rhythm is the effect of *meter* and *grouping* and therefore research on rhythm should incorporate among others investigation of prominence (which functions as a meter) and phrasing (which is related to grouping, see [10]). Despite criticism, rhythm metrics still constitute the methodological basis of studies concerning topics as diverse as discrimination between rhythm classes [11], acquisition of timing patterns in L1 [12] and L2 [13, 14, 15, 16, 17, 18], detection of speech impairments [19] or dialect discrimination [20].

1.2. Phrasal properties of speech rhythm

It is well known that higher levels of prosodic structure such as prominence marking and prosodic phrasing strongly influence the organization of timing across languages. Analyses based on various languages (including Polish) showed that stressed and pitch accented syllables are produced with additional lengthening compared with unstressed syllables [21, 22, 23, 24]. Final lengthening at the edges of phrasal prosodic constituents is also very widespread [23, 25, 26]. Therefore, it has been acknowledged by many authors (e.g., [10], [27], [28], [29]) that perception of rhythm classes should be examined in relation to prosodic timing phenomena – the durational marking of prominences and phrase boundaries, because they are correlated with the potential rhythm class distinctions and constitute an important ingredient in the rhythm percept across languages.

1.3. Features of Polish, German and Korean rhythm

The speech material used in the current study comes from speakers whose native language was Polish, German or Korean. Polish exhibits phonological properties that are associated with both types of rhythm class [21, 23, 30, 31, 32, 33, 34]. Increased duration of prominent syllables and some compensatory shortening effects together with phonotactic complexity of syllables indicate stress timing. On the contrary, the lack of vowel reduction and a fixed lexical stress on the penultimate syllables indicate syllable timing. Therefore, having some features distinctive of stress-timed languages and others distinctive of syllable-timed languages, Polish would be

predicted to behave rhythmically as an intermediate or mixed language. Yet the acoustic evidence in this respect is contradictory: According to PVIs [5], Polish is close to syllable-timed languages, but, according to %V – ΔC, it is grouped with stress-timed English and Dutch [4].

German is a typical example of a stress-timed language with a phonemic vowel length contrast and vowel reduction in non-prominent unaccented syllables that is manifested acoustically mainly by differences in duration and quality, and allows for longer sequences of consonants in both onset and coda position [35]. This in turn leads to lower %V and higher ΔC, nPVI and rPVI [5, 7].

A perceptual study reported in [36] brought evidence that Korean, like Japanese, has mora-timed rhythm. However, this is at odds with the results of other studies (e.g. [7], [37], [38]) which suggest that Korean has "mixed" rhythm that is closer to syllable-timing than to stress-timing. Thus, at the acoustic level Korean rhythm should be manifested by higher %V and lower ΔC and PVIs than in stress-timed languages.

In the analysis of non-native speech rhythm we expect to find the influence of speakers' L1 on the realization of the durational variability of vocalic and consonantal intervals in Polish. It is assumed that non-native accent should be manifested by values of the metric scores intermediate between those reported for speaker's L1 (German or Korean) on the one hand and those obtained for Polish on the other. The perceptibly weaker non-native accent of German speakers (see sec. 3.1) should be manifested by smaller differences in the metric scores between German-accented and native Polish than between Korean-accented and native Polish.

1.4. Objectives of the current study

The objective of the analyses presented in this paper is to characterize Polish rhythm in utterances realized by native and non-native speakers with German and Korean accent and to provide rhythmic classification of Polish whose rhythmic status is unclear. For this purpose different rhythm metrics will be applied – they will be analyzed in terms of their stability (with respect to speech rate) and robustness (with respect to discrimination between the three accents). The quantitative description of speech rhythm using selected rhythm metrics will be complemented by results of analyses of the phonotactic structure of the utterances and study of durational marking of prosodic heads and phrase edges.

2. Methodology

2.1. Speakers and text

The speech material includes recordings of a literary fairy tale "The teapot" (by H. Ch. Andersen), read by 15 speakers: 5 Polish native speakers, 5 speakers with L1 German and 5 with L1 Korean. The text consists of 19 phonetically and prosodically rich sentences. Recordings of speakers with L1 German come from the *Euronounce* corpus [39], whereas the part representing Korean-accented and native Polish was recorded for the purpose of this study. Recordings were carried out in a sound-treated booth, directly to a disk and with a sampling frequency of 16 kHz. German and Korean speakers represented an intermediate level of proficiency in Polish, but the Koreans were less proficient in pronunciation and took Polish Phonetics course to improve their skills. The non-native speakers were competent, but with a perceivable non-native accent which was more salient in Korean-accented Polish (sec. 3.1). The subjects were asked to read the text once (sentence after sentence), at their own pace. Sentences containing disfluencies or mispronunciations were re-recorded.

2.2. Annotation and measurements

The whole speech material was segmented into vocalic and consonantal intervals on the basis of automatic transcription and segmentation [40] which was verified and manually corrected following standard segmentation criteria. All vowels were marked as vocalic intervals and all consonants (except for post-vocalic glides) – as consonantal intervals. A vocalic interval could contain a single vowel or 2-3 subsequent vowels, or a vowel followed by a glide. Intervals could span across syllable and word boundaries. As in [7] prepausal intervals were not excluded from measurements and segments separated by a pause were treated as two distinct intervals. Despite the applied recording procedure the utterances by non-native speakers are not entirely free of mispronunciations and all insertions and substitutions were included in the C and V intervals. On the one hand, differences in the phonetic realization will affect temporal structure of utterances, but on the other hand, if they are small and few they should not significantly affect metric scores. This issue was investigated using analysis of distribution of various types of syllables between the accent groups (sec. 3.2).

For each sentence the following rhythm metrics have been calculated:

- **%V** – the proportion of vocalic intervals, **ΔV** and **ΔC** – the standard deviation of the duration of vocalic and consonantal intervals respectively [4]
- **rPVI-V** (raw Pairwise Variability Index) and **nPVI-V** (vocalic normalized Pairwise Variability Index): the mean of the duration differences between successive C intervals and the mean of the duration differences between successive V intervals divided by the sum of the same intervals respectively [5]
- **VarcoV/VarcoC**: standard deviation of vocalic/consonantal interval duration divided by mean vocalic/consonantal duration [6]

Prosodic annotation included marking of four levels of prominences and two levels of phrasing. Each syllable and vowel was labeled as unstressed, stressed but unaccented, accented and nuclear accented, and as non-final, final in an intermediate phrase or final in an intonational phrase (see [29], [41], [42]). Syllable boundaries were determined according to criteria presented in [43]. Annotation and duration measurements were done in *Praat*. The data was exported to a spreadsheet where classification into C and V intervals was carried out and values of the rhythm metrics were calculated. For statistical analyses *Statistica 10* was used.

3. Results

3.1. Perception test

The aim of the test was to determine the strength of foreign accent in speech produced by non-native speakers. Seven subjects (students at the Institute of Linguistics) listened to utterances realized by Polish, German and Korean speakers, and marked the strength of foreign accent on a graphical scale from *very strong* to *no accent at all*. The test was carried out using *Annotation System* [44]. The results showed that

utterances realized by speakers with L1 Korean were characterized by strong foreign accent, the accent of speakers with L1 German was assessed as moderate, and in native Polish no foreign accent was perceived. All differences are statistically significant. It can be expected that the strength of foreign accent will be reflected in metric scores and durational marking of prominences and phrase edges.

3.2. Phonotactic properties

In all accent groups **CV** syllables constituted about **50%** of all syllables. The second most common structure was **CCV** (PL: 16.9%, DE: 17.5%, KOR: 16.5%), the third one was **CVC** (PL: 12.2%, DE: 11.6%, KOR: 12.8%) and then **V** (PL: 7.9%, DE: 7.9%, KOR: 8%) and **CCVC** (PL: 7.9%, DE: 7.3%, KOR: 7.1%). Other syllable types – CCCV, VC, CCVCC, CVCC and CCCVC, were much less common (< 3%). Differences in the frequency and distribution of syllable (and interval) types between the three accent groups are below 1%. It can be assumed that mispronunciations that occurred in non-native speech did not affected the overall phonotactic structure of utterances. Comparison of phonotactic properties of native speakers' utterances with data from five languages analyzed in [45] showed that similarly to stress-timed languages, Polish has greater variation in complex syllable structure than rhythmically unclassified Czech (6 types vs. 3 types). But on the other hand, Polish complex syllables most often have the CCV structure (not CVC as in stress-timed languages) and frequency of CCVC syllables is higher than in English and German. These results show that in terms of phonotactic properties Polish, like Czech, does not fit into the binary classification into syllable- and stress-timed languages.

3.3. Quantitative description with rhythm metrics

3.3.1. The effect of speech rate

ANOVA results showed significant differences in the speech rate between native speakers and the two non-native accents ($F=31.2$, $p<0.01$). Speech rate measured in the number of C and V intervals per second (cf. [46]) was higher in native Polish than in German- and Korean-accented Polish (9.2 vs. 8.2 intervals/sec.). Therefore, in the utterances produced by non-native speakers, higher values of the raw consonantal metrics can be expected. In order to select the most stable rhythm metrics correlations between their values and speech rate were investigated (Table 1).

Table 1. *Correlations between metric scores and speech rate (* indicates p<0.05).*

Metric	PL	KOR	DE
%V	-0,01	-0,17	-0,23*
ΔV	-0,33*	-0,59*	-0,64*
ΔC	-0,30*	-0,51*	-0,60*
rPVI	-0,36*	-0,49*	-0,35*
nPVI	-0,07	-0,01	-0,57*
VarcoV	-0,07	-0,10	-0,18
VarcoC	0,13	-0,07	-0,20

It can be seen that with one exception (Varco C, PL) the values of the metrics increase with decreasing speech rate. In some cases (mostly in German-accented speech, DE) the inverse correlations are statistically significant. Varcos, and to lesser degree %V and nPVI, seem to be the most stable metrics. These results indicate need of using rate-normalized metrics instead of the raw ones.

3.3.2. The effect of accent

In order to determine whether there are significant differences in the temporal patterning between native and non-native Polish and between the two non-native accents, ANOVA was carried out with *accent* as predictor variable and *metric scores* as dependent variables (Table 2).

Table 2. *ANOVA results: The effect of accent on the metric scores.*

Rhythm metrics	ANOVA		Scheffe's test
	F test	p	
%V	43,6	0,00	all
ΔV	40,6	0,00	KOR x PL, KOR x DE
ΔC	3,1	0,04	PL x DE
nPVI	77,0	0,00	KOR x PL, KOR x DE
rPVI	0.9	0.4	---
VarcoV	27,2	0,00	KOR x PL, KOR x DE
VarcoC	5,0	0,01	PL x DE

Statistically significant differences in all metric scores except for rPVI can be observed between the three accent groups. The results of ANOVA and post-hoc comparisons (Scheffe's test) indicate that the effect of accent is stronger on vocalic than on consonantal metrics. Taking into account these results and correlations with speech rate (Table 1), it can be assumed that %V, nPVI and VarcoV will be the most robust metrics in discrimination between the three accents.

In native Polish the %V has higher value and nPVI lower value in the current study than in [5]: %V – 47.1 vs. 42.3 and nPVI – 42.1 vs. 46.6. The vocalic metrics place Polish far from stress-timed Dutch, German and English and closer to syllable-timed French and Catalan [5, 7]. Values of the consonantal metrics in the current study show lower variation in the C interval durations comparing to results in [5]: ΔC – 61.3 vs. 71.4 and rPVI – 68.2 vs. 79.1, but they still indicate high variation in structure and duration of C intervals. In a two dimensional space determined by vocalic and consonantal metrics, the latter place Polish far from most languages. These results indicate that Polish rhythm can not be classified using the binary distinction between syllable- and stress-timing.

In German-accented Polish, %V, nPVI and VarcoV have lower values than in native Polish, but the difference is statistically significant only in case of %V (Table 2). In Korean-accented Polish the scores of all the vocalic metrics are higher than in Polish and German: **%V** – 49.7 KOR, 47.1 PL, 45.1 DE, **ΔV** – 61.9 KOR, 45 PL, 45.6 DE, **nPVI** – 54.5 KOR, 42.1 PL, 40.7 DE, **VarcoV** – 51.3 KOR, 44.3 PL, 41 DE. The vocalic metrics take intermediate values between those reported for native Korean [37] and those obtained for native Polish, which indicates *transfer of temporal patterning from L1 Korean to Polish*. In the non-native accents consonantal metrics have higher scores than in native Polish, but these differences might result from different speech rates as indicated by significant inversed correlations (Table 1). Differences in the temporal patterning between native and non-native Polish are reflected mostly by the vocalic metrics: %V, nPVI and VarcoV. The results of quantitative analysis using rhythm metrics are in line with the results of the perception test, because they indicate greater differences in

temporal patterning between Korean-accented and native Polish than between German-accented and native Polish.

3.4. Phrasal properties of speech rhythm

3.4.1. Prominence level

Multivariate ANOVA results showed significant effect of prominence level on syllable duration ($F=354.8$, $p<0.01$) and small, but significant effect of speaker ($F=4.5$, $p<0.01$) and speaker and accent ($F=8.4$, $p<0.01$). Generally, in all accent groups syllable duration increases with the prominence level from unstressed to nuclear accented. The exception is durational marking of stressed syllables (S) in native Polish: these syllables are significantly shorter than all other syllables, including unstressed syllables (U) in Polish, but excluding U syllables in the two non-native accents (Tukey's HSD test). However, even though S syllables are generally longer than U syllables in Korean- and German-accented Polish, the difference is not statistically significant. Contrary to native Polish, in non-native accents the difference in duration between A (accented) and S syllables is not significant. There is also significant difference in durational marking of the highest level of prominence (NA) between Polish and Korean speakers. Similar patterns of variation due to prominence were found in vowel durations, except for S vowel durations in native Polish which this time were longer (but not significantly) comparing to U vowels.

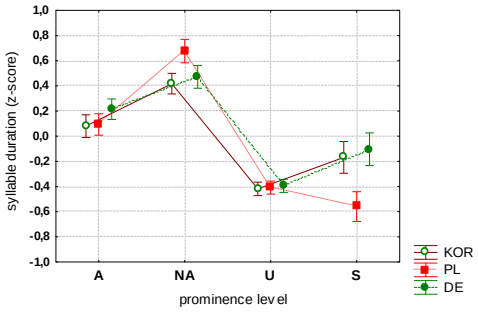

Figure 1: *Mean syllable duration depending on the prominence level (A – accent, NF – nuclear accent, U – no stress & no accent, S – stressed).*

3.4.2. Phrasal position

Similarly to prominence analysis, multivariate ANOVA results showed significant effect of phrasing level on syllable duration ($F=533.3$, $p<0.01$) and small, but significant effect of speaker ($F=15.2$, $p<0.01$), and speaker and accent ($F=19.1$, $p<0.01$). In all accent groups, non-phrase final syllables are significantly shorter than syllables at the edges of intermediate (iip) or intonational phrases (IP). Interestingly, duration of syllables at the edges of intermediate phrases is the longest, but in German-accented and native Polish it is significantly different only from duration of non-phrase final syllables (NF). IPs in native Polish are signaled by significantly increased duration of phrase-final syllables comparing to the non-native accents. Intermediate phrases are marked by significantly longer phrase-final syllables in native and Korean-accented Polish than in German-accented Polish.

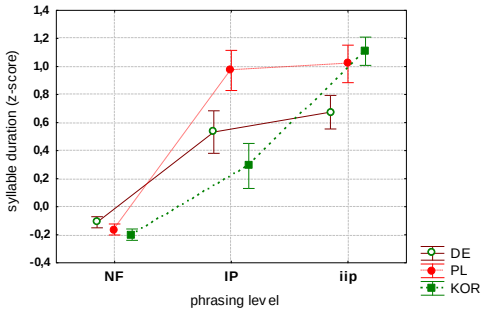

Figure 2: *Mean syllable duration depending on the phrasing level (NF – non-final, IP – intonational phrase, iip – intermediate phrase).*

4. Discussion and conclusions

The results of the analyses indicated significant differences in the rhythmic characteristics between native and non-native Polish. The strength of foreign accent in non-native Polish assessed in a perception study was reflected in more significant differences in the metric scores between native and Korean-accented Polish (strong accent) than between native and German-accented Polish (moderate accent). The results of quantitative analysis using vocalic rhythm metrics showed that Korean speakers transferred some temporal patterns from their L1 to Polish. Generally, Korean-accented Polish is characterized by more vocalic speech (higher %V) and more variation in the duration of V intervals than native Polish and German-accented Polish; the latter accent is characterized by less vocalic speech (lower V%) and less variation in the duration of V intervals than Korean-accented Polish and less variation in C interval duration comparing to native Polish. Generally, %V, nPVI and VarcoV are more stable as regards speech rate differences and more robust than the consonantal metrics. Small, but significant differences in the durational marking of various levels of prominence and phrasing can also be observed between the three accents and they also affect the temporal organization of utterances – this implies the need of including prosodic hierarchy in the analysis of speech rhythm. In the future, the analyses of phrasal properties of Polish rhythm will be complemented by analysis of distribution of prominences and phrasing e.g., position and number of pitch accents and phrase boundaries (see [47]). The phonotactic structure of Polish utterances and the quantitative description using rhythm metrics indicate that in terms of rhythm, Polish does not fit into the binary classification into syllable- and stress-timing. Phonotactically, it is most similar to "rhythmically mixed" Czech, whereas vocalic rhythm metrics provide some evidence of syllable timing and consonantal metrics put Polish aside from both syllable- and stress-timed languages. These results indicate that in order to better characterize Polish rhythm (and speech rhythm in general) it is necessary to go beyond the dimension of timing and to analyze also the contribution of pitch, intensity and tempo to production and perception of rhythmic structure and grouping.

Abstract

When talkers from various language backgrounds use L2 English as a lingua franca, their accents of English are expected to converge, and talkers' rhythmical patterns are predicted to converge too. Prosodic convergence was studied among talkers who lived in a community where L2 English is used predominantly. Speech rhythm was operationalized here as the peak frequency in the spectrum of the intensity envelope, normalized to the speaking rate (in syll/s). Results indicate that talkers produced intensity contours with maximum periodicity at frequencies of about 0.32 times their syllable rates, i.e., peaks in intensity tend to occur every 1/0.32 syllables. These results were collected repeatedly, from 5 recordings conducted over 3 years with the same talkers. We found that variance between talkers in their rhythm decreases over time, thus confirming the predicted convergence in speech rhythm in L2 English. These findings show that speech rhythm in L2 English tends to converge, and that this prosodic convergence continues to proceed over several years, as well as over communicative settings.
Index Terms: speech rhythm; phonetic convergence; accommodation; L2;

1. Introduction

When talkers from different varieties or dialects of a language converse with each other, their dialects and accents tend to converge. This convergence has been reported on various time scales for varieties of L1 Dutch [11], L1 English [7, 5] and L1 French [4]. But does convergence also occur among varieties of an L2 language used as a lingua franca by talkers from various L1 backgrounds? It is widely assumed that a talker's accent will weaken or disappear in intensive contact with other talkers of L1 and L2 English. However, we have only limited insight in how and why L2 accents change over time in highly interactive environments. Do non-native speakers become more native-like, and does interference from their L1 decrease over time? And do native speakers also drift away from their native pronunciation standards? The international community of the University College Utrecht (UCU) provides an excellent environment to study phonetic convergence in L2: its students vary in their native languages (with Dutch being the majority L1), English is spoken as the lingua franca on campus, and the UCU is located in a Dutch-speaking country, so that any changes in English accents can be validly attributed to internal processes within the community.

The core hypothesis in this longitudinal research project is that the native and non-native accents of UCU students will gradually converge to a single common UCU English accent, in which properties of L1 British English, L1 American English, L2 Dutch English, and other varieties will be mixed. With regard to speech rhythm, we hypothesize that talkers' rhythmical patterns will converge. A key property of English is its lexical stress, which typically results in one stressed syllable of a word being more prominent (produced with more effort and longer duration) than the other unstressed ones. A salient rhythmical feature of English is that the unstressed syllables tend to be reduced more dramatically (both spectrally and temporally) than they are in other lexical-stress languages such as Dutch or German, or in non-stress languages such as Japanese.

In the present longitudinal study, we focus on long-term convergence in speech rhythm in L1 and L2 English, over a period of 3 years. Do L2 English speakers become more native-like, in that they will show more reduction of unstressed syllables? Or do L1 English speakers become less native-like, in that they will show less reduction of unstressed syllables? Does the variance between talkers in their preferred rhythmical pattern decrease over the years? These questions will be answered by means of the longitudinal speech corpus described below.

2. Corpus

The Longitudinal University College English Accents Corpus (LUCEA) is a corpus of speech recordings, collected at University College Utrecht (UCU) in Utrecht, the Netherlands. Four consecutive annual cohorts of students were or will be recorded, each at five "rounds" or time points over the three years of their undergraduate study, in longitudinal fashion. Talkers are recorded in Sept of year 1 of their programme (month 1), May of year 1 (month 9), Sept of year 2 (month 13), May of year 2 (month 21), and May of year 3 (month 33; most UCU students are absent on exchange visits in the first semester of year 3). Actual recording dates may differ by a few weeks from the nominal month of recording, due to students' availability. Recordings began in September 2010, and are still in progress.

2.1. Talkers

The talkers in the corpus are mostly full-time degree students, with some incoming exchange students and staff included who are native speakers of English. About 60% of the degree students and of the talkers in the corpus have Dutch as their L1. In addition to the Dutch speakers and the native speakers of English, over 30 other native languages are represented in the corpus. UCU students are required to use English in all their interaction with tutors and teachers. Students live on campus during their entire three-year degree programme, and in culturally and linguistically mixed social settings, English is also the language of choice. Thus the talkers use L1 or L2 English very intensively for interacting in the campus community. Of the student population of about 700, approximately one quarter (about 60 per cohort) participates as a talker contributing speech data to the LUCEA corpus.

The present study targets those talkers for which a full sequence of 5 recordings is available ($n = 18$); all these talkers were students of the first cohort (class of 2013) participating in the LUCEA corpus collection. In the first and last recording sessions, talkers also filled in a questionnaire about their language background, language use, study exchange experience, etc. In the entry questionnaire, 15 talkers declared themselves as native speakers of Dutch, and 1 talker each as a native speaker of Russian, Vietnamese, and German. In the exit questionnaire, 3 talkers (1 female, 2 male) also regarded themselves as L1 English speakers. These answers need not be contradictory, as many students at UCU have a complex language history with multiple native languages (e.g. different languages of mother, father, and country of residence).

2.2. Procedure

Each student talker receives €10 for each recording, with a bonus of €10 if all 5 rounds of recordings are completed. Recordings take place in a quiet office room on the UCU campus. The talker's speech is recorded by means of 7 microphones (Sennheiser ME64/K6p) placed around, behind, and above the talker, and also via a close-talking microphone (Sennheiser Headset HSP 2ew). All 8 channels are recorded digitally by means of a Saffire Pro 40 multichannel preamp and AD converter (at 44.1 kHz, 16 bits).

Talkers are asked to perform between 10 and 12 speech tasks, listed in Table 1, including texts to read aloud, monologues in both the native language and English (if English is not the native language), and a dialogue with the facilitator. Each recording session takes about 45 minutes, in which approximately 25 minutes of speech is collected.

Table 1: *Summary of tasks for talkers to be performed in each recording.*

Nr	Description
1	Say your name, and today's date and time
2	Short extract from the Rainbow Passage
3	*Please Call Stella* [13]
4	*The Boy who Cried 'Wolf'*†
5	Sentence sets for intelligibility testing
6	Five sentences for investigating prosody [14]
7	Extract from Declaration of Human Rights in L1 [12]
8	Extract from Declaration of Human Rights in English [12]
9	2 minute monologue in L1 (informal topic)
10	2 minute monologue in English (informal topic)
11	2 minute monologue in English (formal topic)
12	3 minute dialogue with facilitator

†Two different versions of this text have been used.

3. Method

The present study focused on a small part of the recordings, viz. the 5 English sentences taken from and studied by [14] (Table 1, task 6; see Appendix A). These sentences may be regarded as a semi-random sample in their distribution of stressed and unstressed syllables. Jointly the 5 sentences contain 26 stressed syllables out of a total of 81 syllables, a ratio of 0.321.

Talkers were always instructed to read each sentence without pausing or inhaling in mid-sentence, and without any errors. If necessary, a talker repeated a sentence until this was achieved. Only fluent realizations without error and without pausing were selected for subsequent analysis. Each sentence was excised and stored as a separate audio file. Incomplete recordings (due to errors in post-processing) were discarded, with $N = 423$ recordings by 18 talkers remaining.

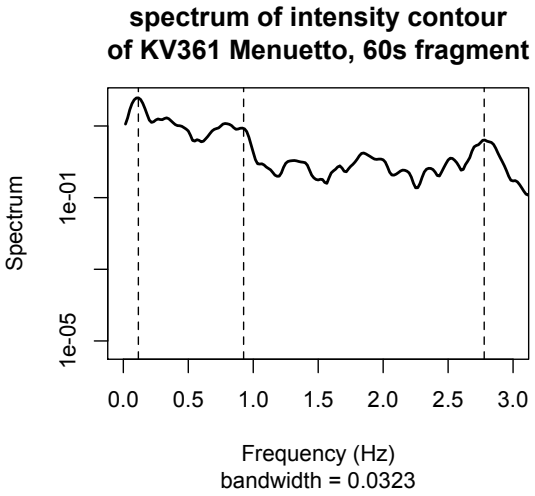

Figure 1: *Spectrum of intensity contour, with marking of salient frequencies.*

The intensity envelope of each sentence was measured by means of Praat [2], using a 25 ms window shift (40 Hz sampling frequency). The resulting intensity contour (in dB units) was exported. Subsequent analysis of the intensity envelope was inspired by [6] and was performed using R [10]. The intensity contour was converted to a spectrum, in order to bring out its periodic components. As an example, consider the spectrum of the intensity envelope of a musical fragment (by W.A. Mozart, KV361, Menuetto, in $3/4$ time) shown in Fig. 1. The peak at 2.77 Hz corresponds with the quarter notes (at a tempo of about 167 beats per minute, or 2.77 per s), and the peak at 0.92 Hz corresponds with the full measures (0.92 per s). The strongest peak at 0.116 Hz corresponds with an 8-measure or 24-beat periodicity of the intensity envelope.

From each spectrum, we then identified the frequency bin with the maximum intensity, i.e., the strongest periodic component of the intensity envelope. The windows used during preceding intensity analysis and spectral analysis and smoothing resulted in an eventual frequency resolution of 0.016 Hz (spacing between frequency bins).

The duration of each sentence was assessed from the duration of the intensity envelope, excluding silent intervals before and after the sentence. The articulation rate (sc. tempo, in syll/s) of each spoken sentence was computed using the syllable counts in Appendix A. (Note that sentences were always spoken without pauses.) The observed peak frequency in the spectrum of the intensity envelope was then normalized to this articulation rate. Thus the strong spectral component that corresponds to the syllable repetition frequency is removed, and the resulting measure represents the periodicity of the intensity envelope, expressed *relative* to the syllable-based periodicity of the intensity envelope. For the spectrum of Fig. 1 (with a base tempo of 2.77 Hz) this would yield a single dimensionless value of $0.116/2.77 = 1/24$, indicating a periodic or cyclical pattern in the intensity envelope that spans over 24 quarter-notes. The

relative strength of this normalized peak frequency was not assessed. Data from 2 sentence recordings were excluded from further analysis because of their unusually high articulation rate (> 8 syll/s), with $N = 421$ spoken sentences remaining.

The normalized peak frequencies of the intensity envelope of each spoken sentence were fed into a linear mixed-effects regression model (LMM) [8, 9], with talkers ($n = 18$) and sentences ($n = 5$) as two crossed random effects, using maximum likelihood estimation. LMM was done using package `lme4` [1] in `R` [10]. Fixed predictors were (i) the "round" or time of recording (coded as 4 contrasts between consecutive rounds), (ii) the talker's status as a native speaker of English (0=no, 1=yes), (iii) the interaction of predictors (i) and (ii), and (iv) the articulation rate (in syll/s, centered to its median). The rounds were also included in the random part at the talker level, i.e., we explicitly modeled the between-talker variance for each round separately.

4. Results and discussion

The coefficients and variances estimated by the LMM described above are listed in Table 2. The estimated normalized peak frequencies in the spectrum of the intensity envelope are also illustrated in Fig. 2.

Table 2: *Estimated coefficients of the LMM. For fixed effects,* r2r1 *refers to the contrast between round 2 and round 1, etc.;* native *indicates the talker's status as native speaker of English (yes=1); colons are used for interaction terms; asterisks mark fixed effects with* $p < .05$ *(based on 2.5% and 97.5% percentiles of bootstrapped estimates over 200 bootstrap replications). For random effects,* u *refers to talkers and* v *to sentences, and* e *to residual error; the 95% confidence intervals are based on percentiles of bootstrapped estimates over 200 replications.*

σ^2_{e}	0.0165	(0.0137, 0.0182)	($n = 421$)

In the present sample of spoken English sentences, the intensity envelope shows a major periodicity at $0.31\times$ the syllable rate. This value matches with the proportion of stressed syllables (0.321) in the test sentences, suggesting that the peak frequency in the intensity envelope, or "normalized stress rate", corresponds with the rhythm of the spoken sentences. In English, unstressed syllables tend to be weaker in intensity (and shorter in duration) than stressed syllables, and this property is indeed captured by the intensity envelope showing periodicity at a rate corresponding with the average inter-stress interval. Thus this stress rate [6], here normalized relative to syllable rate, may be of interest for evaluating speech rhythm.

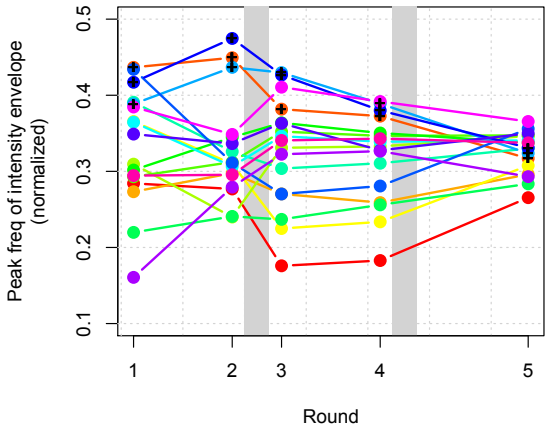

Figure 2: *Estimates of normalized peak frequencies in the spectrum of intensity envelope, broken down by round of recording (along abscissa, on approximate time scale) and by talker (with plussed symbols representing L1 English speakers). Shaded areas represent 2-month summer breaks during which talkers do not live on the UCU campus.*

Indeed, the normalized "stress rate" or peak frequency of the intensity envelope is significantly higher for the 3 native English talkers than for the 15 nonnative talkers in the present sample, as shown in Table 2. In our interpretation, this significant difference may be ascribed to the stronger reduction of unstressed syllables in English as compared to Dutch. This difference in reduction has been reported to extend to L1 English and L2 English spoken by Dutch native speakers [14, 3]. In our sample, 15 of the 18 talkers mentioned Dutch as one of their native languages. If these L2 talkers would reduce their unstressed vowels in their L2 English to a lesser degree than their native counterparts, then the intensity peaks of their stressed and unstressed syllables would also differ to a lesser degree than their native counterparts would produce. This would in turn result in a somewhat *lower* "normalized stress rate" for L2 talkers as compared to what native speakers would produce. For example, the native English speakers all pronounce *chairman* as [ˈtʃɛɚmən], whereas the native Dutch speakers of L2 English tend to pronounce this word as [ˈtʃɛɚˌmæn] with a less reduced second syllable, yielding a higher intensity peak for the unstressed syllable, and hence a lower "normalized stress rate". Thus the significant main effect of native-speaker status on normalized stress rate reflects this relatively subtle prosodic difference between native and Dutch-accented English in degree of syllable reduction [14, 3].

The significant interaction between native-status and recording round indicates that the 15 nonnative talkers do *not* change over time in their normalized stress rate, whereas the 3 native English talkers tend to converge to the somewhat lower, nonnative stress rate observed for the nonnatives. In other

words, the native speakers of English (who are a minority at UCU) tend to adapt their English speech rhythm to that of their nonnative peers (who are a majority), especially at the 4th and 5th recording session (end of year 2 and end of year 3, respectively). The convergence seems to extend into the students' third year on campus; this finding matches similar reports of long-term phonetic accommodation [11, 5]. Moreover, the phonetic accommodation is extended from conversational settings with peer students, and from classroom situations, to the interview setting of the corpus recordings. These findings supports the core hypothesis of long-term prosodic convergence among students in the UCU community.

The core hypothesis of phonetic convergence also predicts that the variance between talkers decreases over time. LMM allows this prediction to be tested, by modeling separate $\sigma^2_{u.}$ between-talker variances for each round of recordings. The resulting variance estimates in Table 2 seem to confirm this prediction to some extent (cf. Fig. 2), but the 95% confidence intervals of these variance estimates do overlap in bootstrap validation. The LMM reported in Table 2 also does not perform significantly better than a simpler model in which between-talker variances are pooled into a single estimate for all 5 rounds (i.e. in which homoskedasticity is assumed; likelihood ratio test, $\chi^2 = 7.62, \mathrm{df} = 14$, n.s.). Thus the decreasing variance between talkers is adequately captured by the significant interaction between native status and recording round (in the fixed part of the LMM, [9]), and there is no significant deviation from homoskedasticity beyond this interaction.

In conclusion, L2 English talkers do not show longitudinal changes in their rhythmical pattern. The native L1 English talkers however tend to move away from their native rhythmical patterns (observed initially), by decreasing the degree of reduction of unstressed syllables; hence they accommodate to the predominant variety of L2 English in the language community. These longitudinal changes confirm that members of this multilingual community, where English is used as the lingua franca, do converge in their speech rhythm of their L1 and L2 English accents.

5. Acknowledgements

We thank the UCU talkers for lending their voices, Roeland van Beek, Thari Diefenbach, Anne van Leeuwen, Lisa Teunissen, Kate Backhouse, Maria Koutiva and Kim Cruden for their assistance in conducting the recording sessions, and David van Leeuwen for technical assistance.

Probing Theories of Speech Timing using Optimization Modeling

Andreas Windmann[1], *Juraj Šimko*[2], *Petra Wagner*[1]

Abstract

We implement two theories about the temporal organization of speech in an optimization-based model of speech timing and conduct simulation experiments in order to test whether both theories can account for the phenomenon of foot-level shortening (FLS) observed in English speech corpora. Results suggest that a model that induces compensatory timing relations between syllables and feet predicts empirical results very accurately. However, we also observe that the FLS effect can equally well be explained under the assumption that suprasegmental timing is confined to localized lengthening effects at the heads and edges of prosodic domains. Implications for theories of speech timing are discussed.

Index Terms: Speech timing, computational modeling

1. Introduction

In this paper, we shall test predictions made by two theories of suprasegmental speech timing. To this end, we will employ a computational optimization model [1], by implementing both theories in the model and evaluating modeling results against attested speech timing patterns of English. Results allow for comparing the empirical adequacy of different predictions and demonstrate the potential of our model as a test bed for different theories of suprasegmental speech timing.

The phenomenon under study is polysyllabic shortening, i.e. the property of syllables to shorten as a function of the number of syllables in some larger prosodic unit. We will concentrate on foot-level shortening (FLS), an alleged shortening effect triggered by the interval from a lexically stressed syllable onset to the next, possibly spanning word boundaries [2]. While not leading to true periodicity of stressed syllable onsets, FLS in English does seem to be well-supported by both experimental studies [3, 4, 5] and corpus analyses [6, 7, 8, 9]. Figure 1 shows two examples of FLS patterns found in English speech corpora, as evident from vowel rather than syllable durations. There is a marked shortening effect on stressed vowel durations which is, however, not linear but seems to be attenuated as syllable count in the foot increases. Similar patterns have been observed in experimental studies and could be interpreted as an effect of durations moving towards a compressibility threshold [12]. Figure 1 does not indicate FLS in unstressed syllables, which has been linked to incompressibility as well [13]. However, [10] do report consistent shortening effects of various prosodic constituents also on unstressed vowel durations.

Findings on FLS seem to support theories in which prosodic timing effects are distributed over larger prosodic domains, leading to inverse relationships between the number of syllables assembled in these domains and the durations of those syllables [14, 2]. This has been explicitly formalized in a class of computational models which assume that the temporal organization of speech is governed by oscillatory mechanisms at different levels of the prosodic hierarchy [15, 16, 17, 18, 9]. On this account, surface speech timing patterns emerge as a result of an interaction, or *coupling*, between the different oscillators, as a result of which they entrain to a stable frequency pattern. FLS would be explained to arise from hierarchical coupling between a dominant oscillator at the inter-stress interval or foot level and a more compliant syllabic oscillator, thus generating a tendency for stressed syllables to reoccur at regular intervals.

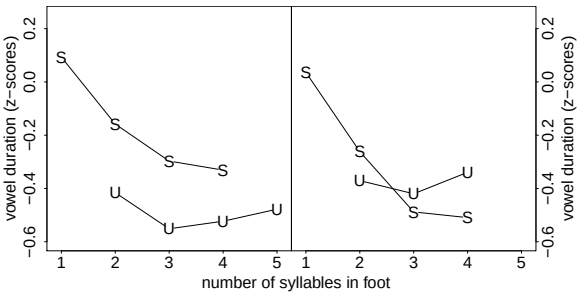

Figure 1: *Foot-level shortening effect on mean stressed (S) and unstressed (U) vowel/syllable durations in English. Graphs are reproduced from numerical results for two speakers from [8].*

In contrast to this, [19] and [20] propose a theory in which suprasegmental timing mechanisms are confined to localized lengthening at the heads and edges of prosodic domains. In this theory, there is little or no role for "domain-span effects", a term used by these authors to denote precisely the kind of inverse timing relationships that oscillatory approaches would predict. [19] and [20] base their claims on experimental findings suggesting that purported shortening effects at the word level in English can be largely accounted for by combinations of localized lengthening effects, such as accentual lengthening and word-final lengthening. However, [20] concede that their model may not necessarily account for FLS effects, which makes it a promising prospect to test for foot-level effects explicitly.

In this paper, we shall investigate whether both theories can account for FLS effects observed in English speech corpora. This will be done by implementing the mechanisms proposed by both theories, informally referred to as the "distributed" vs. the "localized" timing account, in our optimization-based model of speech timing. Predictions made by both theories will then be tested on input data derived from an authentic speech corpus and compared to published results. The paper is structured as follows: in section 2, we describe the general architecture of our model and the additions implemented in order to

accommodate the distributed and the localized timing account. Results of simulation experiments are presented in section 3 and discussed in section 4. Section 5 concludes the paper and addresses perspectives for further work.

2. Model Architecture

Our model is inspired by Hypo & Hyper-articulation (H&H) theory [21], implementing the assumption that speech patterns emerge from the resolution of conflicting demands related to minimization of effort and maximization of communicative success. It derives from an embodied optimization model of articulatory timing [22, 23]. The current model operates on specifications of sequences of lexically stressed and unstressed syllables, representing speech utterances. Given an input sequence, an optimization algorithm computes the vector S of syllable durations that minimizes the composite cost function C. C is a weighted sum of component functions that represent production and perception-related influences on constituent durations.

The basic architecture of the model includes three such components, D_S, T and P_S. D_S and T implement constraints associated with efficiency of information transmission. The durational cost component T captures the overall duration of the utterance, i.e., the time used for conveying the message encoded in the sentence of a part thereof. This component provides a control mechanism for overall speech tempo. D_S is proportional to individual syllable durations, based on the assumption that the syllable is a basic unit of information which speakers strive to transmit in an efficient manner. Motivation for having both T and D_S in the model comes from evidence that different mechanisms may be responsible for changes of local durations and overall speaking rate, cf. [24] and references therein.

Conversely, component P_S represents an impetus to maximize perceptual clarity, by imposing costs on the reciprocal of syllable durations. P_S thus decreases with syllable duration in a convex decaying fashion, assuming that very short durations impede perception while facilitation induced by durational lengthening will eventually reach a ceiling. Independent evidence for this modeling decision comes from gating studies, where subjects have to identify phonemes from acoustic syllable fragments of varying duration [25, 26].

Weighting factors allow for globally imposing premiums on the individual components in order to simulate requirements regarding efficiency (α_D), perceptual clarity (α_P) or overall speaking rate (α_T). The vectors δ_S and ψ_S, assigning weights to individual syllables, can be used to boost their relative perceptual clarity and simultaneously lower the premium on efficient information transmission. This mechanism is used to account for prosodic prominence in the model, assuming that speakers prioritize clarity over efficiency in prominent syllables [27]. We usually set δ_S to the reciprocal of ψ_S, in order to reduce the number of free parameters. Formally, the basic model is thus defined as

$$C = \alpha_D \sum_S \delta_S D_S + \alpha_P \sum_S \psi_S P_S + \alpha_T T \qquad (1)$$

In order to accommodate the distributed timing account, we implemented a version of the basic model with two additional component costs, D_F and P_F, together with respective weighting factors α_{DF} and α_{PF}. D_F and P_F are basically copies of D_S and P_S operating at the stress foot rather than the syllabic level. Thus, the two new components in combination impose a tendency to produce stress feet with a certain optimal duration, while D_S and P_S tend to converge to optimal syllable durations. This leads to an obvious trade-off and will trigger compensatory relationships for feet with different syllable counts. By setting the respective weighting factors, precedence can be given to either the foot or the syllabic level, simulating purported tendencies towards "stress timing" and "syllable timing", respectively. This architecture is conceptually very similar to the coupled oscillator models mentioned above. Independent motivation for such a design might be derived from findings on convergence of syllable and foot durations with certain temporal windows of cognitive processing [28]. Figure 2 visualizes the architecture of the distributed timing model.

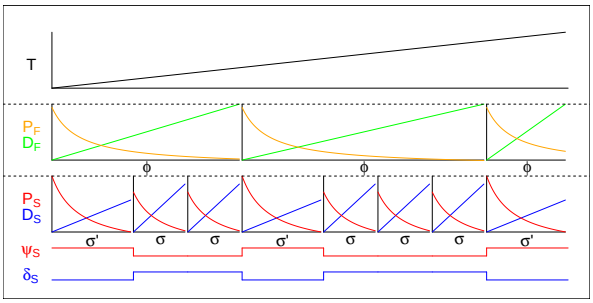

Figure 2: *Distributed timing model. Cost functions T (utterance level), D_F/P_F (stress foot level; ϕ) and D_S/P_S (syllabic level; σ; ' denotes lexical stress) as well as parameters δ_S and ψ_S are plotted as a function of respective constituent durations for a hypothetical utterance consisting of a trisyllabic, a tetrasyllabic and a monosyllabic foot. α_{DF} and α_{PF} are not shown.*

For the localized timing account, no additional cost functions had to be supplied. Its predictions were implemented by additionally enhancing ψ_S and thus boosting the perception-oriented component P for word-final syllables, leaving the model definition in (1) unchanged otherwise. This approach is in keeping with [19]'s reasoning that localized lengthening is utilized to increase the perceptual salience at important points in the speech signal, in this case word boundaries. There are thus no "domain-span" mechanisms in this version of the model (note that T does not induce compression as a function of utterance length if it is linear); only localized lengthening effects at the heads (stressed syllables) and edges (word-final syllables) of words are included. No attempt was made in either of the two versions of the model to incorporate utterance-final lengthening, since utterance-final syllables have usually been excluded in investigations of FLS. Effects of syllable structure and pitch accent were also ignored for the present purpose. Figure 3 visualizes the architecture of the localized timing model.

3. Simulations

Input data for the simulation experiments were derived from the Aix-MARSEC database, a corpus of English broadcast speech [29, 30, 31]. That is, we prepared input "utterances" for the model that were based on actual utterances from the corpus in terms of number of syllables and locations of lexical stress and word boundaries. The Aix-MARSEC database is ideally suited for this purpose because FLS and shortening effects in other domains have been documented in this corpus [6, 10].

Both versions of the model were implemented in R using the built-in optimization function *optim*. In order to keep computing time within reasonable limits, input data were restricted to 2000 utterances from the corpus, amounting to 7512 sylla-

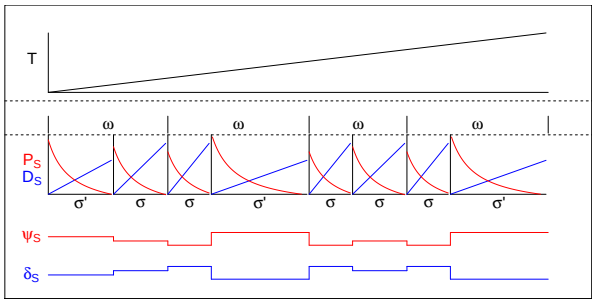

Figure 3: *Localized timing model. The utterance is the same as in Figure 2. The middle panel shows word boundaries (ω). Note the differentiation for word-final vs. non-final syllables in ψ_S and δ_S (in addition to stressed/unstressed differentiation).*

bles. Utterance-initial exametrical syllables, i.e., unstressed syllables not contained in a foot, were excluded. For the simulation with the distributed timing model, we set α_D and α_P to 0.5 and α_{DF} and α_{PF} to 1 in order to simulate the hypothesized dominant timing influence of the foot. ψ_S was set to 2 for lexically stressed and 1 for unstressed syllables, and δ_S was set to $1/\psi_S$, as explained above. All other parameters were set to 1. Simulation results from the distributed timing model are shown in Figure 4.

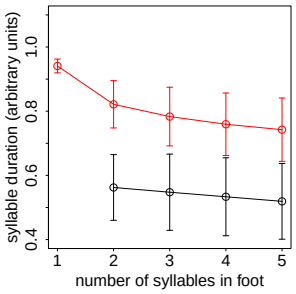

Figure 4: *Results from distributed timing model simulation for stressed (red) and unstressed (black) syllables.*

The distributed timing model reproduces the general pattern shown in Figure 1 remarkably well, particularly for the stressed syllables, which exhibit a marked asymptotic shortening tendency. The model does predict a consistent shortening effect in unstressed syllables as well, but it is quite weak compared to the effect in stressed syllables. Given that many other sources of durational variation are not taken into account in this version of the model, it may be assumed that the shortening effect on unstressed syllable durations is likely to vanish if simulations are carried out with a more full-blown model architecture. The fact that syllables shorten as a function of foot length is in itself of course rather trivial, given that the parameter settings impose temporal compression at the foot level. What is non-trivial about this result, however, is that the model (1) captures the asymptotic nature of the shortening effect in stressed syllables and (2) reproduces the finding of a weaker effect in unstressed syllables. We believe that both outcomes are indeed a consequence of incompressibility, which has been shown to emerge automatically from the architecture of our model [1].

The localized timing model was run on the same input data as the distributed timing model. In this simulation, ψ_S was increased by 0.5 for word-final syllables in order to simulate word-final lengthening. All other parameter settings were the same as in the distributed timing model simulation. Monosyllables were counted as final. Results are shown in Figure 5. Surprisingly, the localized timing model also captures the pattern of results shown in Figure 1 quite well, with asymptotic shortening in stressed and a weaker effect in unstressed syllables. The magnitude of the effect is somewhat smaller than in the distributed timing model simulation, but this of course depends on the exact numerical setting of the parameter values. The important result is that the localized timing model can account for the overall pattern of results. This is a striking finding, given that no explicit timing mechanism at the foot level is included in this version of the model.

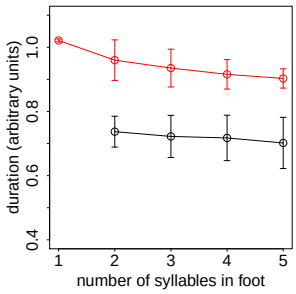

Figure 5: *Results from localized timing model simulation for stressed (red) and unstressed (black) syllables.*

On this account, the explanation for the FLS effect would be an entirely different one: rather than a genuine tendency towards temporal compression at the foot level, the phenomenon would be a mere statistical artifact, arising from an apparent tendency for word-final syllables to occur in shorter feet. An analysis of the whole MARSEC corpus was conducted in order to substantiate this correlation. We computed the probability of a syllable being in word-final position as a function of syllable count in the respective foot, by dividing the number of word-final syllables occurring in feet of a given length by the total syllable count for the respective foot length in the corpus. This was done separately for stressed and unstressed syllables. Results are shown in Figure 6. As can be seen, the probability of a syllable occurring in word-final position indeed decreases as a function of syllable count in the foot, in a fashion which is strikingly similar to the durational effect.

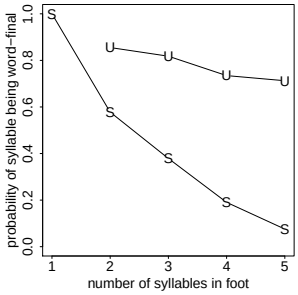

Figure 6: *Probability of syllables occurring in word-final position as a function of foot length in the MARSEC corpus.*

Upon closer inspection, this pattern of results is actually hardly surprising: if a stressed syllable is directly followed by

another stressed syllable and thus constitutes a monosyllabic foot, there is necessarily a word boundary intervening, since by definition, a word cannot contain more than one primary stressed syllable. The probability of being word-final therefore has to be one for monosyllabic stress feet. For bisyllabic feet, the probability of the stressed syllable being word-final is much lower – any bisyllabic word with initial stress followed by any word with initial stress will make for a non-word-final observation here – but there are still two frequent patterns that will generate final observations, 1) words with final stress followed by bisyllabic words with final stress, as in "[STAY a]WAKE", and 2) sequences of a word with final stress, a weak function word and a word with initial stress, as in "[JOHN the] BAPtist" (brackets mark target foot boundaries). For successively longer feet, the frequency of patterns that allow for word-final stressed syllables decreases – it is hard to imagine a pattern with a word-final stressed syllable followed by four unstressed syllables.

For unstressed syllables, the probability of occurring in word-final position decreases with foot length as well, but the effect is much weaker than in stressed syllables. A possible explanation is that longer feet are likely to involve polysyllabic words. In this case, some of the unstressed syllables in a long foot will be word-initial or medial, resulting in a weaker correlation between foot length and the probability to occur word-finally for unstressed syllables. This would explain the weaker or absent effect of foot length on unstressed syllables in the durational domain under a localized timing account.

4. Discussion

Our results show that both the distributed and, interestingly, also the localized account of speech timing can reproduce FLS patterns observed in English speech corpora. In the distributed timing account, the effect would be explained as a tendency towards periodicity of stressed syllable onsets, resulting from a trade-off between realizing optimal syllable and foot durations. Under the localized timing account, FLS would be classified as a mere by-product of language structure, i.e., the stronger tendency for syllables in shorter feet to occur word-finally, where they are subject to a localized lengthening effect.

If the distributed timing theory is correct, our implementation provides a promising explanatory platform for the FLS effect. Crucially, the model not only produces longer syllables in shorter feet, but also captures the precise nature of the shortening effect intriguingly well. We would therefore argue that our distributed timing model offers a more satisfactory account of the phenomenon than the oscillatory approach described in [17], who have to introduce ad-hoc assumptions in order to replicate the difference between stressed and unstressed syllables reported by [7]. [17] effectively "switch off" FLS in unstressed syllables, but it may well be that the effect was just masked by noise from other durational processes in [7], in keeping with our model's predictions. Indeed, [8] reports on the same data that unstressed durations do exhibit a significant shortening effect once the number of *phones*, rather than syllables per foot is used as the independent variable. Since [17] only compare bi- and trisyllabic feet, it is also not clear if their oscillatory model captures the non-linear nature of the shortening in stressed syllables. In our distributed timing model, both the weaker effect in unstressed syllables and the attenuation of the shortening effect in stressed syllables emerge automatically from the independently motivated property of durational incompressibility.

Results of the localized timing model simulations, however, show that it may be entirely unnecessary to invoke a timing mechanism at the foot level in order to reproduce the empirical results. This would be in keeping with [19]'s claim that "domain-span effects" have been falsely attributed to English due to ignorance of confounding influences such as final or accentual lengthening. Word-final lengthening in particular seems to be a well-attested effect in English [32, 33], although it is not entirely uncontroversial [34]. Of course, it cannot be decided based on our simulation results whether word-final lengthening is the trigger of a spurious FLS effect, or if, on the contrary, word-final syllables are longer than non-final ones *because* they tend to occur in shorter feet.

Thus, while our simulation results show that both accounts can generate the observed pattern, they do not allow for falsifying either theory. The predictions of the localized timing model converge with results by [19] and [20], as well as [33], who reports that in his large-scale corpus study, an apparent FLS effect on vowel durations disappears once a vowel's distance to the right word boundary is controlled. On the other hand, it seems that the localized timing model cannot fully account for *experimental* findings on FLS. For example, [5] report that a word-final stressed syllable is longer in a monosyllabic than in a bisyllabic foot, which is also acknowledged by [19] and [20]. There may be alternative analyses, such as a kind of stress clash effect here, however.

We have not tested for shortening effects in domains other than the stress foot. Results from [19, 20] and [33] are compatible with a domain-span effect at the *word rhyme* level, the unit that stretches from the onset of a stressed syllable to the next word boundary, alternatively referred to as *narrow rhythm unit* [35, 10]. However, [20] raise the possibility that this may in fact be a progressive word-final lengthening effect. Further empirical study is necessary in order to decide on these issues.

5. Conclusions

Using optimization modeling, we have shown that a model architecture that imposes distributed timing mechanisms can well account for patterns of foot-level shortening observed in English speech corpora. However, the effect may equally well be explained in a model of speech timing that only includes localized lengthening effects due to a tendency for shorter feet to contain mostly word-final syllables.

From a methodological point of view, results of our simulation experiments confirm that our optimization-based model provides a promising test bed for different theories of speech timing. The model itself is of course not theory-neutral, but it appears that the H&H assumptions it is based on are sufficiently general to accommodate other theories. Detailed studies on empirical data, including proper control for possible sources of durational variation, are required in order to determine which model architecture correctly captures the suprasegmental organization of English speech timing.

The influence of accentuation and onset complexity on gestural timing within syllables

Abstract

This paper presents results from a production experiment using electromagnetic articulography. The main aim of the study was to investigate how phrasal accent and the number of onset consonants influence the gestural timing of syllable constituents in German. Five speakers of German with sensors attached to the tongue tip, tongue body and lower lip were recorded reading sentences with either accented or unaccented target words that contained simplex (one consonant) and complex (two consonants) onsets. The nucleus was always /a/ and the coda consonant was always /p/. We analyzed acoustic segment duration and gestural overlap (in terms of lag measurements). Onset complexity influenced both CV and VC overlap and accentuation affected gestural overlap to a greater extent than acoustic vowel duration. However, the extent of overlap differed between segment sequences and accentuation patterns: while for CC and VC sequences trends for greater overlap in deaccented than in accented condition were found, CV overlap decreased with deaccentuation. Shorter plateau durations in this context explain the diminished CV overlap in a prosodically weak context. The findings are discussed with respect to the predictions made by articulatory phonology regarding gestural timing and with respect to timing stability in weak versus strong prosodic contexts.

Index Terms: Phrasal accentuation, incremental shortening, Articulatory Phonology, EMA

1. Introduction

This study addresses the challenge of investigating the timing of articulatory gestures between all syllable constituents (i.e. onset, nucleus, and coda) in two prosodic conditions and drawing the connection between gestural coordination and variation in acoustic duration.

Segments tend to be shorter in prosodically weaker contexts (i.e. unstressed syllables, deaccented words, at low prosodic boundaries) than in prosodically stronger contexts (i.e. lexically stressed syllables, accented words, at high prosodic boundaries). In particular, vowels were shown to differ in duration with respect to lexical stress and phrasal accent [1]. For consonants, lengthening has been found in the vicinity of high prosodic boundaries [2, 3]. Most studies showing prosody-dependent duration differences are based on acoustic measurements. Acoustic shortening, however, may not always be due to a reduction of the articulatory gestures, but instead to a greater degree of overlap between two gestures that occur in prosodically weak contexts [e.g. 3]. In addition, prosodic reduction effects may also be seen in spatial instead of temporal reduction. In particular, [4] showed that lax as opposed to tense vowels were spatially but not temporally reduced and thus not acoustically shortened.

Segmental duration is not only influenced by prosody but also depends on a couple of other factors. For example, vowels are shorter before obstruents than before sonorants. The duration of the vowel, which usually constitutes the syllable's nucleus, is also affected by the number of the adjacent consonants: vowels flanked by consonant clusters (henceforth complex) tend to be shorter than vowels flanked by single consonants (henceforth simplex). This phenomenon – commonly known as incremental compensatory shortening [5] – seems to be both language specific and dependent on syllable position. According to studies conducted in the framework of Articulatory Phonology (e.g. [6, 7]) vowels are shortened only by preceding but not by following clusters. This prediction arises from the assumption that onset clusters are globally timed, i.e. consonants are organized around a stable midpoint of the cluster – the c-center – causing vowel remote consonants to move away from the nucleus and vowel adjacent consonants to move towards the vocalic nucleus resulting in an increased overlap between the consonant and the following vowel (henceforth CV overlap) [8]. Coda clusters, on the other hand, are assumed to be locally timed, i.e. consonants are in sequential order, therefore not causing any increase in overlap between the vowel and the following consonant (henceforth VC overlap) and vowel shortening. But [9] found a trend towards more vowel shortening before coda clusters in sonorant, accented tokens as opposed to other contexts as well as an influence of accentuation on acoustic vowel duration. In addition, [10] found that onset manner had an influence on VC(C) timing, i.e. the vowel adjacent coda consonant shifted towards the vowel if the onset consonant was a lateral but not if the onset consonant was a nasal.

Previous studies using electropalatography (EPG) and electromagnetic (midsagittal) articulography (EM(M)A) found that prosodic strength affects duration and overlap of consonantal onset clusters. For example, [2] and [3] both found that overall cluster gestures in prosodically weaker contexts were shortened. With respect to overlap, [3] found that consonantal overlap decreased in stressed position and at higher prosodic boundaries. [11], however, reported more overlap when the target words were uttered in focus position than when produced in unaccented position. [11] explained their findings with a shortening of the gesture's plateau in prosodically weaker contexts (instead of indirect shortening due to more overlap).

The aim of this study was to further investigate the interplay between accentuation and articulatory timing patterns with respect to all syllable constituents, i.e. coda and onset consonants (C) as well as the vocalic nucleus (V). We extend our study to prosodic effects on CC, CV and VC overlap and plateau shortening. In particular we are interested in the effects of accentuation and cluster coordination on vowel shortening and VC organization. Three hypotheses were tested:

H1 There is more CV overlap in words with complex onsets than in words with simplex onsets.

H2 There is more overlap in the deaccented condition compared to the accented condition concerning all syllable constituents, i.e. CC, CV and VC sequences.

H3 If there is, however, less overlap in deaccented tokens, than plateau durations should be shortened.

2. Method

2.1. Speech Material and experimental set-up

The test items were non-existent monosyllabic words (representing monomorphemic words) that contained the lax vowel /a/. The vowel was preceded by either simplex (/n/) or complex (/kn/) onsets. The coda was kept simplex containing the labial stop /p/. All test words were produced in sentence medial position in the carrier phrase *"Melanie's Omi* [target word] *imitiert ein Lied." ("Melanie's grandma* [target word] *imitates a song.")* with only one intermediate (and thus one intonation) phrase. This test sentence was chosen as it allows for optimal tracking of the articulators. Each test word indicated the name of Melanie's grandma. The test sentence contained one pitch accent that was either on *Melanie's* (i.e. the target word was deaccented) or on the target word. In order to elicit the test words in accented and deaccented position, we first familiarized the participants with two questions that are each associated with one prosodic pattern. *"**Wessen** Omi* [target word] *imitiert ein Lied?"("**Whose** grandma* [target word] *imitates a song?")* was used to evoke the pitch accent on *Melanie's* in the deaccented condition. The question "***Welche** Omi von Melanie imitiert ein Lied?"* (*"**Which** grandma of Melanie imitates a song?"*) was used to trigger a pitch accent on the target word in the accented condition. In addition, during the recordings, blue coloured letters drew attention to the words that were to be produced with a pitch accent. The experimenter ensured that subjects corrected any incorrect prosodic patterns.

Articulatory recordings were made in a sound attenuated booth at the Institute of Phonetics in Munich. The movement of speech articulators was tracked using 3D Electromagnetic Articulography (EMA, AG 501) [12]. In total, twelve EMA receivers were attached to various parts of each speaker's head. The sensors included in the current analysis were those attached to the tongue tip (TT), tongue back (TB) and to the upper and lower lips (LA). Seven repetitions of each sentence were presented isolated in randomized order on a computer screen.

2.2. Participants

Five speakers (3 females, 2 males) of Southern Standard German aged between 19 and 25 were recorded. None of them reported any hearing or speaking disorders. Three out of the five participants were undergraduate students of phonetics, but they were naïve as to the purpose of the experiment. One participant was the first author of this paper.

2.3. Data analysis

The acoustic data was automatically segmented and labeled using MAuS [13]. Segment boundaries were hand-corrected using praat [14] where necessary and the target word's accentuation pattern (i.e. accented vs. deaccented) was manually labeled. For the present study, we only analyzed temporal articulatory measures, i.e. specific moments in time of vertical and horizontal movements of the relevant sensors. The physiological data was labeled using Emu [15]. The target words' components /k/ and /a/ labels were set based on the vertical movements of the tongue back. For /p/, the lip aperture was calculated as the Euclidean distance between upper and lower lips. For /n/ the tangential velocity of the tongue tip was used. The plateau's onsets and offsets were defined on the basis of changes in the articulators' velocity, which are interpolated values and represent the 20% threshold of the difference between two adjacent maxima in the velocity signal. Prior analyses have shown that vowels vary acoustically depending on the presence or absence of a pitch accent on the target word and also on the number of consonants within a cluster (see e.g. [9, 16]). Because of this (potential) variability, we did not use normalization methods usually applied in c-center studies as they normalize on anchor points using either the following coda consonant [7] or the acoustic vowel midpoint (e.g. [17]). Instead we used the normalization method described in [18]. Following this method, we first determined the lag between two neighboring segments and then normalized the lag on the entire duration of the two gestures. For measuring CC_{lag}, the first consonant's ($C1_{on}$) plateau offset (P_{off}) was subtracted by the second consonant's ($C2_{on}$) plateau onset (P_{on}) and divided by the entire gesture (G) as described in the following equation. Using the start and end of the gesture's plateau was found to be the most stable timing measure, i.e. the one with the lowest variation coefficient [19].

$$CC_{lag} = \frac{P_{on}[C2_{on}] - P_{off}[C1_{on}]}{G_{off}[C2_{on}] - G_{on}[C1_{on}]} \quad (1)$$

The same procedure was applied to the CV_{lag} and VC_{lag} with the exception of subtracting the consonant's ($C2_{on}$) plateau offset by the vowel's (V) plateau onset and the vowel's plateau offset by the coda consonant's ($C1_{off}$) plateau onset (cf. equations (2) and (3)), respectively. Thus, lower lag values indicate more overlap.

$$CV_{lag} = \frac{P_{on}[V] - P_{off}[C2_{on}]}{G_{off}[V] - G_{on}[C2_{on}]} \quad (2)$$

$$VC_{lag} = \frac{P_{on}[C1_{off}] - P_{off}[V]}{G_{off}[C1_{off}] - G_{on}[V]} \quad (3)$$

Plateau durations were calculated by subtracting the plateau onset by the plateau offset of each gesture. Figure 1 schematically displays the specific landmarks used for analysis.

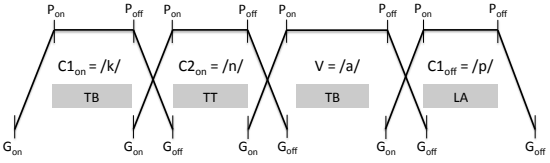

Figure 1: *Schematic illustration of gestures and landmarks used in the present analysis.*

For the statistical analyses we conducted repeated measures ANOVAs. CC_{lag}, CV_{lag}, VC_{lag} and plateau durations of all syllable constituents each served as the dependent variable. ONSET COMPLEXITY (simplex vs. complex) and ACCENTUATION (accented vs. deaccented) were the independent variables. Speaker was entered as a random factor.

3. Results

3.1. Acoustic vowel durations

Prior to the articulatory analyses, we tested whether onset clusters and different prosodic patterns acoustically influenced lax vowels. The results show that, especially in the accented condition, there was vowel shortening due to complex onsets (mean = 66.9ms) compared to simplex onsets (mean = 76.3ms). There was no vowel shortening due to deaccentuation. In spite of this result, there may be articulatory shortening (see [4] for discussion).

3.2. CC_{lag} and plateau durations

In order to account for the influence of ACCENTUATION on the temporal organization of onset clusters and plateau durations, we analyzed the CC_{lag} between /k/ and /n/ in accented and deaccented words (i.e. only words containing complex onsets were used).

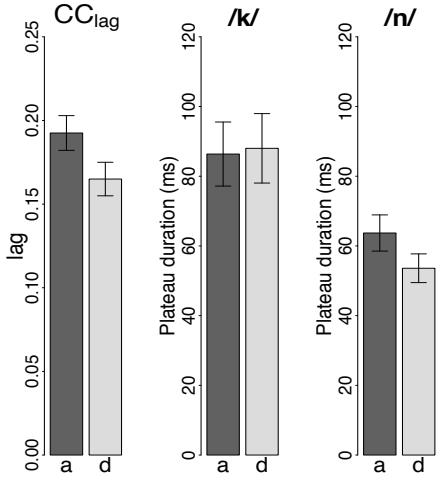

Figure 2: *CC_{lag} (left) between /k/ and /n/, plateau durations for /k/ (middle) and /n/ (right) in accented (a; dark grey) vs. deaccented (d; light grey) tokens.*

ACCENTUATION did not significantly affect the timing of onset clusters. However, a trend towards more overlap in terms of lower lag values can be observed in the deaccented condition in the left plot of Figure 2. This means that there was a tendency towards more overlap in deaccented than in accented words.

Concerning plateau duration of /k/ and /n/, there was no significant effect of ACCENTUATION. While the middle plot of Figure 2 shows that plateau durations of /k/ were about the same in accented and deaccented condition, the right plot of Figure 2 indicates tendencies for shorter plateau durations in deaccented words although, again, this was not statistically significant.

3.3. CV_{lag} and plateau durations

In order to investigate the influence of ONSET COMPLEXITY and ACCENTUATION both on the timing between the vowel adjacent onset consonant ($C2_{on}$) and the vowel and on plateau durations, we analyzed words containing both simplex (/n/) and complex (/kn/) onsets.

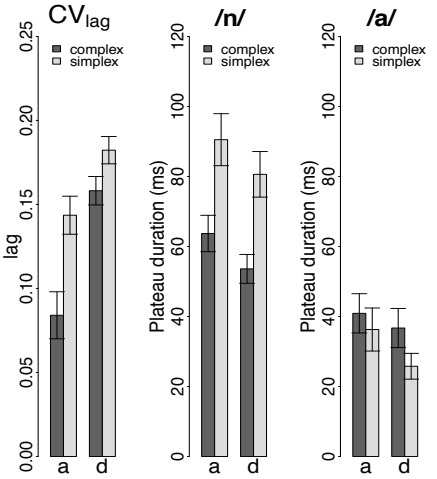

Figure 3: *CV_{lag} (left) between /n/ and /a/, plateau durations for /n/ (middle) and /a/ (right) in accented (a; dark grey) vs. deaccented (d; light grey) tokens.*

ACCENTUATION had a significant ($F[1,4]=18.6$, $p<0.05$) influence on the timing of $C2_{on}$ and the following vowel. There were higher lag values in the deaccented condition (cf. Figure 3.). This means, that, in general, there was less overlap in deaccented words compared to accented words.

The independent variable ONSET COMPLEXITY had no significant effect, although, again, a trend towards more overlap in terms of lower lag values can be observed in complex onsets compared to their simplex counterparts (cf. Figure 3), indicating a shift towards the vowel. This trend was much more pronounced in the accented than in the deaccented condition. That is, although there was no significant interaction, the effect of ACCENTUATION, tended to be greater in words containing complex onsets as opposed to simplex onsets (cf. left plot of Figure 3).

Concerning plateau duration of /n/, there was a significant influence of ONSET COMPLEXITY ($F[1,4]=12.3$, $p<0.05$). The plateau duration was shortened in complex onsets compared to simplex onsets in both prosodic conditions. There was no effect of ACCENTUATION.

For /a/, however, only the independent variable ACCENTUATION significantly influenced the plateau duration ($F[1,4]=67$, $p<0.01$). That is, the vowel's plateau was shortened in deaccented words although there was no shortening effect due to deaccentuation in the acoustics. ONSET COMPLEXITY did not effect the nucleus' plateau duration.

3.4. VC_{lag} and plateau durations

In order to investigate the influence of ONSET COMPLEXITY and ACCENTUATION both on the timing between the vowel and the following consonant ($C1_{off}$) and on plateau durations, again, we differentiated between simplex (/n/) and complex (/kn/) onsets.

Concerning VC sequences, the results have shown that neither ONSET COMPLEXITY nor ACCENTUATION had a significant influence on the timing between the vowel and $C1_{off}$. However, again, a trend towards more overlap in terms of lower lag values in the deaccented condition can be observed (cf. left plot of Figure 4). That is, there was a

tendency towards more overlap in words produced without a pitch accent compared to words produced with a pitch accent.

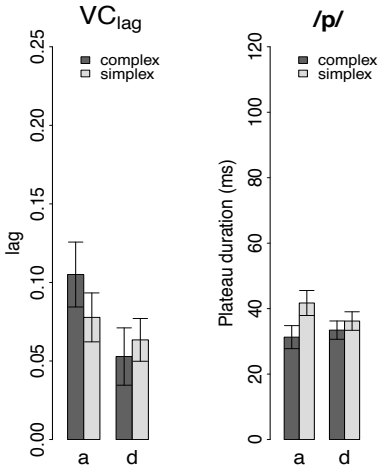

Figure 4: *VC_{lag} (left) between /a/ and /p/, plateau durations for /p/ (right) in accented (a; dark grey) vs. deaccented (d; light grey) tokens.*

The vowel plateau duration was significantly influenced by ACCENTUATION (cf. right plot of Figure 3), as described in the section above. Concerning /p/, there was a significant influence of ONSET COMPLEXITY ($F[1,4]=60.8$, $p<0.01$). This means that the coda's plateau was shortened as the number of onset consonants increased.

4. Discussion and Conclusion

The results of the present study are somewhat tentative as only some of the main and none of the interaction effects reached significance. This may be due to the general weak temporal compression effects in lax vowels (see for example [4]). In addition, there were only five speakers producing seven repetitions of four tokens (accented vs. deaccented; simplex vs. complex), i.e. the statistical power may have been too low. Nevertheless, clear trends showed that accentuation differently affects the gestural timing within a syllable depending on onset complexity. In particular, accentuation significantly influenced CV overlap and the vowel's plateau duration whereas onset complexity had a significant effect on the plateau duration of the vowel-adjacent consonants.

Concerning CC sequences, there was a trend towards more overlap in deaccented words. This finding partially supports hypothesis H1 and is in line with [2] and [3]. Despite this trend we found tendencies towards shorter plateau durations of $C2_{on}$ in the deaccented condition, although [2] found gestural lengthening of this consonant in lexically stressed position. Thus, contrary to the predictions made in hypothesis H3, plateau shortening may also co-occur with more overlap.

There were two findings regarding CV sequences: first, consonants preceding vowels are shifted into the vowel in complex onsets confirming hypothesis H1. This result supports the predictions made by Articulatory Phonology [8]. The second one is that the CV lag is greater in deaccented than in accented tokens, which can be explained by shorter plateau durations of both, /n/ and /a/. This result contradicts hypothesis H2 and confirms hypothesis H3 and thus is in line with findings described in [11].

In addition, we found that the cluster dependent shift tends to be greater in accented than in deaccented tokens. This may be explained by additional lengthening of the plateau duration in accented as opposed to deaccented tokens, which may then result in a greater shift into the vowel. This is not to say that articulatory lengthening in principal results in more overlap. Articulatory strengthening should cause greater coarticulatory resistance [20] resulting in less overlap (e.g. there was a tendency towards less overlap in accented CC sequences). In this particular case of incremental onset shortening, however, the shift towards the vowel seems to be stronger in the accented condition, because temporal overlap between longer plateau gestures (due to accentuation) is reached faster. This means that the predictions made by Articulatory Phonology depend not only on syllable position (i.e. onset vs. coda clusters) or the cluster's composition (cf. [16]), but also on prosodic structures.

Concerning VC sequences, there was a trend towards more overlap in deaccented words, which is again in line with [2] and [3] and partially supports hypothesis H1. Despite this trend, we found shorter plateau durations of the vowel in the deaccented condition. This again indicates that shorter plateau durations can also co-occur with increased overlap. In addition, the onset complexity influenced the VC timing. There was more CV overlap but less VC overlap in the accented condition. Moreover, the onset composition also affected the plateau duration of the coda consonant, i.e. there were shorter plateau durations of $C1_{off}$ as the number of onset consonants increases. This indicates that onsets and codas do not behave independently of each other within a syllable (see also [21]) and supports the findings presented in [10].

This study allows no direct comparison of plateau shortening between segments of different articulators, since the tongue tip is flexible resulting in short gestures and long plateau durations for nasals, whereas the tongue back moves slowly resulting in long vowel gestures and short plateau durations for vowels (cf. middle and right plot of Figure 3). For this reason, the results concerning plateau durations have to be extended by also taking into account gesture durations.

In summary, two major conclusions arise from this study. The first one is that lax vowels may be articulatorily compressed due to deaccentuation without showing acoustic shortening. The second one is that syllable constituents are affected differently by prosodic conditions and that onsets and codas do not behave independently of each other within a syllable. These findings need to be included in theories modeling syllable structure such as Articulatory Phonology.

Abstract

There is an increasing consensus to regard gesture and speech as parts of an integrated communication system, in part because of the findings related to their temporal coordination at different levels. In general, results for different types of gestures show that the most prominent part of the gesture (the apex) is typically aligned with accented syllables [6, 10-12, 14, 17]. The aim of the present study is to test for this coordination by focusing on head movements taken from a semi-spontaneous setting in order to look at the effects of upcoming phrase boundaries on their timing. Our results show that while apexes of head gestures are synchronized with accented syllables, upcoming phrase boundaries have an effect on the timing of three gestural points, namely the start, apex, and end time of head gestures. Crucially, these points are aligned differently with respect to the stressed syllable for trochees as compared with iambs/monosyllables, showing that head nods are retracted before upcoming phrase boundaries. This result corroborates previous results by Esteve-Gibert & Prieto [17] for pointing gestures in laboratory settings.

Index Terms: audiovisual speech, head gestures, prosodic structure, face-to-face communication, Catalan

1. Introduction

In face-to-face communication, meanings and intentions are conveyed by means of multimodal strategies, i.e., through both audio and visual channels. In fact, there is progressively more consensus on the idea that gesture and speech both form part of the same system of human communication [1-7]. McNeill [8] listed five main reasons to justify the tight relation between the two modalities: that they (1) co-occur in 90% of cases, (2) develop together in children, (3) are phonologically synchronous, (4) are semantically and pragmatically co-expressive, and (5) break down simultaneously in aphasia.

Several experimental studies have focused on the third of these reasons, namely that gesture and speech are synchronous from a phonological point of view. A number of these studies have found that temporal coordination can be observed between the phases of a gesture movement and related phonological events, in that the prominence in gesture and the prominence in speech co-occur in time [6, 9-14] [see 25 for an overview]. Yet, there is some debate as to what moments or events constitute the anchor points for this alignment between gesture and speech prominence. For the gesture movement, it is generally agreed that the prominence should be located in the *stroke phase*, i.e., the interval of time in which there is a peak of effort [8], or, even more precisely, at the *gesture apex*, i.e., the specific point in time (i.e., not an interval) in which the movement reaches its kinetic 'goal' [15].

There is less consensus on what constitutes the prominent part of speech that temporally coordinates with gesture. In several studies the prominent part of speech is understood as the focused word in the discourse, and they conclude that the stroke of the gesture coordinates with that word [9, 13, 16]. However, other studies take the lexically stressed syllable of (especially) that focused word as the key anchor for the gesture prominence, finding that the stroke of the gesture and the gesture apex coincide with the stressed syllable [10, 12]. And yet other studies integrate the two previous accounts and find that what aligns with the prominent part of the gesture is not simply the stressed syllable of the word in contrastive focus position, but more precisely the moment at which the pitch peak is produced within this contrastive stressed syllable [6, 11, 14, 17].

Esteve-Gibert & Prieto [17] analyzed the coordination between the gesture apex of a pointing gesture and the intonation peak in target words produced with different stress patterns (trochees, iambs, and monosyllables) by Catalan-speakers. Crucially, these words were produced in a contrastive focus condition in order to trigger different positions of the intonation peak within the stressed syllable. They found that the gesture apex and F0 peak co-occurred in time: whereas they were located at the end of the stressed syllable for trochees, they were associated with the middle of the stressed syllable for iambs and monosyllabic words. The main contribution of this article was to show that both intonation and gesture (pointing) movements were bound by prosodic phrasing, such that retracting effects occurred when there was an upcoming phrase boundary (as in monosyllables and iambs), while lagging effects occurred when there was no pre-tonic or post-tonic syllable after a preceding phrase boundary to contain part of the gesture prominence (i.e., in monosyllables).

It is important to point out that almost all the studies listed above described experimental research carried out in tightly controlled settings that hardly resemble natural interactions in face-to-face communication. Also, many of those who found that the gesture prominence coincides in time with the lexically stressed syllable analyzed deictic gestures. To our knowledge, only Loehr [18] investigated the temporal alignment between any kind of communicative hand movements (deictic gestures, iconic, and also beat gestures) and prosodic units (namely pitch accents and phrasing) in natural face-to-face interactions. Using the ToBI annotation system for American English (described in [19]), the author found that the gesture apexes coincided with pitch accents, and that the limits of the gesture phrase (defined as the combination of the gesture stroke and the preparation time needed for the gesture to reach the stroke) tended to coincide with the beginning of the intermediate phrases.

The aim of the present study is to investigate the role of two levels of prominence (accented syllables and prosodic boundaries) in the temporal coordination of head gestures and speech in semi-spontaneous face-to-face communication. Our specific purpose is to test the claim that the prosodic structure influences the timing of the gesture movement in the sense that the placement of the gesture apex within the stressed syllable depends on the metrical pattern of the target word. This has only been tested previously in laboratory settings in which participants did not have a specific communicative purpose while producing the speech and gesture signals. In the present study participants were engaged in a Guess Who game [20] and were not aware of the purpose of the study. An additional interest of the present investigation is that we focus our analysis on head gestures, which can have a potentially different behavior from other types of gestures like hand or eyebrow gestures (though some studies suggest that they show a behavior similar to that of arm and eyebrow movements; see [21] on beat gestures).

2. Methodology

2.1. Participants and procedure

Thirteen Central Catalan-speakers (1 male, 12 female), all of them undergraduates at the Universitat Pompeu Fabra in Barcelona, participated in a production task using two digital variants of the *Guess Who* board game as created by Suleman Shahid and colleagues at Tilburg University [22]. Participants played the game in pairs (i.e., with another native speaker), taking turns in adopting the different roles available. As Ahmad et al. [22] point out, the dynamic nature of games makes them a good tool for investigating human communication in different experimental setups, especially if the outcome of a game is controllable in a systematic manner.

In the *Guess Who* game, participants were presented with a board containing 24 colored drawings of human faces. These faces differed regarding various parameters, such as gender or the color of skin, hair, and eyes. Some faces were bald, some had beards or moustaches, and some were wearing hats, glasses, or earrings. As in the traditional version of *Guess Who*, the purpose of the game was to try to guess the opponent's mystery person before he or she could guess the participant's own. In this way, the game could be used to elicit in a naturalistic way target words with different metrical structures, namely trochees (e.g., *DOna* 'woman', *BARba* 'beard', *NEgre* 'black'), as well as iambs (e.g., *marRONS* 'brown', *barRET* 'hat', *verMELL* 'red') and monosyllables (e.g., *ROS* 'blond', BLAUS 'blue', NOI 'boy')[1].

During the game, participant A had to ask participant B questions to try to determine the mystery person on B's board. Players took turns asking questions about the physical features of their respective "mystery persons" in an effort to eliminate the wrong candidates. The winner was the player who guessed his/her mystery person first. In order to elicit not only questions but also statements, a variation of the game was designed. In this statement-elicitation variation of the game, participants took turns making statements about their mystery person, while the other player listened and eliminated all characters that did not exhibit a particular feature. Again, it was the player who guessed the identity of their "mystery person" first that won. Both participants within a pair took turns in the course of both variations of the game and therefore both provided examples of questions and statements.

Crucially for our goals, the types of simple questions and statements elicited with this procedure had the target words in focus position at the end of the prosodic phrase (e.g., *És una dona*? 'Is it a woman?', *És un home* 'It's a man', *Té bigoti?* 'Has he got a moustache?', *Porta un barret* 'She wears a hat', etc.).

Participants sat in the same room, facing each other across a table and in front of two laptop computers arranged so that they could not see each other's screen. Two camcorders were placed in such a way that they could record the upper part of each participant's body. Once the participants were seated, the camera was raised or lowered according to the participant's height. The experimenter then explained the game and gave instructions about the procedures to be followed for each of the two variations, which took place consecutively. Altogether each game lasted approximately twenty minutes, the time it took to play and win both variants in each set.

2.2. Coding

The relevant utterances (i.e., the questions about the mystery person and the statements used as cues) were annotated in terms of speech and gesture features. For speech, we used Praat [23] to mark the beginning of the opponent's responses and to indicate the duration of the word in focus position as well as the nuclear syllable. Then we imported the Praat label files into ELAN [24]. Figure1 shows an example of labeling with ELAN.

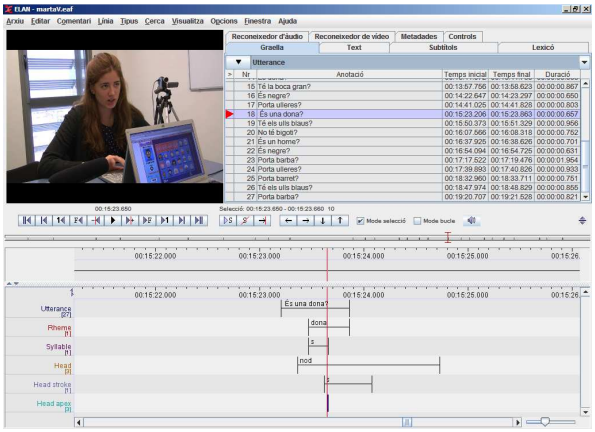

Figure 1: *Example of ELAN labeling.*

As for the gesture annotation, three tiers were created in ELAN, one to label the temporal limits of the head movement, another to locate the stroke of the head movement, and another to label the location of the gesture apex. Four possible head movement were taken into account: head nod, head upward, head tilt and other. *Head nod* referred to a downwards confirmation movement of the head; *upward* referred to a head movement directed upwards (in the opposite direction from

[1] Capital letters indicate the stressed syllable.

nodding); *head tilt* referred to a head inclination or sidewards movement; and *other* referred to any other movements timed with speech, e.g. negation gestures. Following the standard procedure, the annotation of the head movement timing consisted of locating the three gesture phases, namely the preparation phase, the gesture stroke, and the retraction phase. The head movement apex was located at the peak of effort of the head movement [4, 8].

3. Results

The total number of head gestures annotated was 114, consisting of 53 head nods, 42 head tilts, 15 head upwards, and 4 head gestures labeled 'other'. 67 of these gestures appeared in statements and 47 in questions.

3.1. Timing of the gesture apex

Figure 2 shows the temporal distance between the head gesture apex with respect to the end of the accented syllable. These results show that the gesture apex is aligned approximately with the end of the syllable for trochees (M = –67 ms), while it is aligned earlier in the case of monosyllables (M = –265 ms) and iambs (M = –404 ms). These results are consistent with the tendencies described in the literature for stress-final words.

A one-way ANOVA was run with the distance between the gesture apex and the stressed syllable end in milliseconds as the dependent variable and the stress pattern (three levels: trochees, monosyllables, and iambs) as the independent variable. Stress pattern was found to be significant ($F(2, 111) = 5.72$, $p = .004$, ${}_p\eta^2 = .09$). Bonferroni post-hoc tests revealed significant differences between trochees and monosyllables ($p < .05$), and also between trochees and iambs ($p < .05$), but not between monosyllables and iambs (p = n.s.).

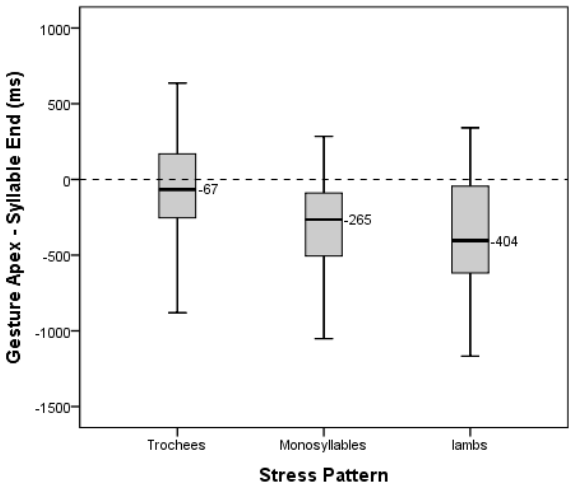

Figure 2: *Distance in time between the apex of the head gesture and the end of the accented syllable (in ms), as a function of the stress pattern of the word (trochees, monosyllables, and iambs).*

The results in this section reveal that the temporal location of the apex of head gestures is significantly affected by the distance to the upcoming phrase boundaries, that is, the apex has to be retracted when the gesture associates with word-final nuclear syllables. Interestingly, this replicates [17]'s results for the coordination between pointing gestures and speech, as they found that the apex of the pointing gesture was retracted before an adjacent phrase boundary (as in monosyllables and iambs), in comparison with gestures associated with non-adjacent phrase boundaries (as in trochees).

3.2. Timing of the gesture start

Figure 3 shows the temporal distance between the start of the head gesture with respect to the end of the accented syllable. These results show that for trochees the head gesture start is aligned closer relative to the end of the syllable (M = –389 ms), than in the case of monosyllables (M = –670 ms) and iambs (M = –734 ms), where it is aligned much earlier.

A one-way ANOVA was run with the distance between the gesture start and stressed syllable end in milliseconds as the dependent variable and stress pattern as the independent variable. Stress pattern was found to be significant ($F(2, 111) = 7.30$, $p = .001$, ${}_p\eta^2 = .12$). Bonferroni post-hoc tests revealed significant differences between trochees and monosyllables ($p < .01$), and also between trochees and iambs ($p < .05$), but not between monosyllables and iambs (p = n.s.).

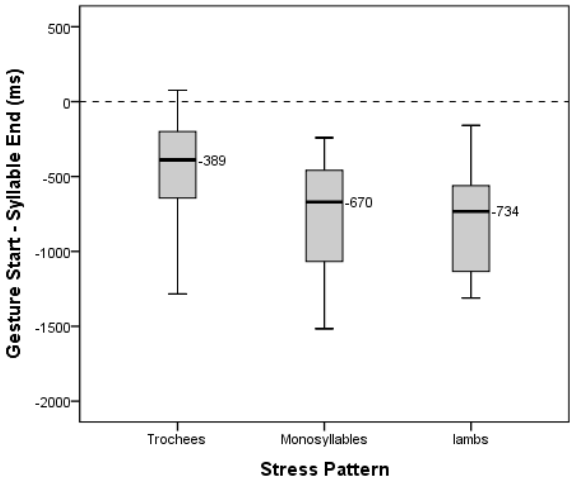

Figure 3: *Distance in time between the start of the head gesture and the end of the accented syllable (in ms), as a function of the stress pattern of the word (trochees, monosyllables, and iambs).*

The results in this section again show an asymmetry between the temporal association of head gestures with trochaic words as compared to iambic and monosyllabic words. In our interpretation, the fact that head gestures start earlier in monosyllables and iambs with respect of the end of the accented syllable indicates that the scope of the head movement is the entire focused word, not only the accented syllable, although results in 3.1 indicate that the anchoring landmark in speech for the gesture apex is the accented syllable.

3.3. Timing of the gesture end

Figure 4 shows the distance in time between the gesture end and the end of the accented syllable. These results show that the gesture end is more closely aligned with the end of the syllable in the case of monosyllables (M = 111 ms) and iambs (M = –21 ms), than in the case of trochees (M = 344 ms).

A one-way ANOVA was run with the distance in time between the gesture end and the stressed syllable end as the dependent variable and stress pattern as the independent variable. Stress pattern was found to be significant ($F(2, 103) = 5.44$, $p = .006$, ${}_p\eta^2 = .10$). Bonferroni post-hoc tests revealed significant differences between trochees and monosyllables ($p < .05$), and also between trochees and iambs ($p < .05$), but not between monosyllables and iambs (p = n.s.).

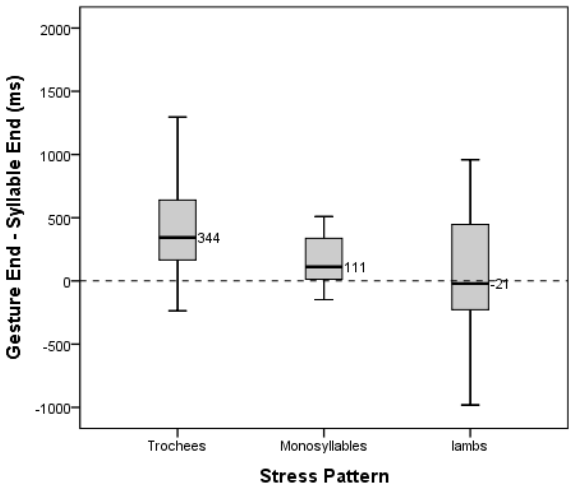

Figure 4: *Distance in time between the gesture end and the end of the accented syllable (in ms), as a function of the stress pattern of the word (trochees, monosyllables, and iambs).*

The results of this section show that the end time of head gestures is located later in trochees than in monosyllables and iambs, something that is related to the fact that this stress pattern has a final unstressed syllable available that can accommodate the retraction phase of the head gesture.

4. Discussion and conclusions

The aim of the present study was to test the claim that prosodic structure influences the timing of gesture movements in the sense that the location of the different phases of the gesture with respect to the stressed syllable depends on the metrical pattern of the target word. This has been tested with head gestures observed in a semi-spontaneous setting, while previous studies examined co-speech gestures produced in laboratory controlled settings.

Our results showed that head gestures are aligned differently with respect to the stressed syllable for trochees than they are for iambs and monosyllables. In trochees, the apex of the gesture is closely aligned with the end of the stressed syllable, the gesture start occurs together with the start of the stressed syllable, and the end of the gesture is located within the final unstressed syllable. By contrast, in iambs and monosyllables, the apex is located in the middle of the stressed syllable, the start of the head movement occurs well before the accented syllable and the ending time occurs right after the accented syllable. These results reveal that the scope of the entire head gesture movement operates on the entire focused word, since preceding and upcoming word boundaries determine the start and end time of the gesture. However, the timing of the gesture prominence (the gesture apex) is determined by the position of the stressed syllable: it occurs earlier when the stressed syllable is followed by a phrase boundary, and it occurs later with respect to the end of the stressed syllable when there is post-tonic material where to accommodate the retraction phase of the gesture. All in all our results show that the timing patterns of head gestures are constrained by prosodic structure and corroborate previous findings in the sense that the most prominent part of the head gesture (the apex) has been shown to be aligned with accented syllables [6, 10-12, 14, 17].

Further research is needed to investigate potential effects of sentence type on the temporal coordination of gesture and prosody. The prosodic structure of statement and questions is different, and this might have an impact on the temporal coordination. Our study does not have enough data to undertake these comparisons, so future studies are crucial to shed light on this issue. The study of the temporal coordination between gesture and speech (in particular, prosody) is important to understand how both modalities are entrained and if they are in fact part of the same system in communication, as proposed in the literature [1, 4, 8]. The fact that gesture and speech are produced in different physiological systems might impose biomechanical constraints in their coordination [25]. However, the evidence presented in this study and in previous work suggests that the analysis of the temporal coordination of both modalities is crucial to investigate the cognitive processes involved in speech and gesture production.

5. Acknowledgments

We would like to thank Suleman Shahid and Constantijn Kaland for their help with setting up the recording sessions, and Igor Jauk for his help with labeling the Catalan corpus. We are grateful to the participants in all the experiments for voluntarily giving us their time. This research has been funded by a research grant awarded by the Spanish Ministry of Science and Innovation (BFU2012-31995 “Gestures, prosody and linguistic structure”), by a grant awarded by the Generalitat de Catalunya (2009SGR-701) to the *Grup d’Estudis de Prosòdia*, and by a “Study abroad scholarship for research outside of Catalunya” 2010 BE1 00207, awarded by the Generalitat de Catalunya.

Abstract

The three-way distinction of quantity occurs in several Finnic and Saami languages. The paper focuses on the length contrast of consonants in Inari Saami. Similarly to Estonian and other Finno-Ugric languages where three quantities are described, in Inari Saami the distinction between single consonants, short geminates or consonant clusters, and long geminates or consonant clusters appears only on the boundary of a stressed and unstressed syllable of a disyllabic foot. Our results show that in Inari Saami the duration of consonants is inversely related to the duration of both preceding and following vowels, and there is a tendency towards foot isochrony. The results are in line with previous studies on quantity opposition in Inari Saami and in other Finnic languages, showing the ternary distinction of consonant quantities as a foot-level feature of the language.

Index Terms: Inari Saami, geminates, three-way quantity

1. Introduction

The sound system of Inari Saami reveals three phonologically distinctive quantities. The ternary duration contrast occurs in several Saami languages, including North Saami which has a central position in the Saami language area [1]–[3]. Inari Saami is an eastern Saami language spoken by about 200 native speakers in northern Finland. The Inari Saami phonology is characterized by left-headed feet, word-initial primary stress, and a distinction between short and long vowels and consonants both in stressed and unstressed syllables. The three-way distinction of quantity appears only with consonants in primary stressed feet that are left headed. The ternary contrast is realized by the distinction of single consonants, short and long geminates (traditionally called half-long and long consonants), or consonant clusters on the boundary of the stressed syllable and the following unstressed syllable, e.g. *palo* [pɑlo] ‘fear, Gen/Acc.’, *paḷo* [pɑllo] ‘fear, Nom.’, *kallu* [kɑlːlu] ‘forehead, Nom.’, *ša'lde* [ʃɑlte] ‘bridge, Gen/Acc.’, *šalde* [ʃɑlːte] ‘bridge, Nom.’, *tääḷu* [tæːllu] ‘house, Nom.’, *täállun* [tæːlːlun] ‘house, Ess.’. In orthography, short geminates (or half-long consonants) are marked with a dot under a single letter, long geminates (or long consonants) are written with two letters. An apostrophe before a consonant cluster indicates that the cluster is short, see [4].

The phonological distinction between short and long geminates is a productive feature of Inari Saami word prosody, i.e. it occurs with all consonants. Also the consonant clusters are prosodically short and long; short geminates and consonant clusters occur in feet of the second quantity degree (Q2), long geminates and consonant clusters occur in feet of the third quantity degree (Q3).

Previous studies have indicated that segmental durations are interrelated in Inari Saami feet and there is a tendency to foot isochrony, which means that the length of the first and second syllables are inversely related [2], [5]. However, unlike Southern Finnic languages with ternary quantity opposition, the Saami languages including Inari Saami also preserved the quantity distinction of vowels in an unstressed syllable [1], e.g. *palloon* [pɑlːloːn] ‘fear, Ess.’.

The nature of temporal relations between consonants and surrounding vowels in Inari Saami is not completely clear. Earlier studies of Inari Saami quantities have focused on the relations of the consonants with the preceding vowel [2], [6]. Southern Finnic languages with a three-way quantity, on the other hand, have shown an inverse relation between consonants and the duration of the following vowel. Markus et al. found that this is relevant also in the case of Inari Saami [5]. In this paper we study the temporal features of all sounds in Inari Saami disyllabic feet with short consonants, short and long geminates and consonant clusters.

2. Materials and method

The data of this study were recorded using an Edirol R-09 digital recorder in 2013 from four male native speakers of Inari Saami. Two of the subjects were born in Inari, one in Syysjärvi and one in Ylivieska. Their parents were speakers of central and northern varieties of Inari Saami. Currently one speaker still lives in Syysjärvi, one has moved to Helsinki and two live in Ivalo. At the time of recording the age of the speakers was between 62 and 77 (average being 70.8). In addition to their native language, all subjects speak Finnish, three have a good knowledge of North Saami, and three also marked English or German as their foreign languages.

The total set of materials comprised 299 words with consonantal quantity embedded in 96 carrier sentences in Inari Saami. All test words were disyllabic with a phonologically short vowel as a syllable nucleus, while the intervocalic consonant was a short consonant (Q1; e.g. *sare* [sɑre] ‘blueberry, Gen/Acc.’, *kove* [kove] ‘picture, Gen/Acc.’), a short geminate (Q2; e.g. *saṛe* [sɑrre] ‘blueberry, Nom.’, *koṿe* [kovve] ‘picture, Nom.’), or a long geminate (Q3; e.g. *komme* [komːme] ‘ghost, Nom’, *hekki* [hekːki] ‘cage, Nom.’), a short consonant cluster (Q2; e.g. *pu'ško* [puʃko] ‘Esox, pike, Gen/Acc.’, *a'lge* [ɑlke] ‘boy, Gen/Acc.’) or a long consonant cluster (Q3; e.g. *puško* [puʃːko] ‘Esox, pike, Nom.’, *alge* [ɑlːke] ‘boy, Nom.’). Different vowels and syllable boundary consonants were selected to avoid the influence of the intrinsic duration on average segment duration. The analysed word structures were as follows: CVCV, (C)VCCV and (C)VC:CV (referred to as Q1, Q2 and Q3, respectively).

The test words were placed in phrase-medial and phrase- or sentence-final position of the carrier sentence, e.g. *Ohtâ **maṇe** lii taa*, *mut ohtâ **lodde** lii tobbeen* ‘One egg is here, but one bird is there’; *Must lii ohtâ **saṛe**, mut sust lii ohtâ **juŋŋâ*** ‘I have one blueberry, but you have one lingonberry’. The distribution of the analyzed tokens is shown in Table 1. Some utterances were left out from the analysis, mainly due to background noise or because they were misread.

Table 1. *Number of analyzed tokens produced by the four speakers.*

	Sp1	Sp2	Sp3	Sp4
Q1 short	6	7	6	7
Q2 geminate	14	14	14	14
Q2 cluster	8	8	8	8
Q3 geminate	24	22	23	24
Q3 cluster	24	22	22	24

Segment boundaries were labelled in Praat [7] and the duration of each segment was extracted with a script. Using the LME4 package in R, the log-scaled segment durations were tested with a mixed effects model for three factors: Position (levels: phrase-medial, phrase-final), Quantity (levels: Q1, Q2, Q3) and Consonantal (C2) structure (levels: geminate, consonant cluster).

3. Results and discussion

First, we present the segmental durations in disyllabic words, and then we compare the duration ratios of intervocalic consonants and their surrounding vowels (i.e. the ratios of V1/C2 and C2/V2).

3.1. Duration of segments

The average segmental durations are presented in Table 2. In the table, C1 marks the word-initial consonant. V1 is a short vowel in the first syllable, C2 a short consonant (Q1), the total duration of a short (Q2) and long (Q3) geminate, or the total duration of a short (Q2) and long (Q3) consonant cluster, and V2 a short vowel in the second syllable. The total duration of the disyllabic foot is also given. In the first, second and third part of the table respectively the average segment durations of words in the phrase-medial, phrase-final position and in both positions together are given. Figure 1 illustrates an overall average of segment durations (phrase-medial and phrase-final words pooled together).

It can be seen from Table 2 that the C1 duration is roughly 100 ms in all tested quantity degrees and phrasal positions. None of the tested factors were significant for the C1 duration.

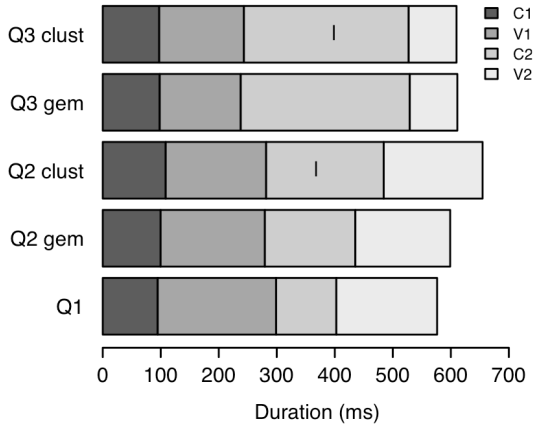

Figure 1: *Average segment durations in the analyzed word structures. The segment boundary in the consonant cluster is marked with a vertical bar.*

Table 2. *Average segment durations and standard deviations (in milliseconds) in the phrase-medial, phrase-final position and both positions analyzed together.*

Pos.	Structure	C1	V1	C2	V2	Total
Phrase-medial	Q1 short	97	181	82	163	522
	s.d.	15	28	14	21	47
	Q2 geminate	96	166	137	148	547
	s.d.	23	26	23	21	52
	Q2 cluster	110	161	185	148	577
	s.d.	17	31	26	26	60
	Q3 geminate	97	132	242	78	532
	s.d.	27	22	68	16	82
	Q3 cluster	96	135	238	75	527
	s.d.	16	19	50	13	65
Phrase-final	Q1 short C	93	224	122	183	623
	s.d.	16	46	32	50	88
	Q2 geminate	103	194	175	179	651
	s.d.	24	35	41	44	92
	Q2 cluster	107	186	220	192	679
	s.d.	17	29	37	39	91
	Q3 geminate	100	148	342	86	658
	s.d.	31	25	73	22	95
	Q3 cluster	99	158	334	91	664
	s.d.	17	21	56	20	75
Average	Q1 short C	95	204	104	174	576
	s.d.	16	44	32	40	87
	Q2 geminate	100	180	156	164	599
	s.d.	23	34	38	37	91
	Q2 cluster	109	173	203	170	628
	s.d.	16	32	36	40	92
	Q3 geminate	98	140	291	82	594
	s.d.	29	25	87	20	109
	Q3 cluster	97	146	284	82	593
	s.d.	16	23	72	18	98

Table 2 shows that the average duration of V1 is the longest in the case of Q1 (204 ms), somewhat shorter in the case of Q2 (173–180 ms), and the shortest in the case of Q3 (140–146 ms). The main effect of Position is significant [$\chi^2(df=1, N=299)=28.9, p<0.001$], but there are no interactions with Quantity and C2 structure. The effect of Position refers to the lengthening of segments in phrase-final position. There is also a significant main effect of Quantity [$\chi^2(df=2, N=299)=63.41, p<0.001$], and post-hoc test indicates that the duration of V1 varies significantly in the opposition of Q1 and Q2 vs. Q3 ($p<0.001$). The V1 duration in Q1 vs. Q2 is not significantly different. Additionally, there is no effect of C2 structure.

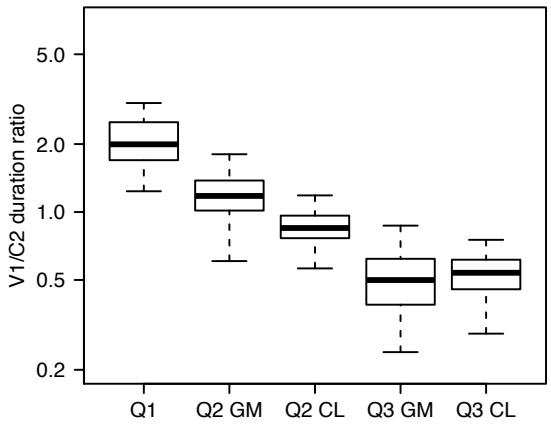

Figure 2: *Duration ratios of V1 to C2.*

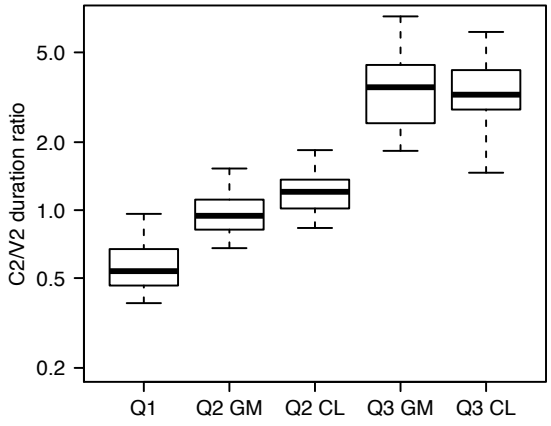

Figure 3: *Duration ratios of C2 to V2.*

As expected, the intervocalic short consonant has the shortest duration (104 ms). The short geminate is longer (156 ms) than the short consonant and the short consonant cluster is somewhat longer than the short geminate (203 ms). The long geminate and consonant cluster are the longest (291 ms and 284 ms respectively). Standard deviations show a greater variation in the duration of both long (Q3) geminate and consonant cluster. The Position has a main effect on the duration of intervocalic consonant(s) (C2) [χ^2(*df*=1, *N*=325)=71.965, p<0.001], which, as in the case of V1, indicates the phrase-final lengthening of a word. The duration of C2 in different quantities varies significantly [χ^2(*df*=2, *N*=325)=137.31, p<0.001], being the shortest in Q1 and the longest in Q3. There is also an interaction between Quantity and C2 structure [χ^2(*df*=2, *N*=325)=16.1, p<0.001]. Pairwise post-hoc testing shows a significant difference between all levels of Quantity (p<0.001), but C2 structure has a significant effect only in the case of Q2 (p<0.05) where a geminate is shorter than a consonant cluster. In Q3 a geminate and a consonant cluster are of similar duration.

V2 shows a similar pattern to V1, being the longest in Q1 (174 ms), shorter in Q2 (164–170 ms), and the shortest in Q3 (82 ms). Again, Position has a significant effect, but without any interactions [χ^2(*df*=1, *N*=299)=22.1, p<0.001]. As in the case of V1 and C2 it also points to the phrase-final lengthening. There is a significant main effect of Quantity [χ^2(*df*=2, *N*=299)=167.24, p<0.001] and post-hoc test shows the difference between Q1 and Q2 vs. Q3 (p<0.001), but no difference between Q1 vs. Q2.

The duration of the whole word varies significantly only between different phrasal positions [χ^2(*df*=1, *N*=299)=85.6, p<0.001], but quantities do not reveal a significant difference. This lack of difference between the word structures with different quantity degrees can be accounted for by a strong tendency to foot isochrony.

It can be concluded that the phrasal position influences the duration of all segments except C1. Segments are longer in the phrase-final position than in the phrase-medial position, but the phrasal position does not interact with the other tested factors. There is an interrelation between the durations of the intervocalic consonant(s) and the surrounding vowels: while the duration of C2 increases both the duration of V1 and V2 decreases. In consequence, the total duration of feet reveals a tendency to foot isochrony. The average foot durations are similar in all the quantities.

3.2. Duration ratio of segments

In Table 3 the duration ratios of V1 to C2, and C2 to V2 are presented. Figure 2 illustrates the duration ratios of V1 to C2 and the duration ratios of V2 to C2 are presented in Figure 3. As the phrasal position seems to have an overall lengthening effect and it does not interact with the different segmental patterns, the phrasal positions are pooled together in this section.

Table 3. *Average V1/C2 and C2/V2 duration ratios.*

Structure	V1/C2	C2/V2
Q1short	2.0	0.6
Q2 geminate	1.2	1.0
Q2 cluster	0.9	1.2
Q3 geminate	0.5	3.5
Q3 cluster	0.5	3.5

The average duration ratio of V1/C2 is 2 in Q1, 0.9–1.2 in Q2 and 0.5 in Q3. The first syllable vowel (V1) in Q1 words is twice as long as a single consonant (C2). Before the short (Q2) geminate and consonant cluster the vowel is shorter than before a single consonant, which in turn is shorter than a Q2 geminate and consonant cluster. In the case of Q2 the durations of the first vowel and the geminate or consonant cluster are almost equal. The V1 duration is the shortest and the C2 duration the longest in the case of Q3 and because of that the duration of a Q3 geminate and consonant cluster is twice as long as that of the first syllable vowel.

The duration of V2 is also strongly affected by the duration of the preceding consonant; there is an inverse relation. The duration ratios of C2/V2 are as follows: 0.6 in Q1, 1.0–1.2 in Q2, and 3.5 in Q3. The duration of the second syllable vowel is the longest after a short consonant: V2 is almost two times longer than C2. In the case of Q2 a short geminate and consonant cluster have almost same duration as the second syllable vowel. V2 is the shortest after the long

(Q3) geminate and consonant cluster that is more than 3 times longer than the following vowel.

Considering both duration ratios, the general correlation between the durations of neighbouring segments can be stated as follows. In the case of Q1: the duration of V1 > the duration of a short consonant < the duration of V2. In the case of Q2: the duration of V1 = the duration of a short geminate or consonant cluster = the duration of V2. In the case of Q3: the duration of V1 < the duration of a short geminate or consonant cluster > the duration of V2.

The duration ratio of the short consonant to the short geminate and long geminate is 1 : 1.5 : 2.8, and to the short consonant cluster and long consonant cluster it is 1 : 2 : 2.7. The duration ratio of the short geminate to the long geminate is 1.9 and of the short consonant cluster to the long consonant cluster it is 1.4. These ratios show that the duration of short geminates is closer to the duration of the short consonants than the duration of the short consonant clusters. The short geminate is one and a half times longer than the short consonant, and almost two times shorter than the long geminate. The short consonant cluster is two times longer than the short consonant and almost one and a half times shorter than the long consonant cluster. Long geminates and consonant clusters are almost three times longer than short consonants.

The results are in line with previous studies on quantity opposition in Inari Saami and other Finnic languages showing the ternary distinction of consonant quantities as a foot-level feature of the language. Bye et al. report that all their speakers make a ternary distinction in consonant duration after a short vowel [2]. However, in their data, the duration of V1 and V2 had a greater between-speaker variation, which is explained partly with a different language background of speakers. Similarly to the speakers of the current study, some of their speakers had a reverse relation of V1 and C2: a short V1 was longer before a short geminate than before a long geminate, and yet longer before a short consonant. However, for three of their speakers the difference of V1 before a short consonant and geminate was not significant. In line with this, the present study showed that the duration of surrounding vowels is significant only between Q1 and Q2 vs. Q3 but not between Q1 vs. Q2. Bye et al. report that only one speaker displayed a ternary inverse duration relationship between consonant and V2 but for other speakers there was no significant difference in V2 duration after a short consonant and geminate [2]. The latter applies to the pronunciation of our speakers, too.

Similar temporal ratio patterns between the intervocalic consonants and the surrounding vowels have been shown to be an efficient way to describe the quantity system of other languages that have a ternary contrast of consonant duration (e.g. [5]). In Estonian the variation of the intervocalic consonant duration does not affect V1 duration, but V2 duration is the longest after a short consonant and shortest after a long geminate. In Livonian, the variation of the intervocalic consonant duration does not affect V1 duration either, but there is a significant difference in V2 duration after a short consonant and geminate vs. a long geminate. Markus et al. have also reported duration ratios of consonants in different quantity [5]. In Estonian and Livonian the duration ratio of CC/C is respectively 2.19 and 1.49 and that of C:C/CC 1.4 and 1.52. The duration ratios of Inari Saami geminates seem to resemble that of Livonian, but the ratios of consonant clusters is more similar to that of Estonian long and short geminates.

4. Conclusions

Inari Saami has a ternary contrast of consonant quantity that occurs after a short vowel. Similarly to Estonian and some other Finno-Ugric languages where three-way quantities are described, in Inari Saami the distinction between short consonants, short geminates or consonant clusters, and long geminates or consonant clusters appears only on the boundary of a stressed and unstressed syllable of a disyllabic foot. In Inari Saami the duration of consonants is inversely related to the duration of both preceding and following vowels. The duration of V1 is significantly longer before a short consonant, short geminate and consonant cluster than before a long geminate and consonant cluster. The same difference concerns the duration of V2. Consequently there is a strong tendency towards foot isochrony. Duration ratios between consonants in different quantity indicate that the duration of the short geminate is closer to the duration of the short consonant than to the duration of the long geminate (the ratios 1.5 and 1.9). However, the duration of the short consonant cluster is closer to the duration of the long consonant cluster than to the duration of the short consonant (the ratios 2 and 1.4).

5. Acknowledgements

The authors are very grateful for the Inari Saami informants for participating in this study. Our special gratitude belongs to Hans Morottaja who helped us to find speakers. We would like to thank Eva Liina Asu for proofreading this paper. The second author would also like to thank Nele Salveste and Juraj Šimko for inspiring discussions. This research was partly funded by the Estonian Research Agency grant No. IUT2-37.

Slovak prosody in the phonetics-phonology debate: Yers and emergent prosodic breaks

Štefan Beňuš

Department of English and American Studies, Constantine the Philosopher University, Nitra, Slovakia
Institute of Informatics, Slovak Academy of Sciences, Bratislava, Slovakia
sbenus@ukf.sk

Abstract

Prosody is central for understanding the cognitive system underlying human speech and relates to both more granular aspects of our phonological competence as well as more continuous aspects of observable articulatory movements and resulting acoustic characteristics. The understanding, and formal treatment, of the relationship between these two inter-related components of human speech is at the core of the cognitive approach to speech. In this presentation I contribute to this discussion by drawing links between two seemingly unrelated lines of my research on Slovak [1, 2], and argue that understanding the continuous prosodic nature of speech is critical for improving our understanding of cognitive competence underlying it. The first aspect concerns yer vowels as the proto-typical problem of Slavic phonology [1], the second involves the nature of prosodic boundaries [2].

In Slavic phonology, 'yer', or 'jer' is a widely used and recognized term for vowels that alternate with zero in many Slavic languages and can be traced to Old Church Slavonic and Indo-European. In Slovak, the presence of mid-vowels /e/ and /o/ in some words alternates with their absence as in (1).

(1) Alternations with yers in Slovak.

Nom.Sg.	Transcription	Gen.Sg.	Instr.Sg.	Gloss
pal**e**c	[palets]	palc-a	palc-om	'thumb'
lak**e**ť	[lakec]	lakť-a	lakť-om	'elbow'
p**e**s	[pes]	ps-a	psom	'dog'
kot**o**l	[kotol]	kotl-a	kotl-om	'cauldron'
pár**o**k	[pa:rok]	párk-a	párk-om	'sausage'

(2) Yer and non-yer vowels occur in similar environments

Yer	Gen.Sg.	Gloss	Non-yer	Gen.Sg.	Gloss
kábel	kábl-a	cable	Ábel	Ábel-a	name
palec	palc-a	thumb	balet	baleta	balet
párok	párk-u	sausage	nárok	nárok-u	requirement
smútok	smútk-u	sorrow	súťok	súťok-u	confluence

The patterns in (2), together with other features of Slovak, show that the yer vs. non-yer alternations cannot be treated as insertions or deletions since the environment could not be specified. Therefore, given well known reasons stemming from alternations as in (2), all phonological accounts assume that yer vowels are underlyingly different from non-yer vowels. This is common to all formal yer treatments despite important differences in theoretical machinery and predictions generated in phonological analyses using various formalizations [e.g. 3, 4, 5, 8, 9]. The second assumption, shared by all traditional accounts, is that the underlying difference between yer and non-yer vowels is neutralized in phonology (e.g. the traditional rule of Lower in [3]), and there should thus be no phonetic difference between the two vowel classes. I will review the phonetic evidence in [1] that analyzes the acoustic and articulatory aspects of producing words like in (2) and suggests that yer vowels are prosodically weaker than their non-yer counterparts and resemble vowels produced in faster speech rate. Hence, sub-phonemic prosodically-based differences might participate in modeling deep morpho-phonological alternations.

The second line of research investigates the spontaneous emergence of high-level prosodic boundaries induced by resolving low-level requirements for slower speech rate or more precise articulation in the vicinity of the syntactic affordance for such boundaries [2]. We investigate the patterns of temporal coordination among the bilabial gestures (m-opening, b-closing) and the tongue body gesture forming the vowel canonically following /b/ in real-word Slovak sequences in (3).

(3) Stimuli for emergence prosodic break; "#" denotes syntactic affordance

Slovak	IPA
Čítam (#) iba mu ...	[tʃi:ta**m**(#)i**ba**mu...]
Cítim (#) aby mu ...	[tsi:ci**m**(#)a**bi**mu]

We observed that the continuous variation of low-level tempo and hypo-hyper articulation resulted in continuous re-organization of the gestures reflecting the continuous variation in the boundary strength. The extrapolation between our findings and those reported in literature for linguistically planned brakes suggests a plausible hypothesis that both species of prosodic boundaries, i.e. 1) planned, top-down, traditionally phonological ones stemming from the interface between prosody and syntax/pragmatics and 2) emergent, bottom-up ones, realized though low-level phonetic variations, can stem from a single underlying mechanism, and can be implemented in the same way. Moreover, the observed systematicities can be accounted for using the formal optimization-based Embodied Task Dynamics model [6, 7] in which the variation in inter-gestural timing stemming from the prosodic characteristics arises through localized changes in relative demands on efficient perception, articulatory precision and temporal cohesion among the sequenced gestures.

Both lines of research thus suggest that exploring traditional phonological alternations as embedded in continuous prosodic substrate can provide novel insights into the cognitive mechanisms underlying our communicative competence.

On the Origins of the Prosodic Word in Russian

Jaye Padgett

Department of Linguistics, University of California, Santa Cruz, USA
padgett@ucsc.edu

Abstract

The Prosodic Word (Pwd) is a foundational notion in phonological theories, being relevant for the statement of many phonological generalizations. In spite of their importance, there are basic open questions about prosodic words. Where do they come from? Can their structure in one language vs. another be predicted? In this paper I suggest a research program that attempts to address such questions by viewing prosodic words as emergent over time from the interaction of phonetics, phonologization, and syntactic structure.

Index Terms: prosodic word, domain generalization, Russian

1. Introduction

The Prosodic Word (Pwd) occupies a central position in the theory of Prosodic Phonology, e.g. [1], [2], [3], [4], [5]. A key motivation for the Pwd, as separate from the morphosyntactic word, is the lack of isomorphism between the two kinds of word. For example, word-final devoicing in Russian affects open-class lexical items but not prepositions, leading to contrasts like *sa**t** mʲiˈxailə* 'Mikhail's garden' vs. *pə**d** mɛsˈkvoj* 'near Moscow', in which the underlying /d/ of /sad/ 'garden' is devoiced (cf. *sada* 'garden (gen.)') but the /d/ of the preposition /pod/ is not. This contrast, among other facts, leads many researchers to conclude that the first phrase consists of two prosodic words, i.e. [sat]$_{\text{Pwd}}$ [mʲiˈxailə]$_{\text{Pwd}}$, while the second consists of one, i.e. [pəd mɛsˈkvoj]$_{\text{Pwd}}$, and to assume that devoicing affects consonants at the end of the prosodic word [6], [7], [8], [9], see discussion and references in [10].

The word is relevant to phonetic theories as well. For example, phonetic domain-initial strengthening and domain-final lengthening are most strongly observed at the highest level of the prosodic hierarchy such as the utterance and are more weakly present at the level of the word [11], [12]. There is also evidence that degree of coarticulation can depend on whether the relevant segments span a prosodic word boundary or are within a prosodic word [13].

In spite of their importance, there are many basic questions about prosodic words that remain unanswered (see discussion in [14]). How many prosodic categories are there? Are they innately given or emergent constructs, and if the latter, what explains their emergence and the precise form they take? What are the constraints on the structure of prosodic categories? It is much easier to ask these questions than to answer them, and this paper has the modest goal of suggesting a research program in which prosodic words (and possibly other higher prosodic constituents) are viewed as constructs that emerge over time through the interaction of phonetics, phonologization, and syntactic structure. A key component of this pursuit is something called *domain generalization*.

2. Domain generalization

Word-final devoicing as in Russian is attested in many unrelated languages. The account of it detailed in this section follows [15].

2.1. Phonetics-phonology mismatch

Many researchers have posited that final devoicing originates as a phonologization of utterance-final phonetic devoicing (e.g., [16], [17]). Gradient utterance-final devoicing occurs in many languages and can be attributed to a drop in sub-glottal pressure toward the end of an utterance [18] as well as spreading of the vocal folds in anticipation of non-speech breathing posture (e.g., [19], [20]). In addition, it has been argued that an obstruent voicing contrast might be hard to perceive unless the relevant obstruents directly precede a sonorant consonant or vowel [21]; since utterance-final consonants precede a pause, there may be perceptual as well as articulatory underpinnings to devoicing. These phonetic underpinnings are relevant to utterance-final position, but not word-final position (putting aside words that happen to be utterance-final). In phrasal contexts like *sa**t** mʲiˈxailə*, in which the word-final obstruent is utterance-medial and precedes a sonorant, there are no articulatory or perceptual underpinnings for word-final devoicing analogous to those described above. Yet many languages have phonologized final devoicing specifically at the level of the word all the same.

2.2. Domain generalization

The idea of *domain generalization* is that language learners, even while encountering a generalization about utterance-final position, are predisposed to learn them as word-final. Suppose that phonological generalizations are built from a store of lexical representations [22], [23]. It is plausible to assume also that we store many more words than phrases or utterances. First, we encounter many more words than utterances (since words make up utterances). Second, words are also easier to remember, because they tend to be shorter than utterances, and a given word is reinforced in memory more often by repeated exposure than a given utterance. Words are therefore a more likely source of generalization.

Domain generalization implies that word-final devoicing comes about in the following way. At an initial stage of a given language (here we entertain the scenario using Modern Russian forms), devoicing begins as a phonetically motivated utterance-final process, as in Stage 2 below. At this stage words like /sad/ 'garden' are realized with final devoicing when they occur in utterance-final position but not elsewhere. But under the influence of the many stored devoiced variants like [sat] of words like /sad/, the learner generalizes devoicing to *all* words. This is Stage 3. This process can be seen underway in Polish, where some dialects maintain utterance-final devoicing and others have innovated word-final devoicing [24].

Stage 1	/**sad** vixodʲit v drugoj **sad**/
(No devoicing)	[**sad** vixodʲit v drugoj **sad**]
	'The garden lets out onto another garden'
Stage 2	/**sad** vixodʲit v drugoj **sad**/
(Utterance-final devoicing)	[**sad** vixodʲit v drugoj **sat**]
Stage 3	/**sad** vixodʲit v drugoj **sad**/
(Word-final devoicing)	[**sat** vixodʲit v drugoj **sat**]

2.3. Artificial grammar experiment

In order to test the hypothesis that learners are biased toward word-based generalizations, as domain generalization implies, two artificial grammar experiments were carried out in [15]. Participants were exposed to constructed languages in which both voiced and voiceless obstruents occurred in syllable onset position but word-final obstruents were only observed in utterance-final position and were only voiced or voiceless (depending on experimental condition). Participants were thus implicitly given information about the voicing of word-final obstruents in utterance-final position, but no information about word-final obstruent voicing otherwise, a poverty of stimulus design ([25], [26], [27]). Results showed learning of the utterance-final devoicing (or voicing) generalization, and also extension of the learned pattern to word-final position even for words in utterance-medial position, supporting domain generalization.

3. The Russian prosodic word

3.1. The prosodic word as emergent

What facts motivate the Russian Pwd? As noted above, an important motivation comes from the facts of final devoicing and prepositions. According to this diagnostic, a preposition (or string of prepositions) plus one open-class lexical item constitute a prosodic word, e.g., [pəd mɐsˈkvoj]$_{\text{Pwd}}$, 'near Moscow'. Devoicing is Pwd-final, accounting for the lack of devoicing in /pod/ 'near'. Voicing assimilation among obstruents also occurs within the Pwd, as in [pɐt ˈpapəj]$_{\text{Pwd}}$ 'under papa' from /pod ˈpapa/.

Russian also has various enclitics, and these also trigger voicing assimilation, as in [ˈsog ʐʸi] 'juice (emphatic)' from /sok ʐʸe/, cf. [ˈsok tə] 'juice (topical)'; or [ˈsat tə] 'garden (topical)' from /sad to/, cf. [ˈsad ʐʸi] 'garden (emphatic)'. Such voicing assimilation does not occur as readily across the boundaries of open-class lexical items, suggesting that enclitics are also incorporated into the Pwd. However, final devoicing applies before these enclitics, as can be seen whenever an enclitic begins with a sonorant, e.g. [ˈsok lʲi] 'juice (interrogative)' and (crucially) [ˈsat lʲi] 'garden (interrogative)'. If devoicing is Pwd-final, then enclitics cannot be within the prosodic word in such examples.

Such considerations lead researchers to posit two 'word-like' prosodic levels for Russian, which we might call the 'prosodic word' and 'clitic group' or the 'minimal' and 'maximal' prosodic word, or which we might distinguish in some other way. One structure argued for is shown in Figure 1 (see [10], [28] for detailed arguments). In this structure the preposition /iz/ and noun /knʲig/ group together as a Pwd (notated ω). However, the interrogative enclitic /lʲi/ is outside of this Pwd (incorporated directly into the prosodic phrase), accounting for the final devoicing of /knʲig/.

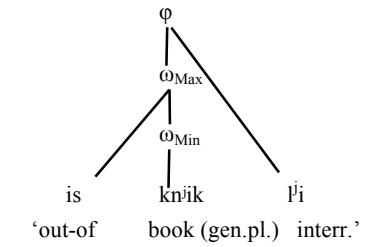

Figure 1: *Prosodic structure for proclitics vs. enclitics*

Though this structure succeeds in capturing the necessary distinctions, it raises the question: what explains the structure? From the point of view of prosodic theory the structure could just as easily be as in Figure 2.

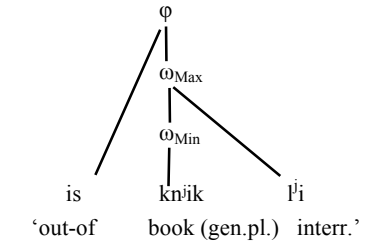

Figure 2: *Prosodic structure for proclitics vs. enclitics*

In the conventional approach to this problem, phonological facts like final devoicing are seen as (partly) determined by prosodic structure. As an alternative approach to answering the question above, we might instead try to derive the prosodic structure from the phonological facts. Final devoicing, as we have seen, arises historically when utterance-final devoicing (which is phonetically motivated) is generalized to the ends of all words. A word class that stands apart in not undergoing final devoicing, and which therefore motivates the Pwd, is the class of prepositions. Yet prepositions are a class of word that can never appear in utterance-final position in Russian, because they cannot be stranded (with marginal exceptions, see [29]).

The idea, then, is that domain generalization, assumed here to be the source of word-final devoicing, did not affect the class of prepositions, because Russian speakers had no experience of utterance-final prepositions and therefore no experience of devoiced prepositions. It is the array of facts this scenario engendered that leads the phonologist to posit the Pwd.

It does not follow from this idea that notions like the Pwd are imaginary or relevant only to linguists. Russian learners might well posit an organizational unit like the Pwd in response to the Russian facts, especially if this unit is useful in other ways. (See below.) However, the suggestion here does imply an understanding in which the Pwd is not, for example, an innate category provided by a universal grammar (see also [30] on this point). Rather, it *emerges* from a complex interaction of factors, including phonetic facts (providing the underpinning of utterance-final devoicing), phonologization (with domain generalization a key component of

phonologization, extending the generalization to open-class words in any position, and syntactic structure (explaining the exceptionality of prepositions).

3.2. Other evidence for the Russian prosodic word

What other facts motivate the Russian Pwd? There are at least two other noteworthy lines of evidence.

First, the Pwd is traditionally held to be the domain of lexical stress in Russian. Put another way, prepositions are part of the lexical stress domain: they do not carry stress independently; more importantly, a stress that 'belongs to' a following noun sometimes retracts onto the preposition itself, as in [ˈpod ruku] 'by the arm', compare [pəd ruˈkoj] 'at hand' [6], [7].

Second, the Pwd is relevant to the statement of vowel reduction facts [31], [28]. The vowels /o/ and /a/ reduce to [ə] when unstressed – compare [ˈ**ɡo**t] 'year' to [ɡədɐˈvoj] 'annual' (from /godoˈvoj/) and [ˈpr**a**f] 'law (gen.sg.)' to [prəvɐˈvoj] 'legal' (from /pravoˈvoj/. An exception is when these vowels immediately precede the stressed syllable of a word; in such cases the relevant syllable is much longer and the vowel is realized as something like [ɐ] [32], also seen in the examples above. This exception only applies within words, however: the word-final /o/ of /ˈmalo/ in /ˈmalo ˈskazano/ 'little said' reduces completely even though it precedes a stressed syllable in the following word: [ˈmal**ə** ˈskazənə]. It is significant, therefore, that pretonic reduction is to [ɐ] also for prepositions, e.g., [pɐt ˈpapəj]$_{\text{Pwd}}$ 'under papa' from /pod ˈpapa/, further supporting the analysis of such sequences as involving single Pwds.

That fact that at least three independent phonological processes – final devoicing, stress, and vowel reduction – apparently converge on the same Pwd analysis for preposition + word complexes presents a challenge for the view that Pwds emerge from the interaction of syntactic, phonetic, and phonological factors, as suggested here. If a domain such as Pwd is not given in advance but emerges as suggested earlier, how do these independent processes converge on the same domain? One possible answer is that speakers indeed posit Pwds based on facts like those of devoicing (or one of the other processes mentioned above), but that once posited, the Pwd can become relevant for, or even trigger, other phonological processes. In such a view, though not innate, Pwds are real, grammaticized organizational units, we might hold to the expectation that there are few such categories. However, this understanding of Pwds would be very hard to distinguish from the view that they are innate.

The alternative possibility is that different phonological phenomena lead to Pwd-like behavior independently, so that what counts as a 'Pwd' will depend on what phenomenon is in question; they need not converge on one answer. This is the view advocated in [30], for example, which argues that "prosodic domains are language-particular, intrinsic and highly specific properties of individual phonological rules or constraints" (though [30] allows that if enough processes appear to target the same domain they will have "a gravitating effect within the system, attracting phonological patterns which evolve in the course of sound change"). The discussion of Russian final devoicing here envisions one way that such language-specific organizational units might come about.

Further research is required to understand best how the Russian facts bear on these questions, but some evidence is already at hand that what we call a Pwd in Russian depends on which phenomenon we look at. One example comes from facts analyzed in [28]. A certain kind of compound can take stress in each member, e.g., *ˌbombə-uˈbʲeʐʸiʃːə* 'bomb shelter' and *ˌmʲedʸ-instʲiˈtut* 'medical institute'. This fact suggests an analysis of such compounds as involving two Pwds: [ˌbombə]$_{\text{Pwd}}$-[uˈbʲeʐʸiʃːə]$_{\text{Pwd}}$. Yet a word-final /o/ or /a/ in the first member of such compounds does not reduce to [ə] but to [ɐ] e.g., *ˌsaxərɐ-ˈvarnʲɪ* 'sugar refinary' from /ˌsaxar**o**-ˈvarnʲa/. The vowel reduction facts therefore suggest an analysis of such compounds as involving *one* Pwd: [ˌsaxərɐ-ˈvarnʲɪ]$_{\text{Pwd}}$. (Cf. [ˈmal**ə**]$_{\text{Pwd}}$ [ˈskazənə]$_{\text{Pwd}}$, discussed above.) Likewise final devoicing does not target the first word of such compounds, as the example *ˌmʲedʸ-instʲiˈtut* shows. Of course, these inconsistencies are a problem only if we expect all phonological processes to point to one and the same 'Pwd'.

4. Conclusions

The sources of evidence for something like the Pwd are diverse, including word-edge segmental phonology like final devoicing, but also facts about rhythm or stress, tone, apparent reference to morphosyntactic features, and effects of frequency. The discussion here has had nothing to say about the potential origins of phenomena other than word-final devoicing and the means by which they also converge on something like the prosodic word. But the point of this paper is that we might begin to make sense of the sometimes conflicting evidence about prosodic words, and explain aspects of their structure, if we view them as organizational constructs that emerge over time from the interaction of independently posited properties of a language. The hope is that this kind of thinking can be applied to these other sources of evidence as well.

Local and Global Acoustic Correlates of Information Structure in Bulgarian

Bistra Andreeva [1], *Jacques Koreman*[2], *William Barry*[1]

[1] Computational Linguistics & Phonetics, Saarland University, Germany

Abstract

In this study the local and global prosodic exponents of information structure are examined in the production of six Bulgarian question-answer elicited sentences under different focus conditions (broad focus and non-contrastive and contrastive narrow focus). Local cues are the phonetic properties of the nuclear accented syllables, while global cues reflect broader phonetic patterns in the intervals before and after the nuclear accented syllable, which in some cases vary independently of the tonal accent. Results show that speakers consistently discriminate broad and narrow focus by both local and global acoustic cues. Contrastive and non-contrastive accents are differentiated exclusively by local cues, but only when the focus is early in the sentence.

Index Terms: information structure, prosody, local and global cues, Bulgarian

1. Introduction

Most languages employ prominence-giving mechanisms to mark the relative informational importance of particular words in a phrase, often combined with word order and special lexical items or syntactic constructions. It is common to distinguish three elements of information structure (IS, e.g. [19]): 'topic' (the subject matter, on which new information is to be offered), 'focus' (the new information offered) and the 'given information' (information given previously or assumed to be known). These elements can be realized prosodically by means of a 'topic accent', a 'focus accent' or by 'de-accentuation'. At some basic production level, the speaker invests more effort in accentuated words compared to the words conveying given information, with the consequent acoustic effects of greater duration and intensity, higher or changing fundamental frequency (F0) and in some way more distinct spectral properties [10, 17, 24, 33]. However, there is evidence that languages differ in the amount each of the acoustic dimensions changes under accentuation [4, 25, 26] and there is considerable debate about which properties are used by the listener to identify prominent words or syllables. Pitch (measured as F0) is often seen as dominant [28, 14, 18], but duration [9, 20], intensity [9, 24, 35] and even voice quality [33] have also been singled out as important if not dominant determinants of perceived prominence.

Depending on the information provided by the pre-context, the focused part of a phrase can be restricted to one word – 'narrow focus' – or extend over much of the phrase – 'broad focus'. Within 'narrow focus', there is considerable disagreement in the literature about whether 'contrastive' and 'non-contrastive' focus are two distinct IS categories. Clearly, the context may or may not specify a semantic entity to which the focused word is in explicit contrast, providing a textual basis for a distinction. However, e.g. Rooth [31] sees an implicit contrast in any narrow focus; any expression has two semantic representations: the meaning of the expression itself and a set of alternatives. In the case of explicit contrast the alternative is known, but for Rooth the meaning of the expression does not change if the alternatives are not explicit.

Clear prosodic evidence for or against a contrastive – non-contrastive distinction is not apparent from the literature. Some have argued that there is no difference [16, 12, 34], while others have found evidence and argued that some acoustic features differ between contrastively vs. non-contrastively focused elements [13, 27, 7, 23].

Somewhat surprisingly perhaps, there is also disagreement about the reliability of the broad – narrow focus distinction. Of course, acceptance of the same utterance following both a pre-context cueing narrow focus and one cueing broad focus can only occur when the narrow focus is on the final lexical item. But given this condition, equal acceptance has been shown in several studies [11, 21, 37], while others claim that their subjects have consistently been able to make a distinction [8, 32].

In this paper, the prosodic exponents of broad focus and of non-contrastive and contrastive narrow focus are examined in the Sofia variety of Contemporary Standard Bulgarian.

Important factors in the realization of the information structure in Bulgarian utterances are:

- *word order*, remarkably flexible and discourse conditioned, as in all Slavic languages;
- morphological category of *definiteness*, unusual in the Slavic language family;
- *clitic replication* of nominal material;
- intonation.

Avgustinova [5] models the IS of Bulgarian utterances as interplay of the first three factors, while Miševa [29] and Nikov & Miševa [22] address the role of intonation. They experimentally investigated the regularities of F0 changes expressing phonetic prominence presented in terms of the traditional theme-rheme partitioning of the sentence. They conclude that the linguistically relevant phonetic characteristic of the given material (theme) is simply the absence of accentual prominence, i.e. de-accentuation. New material (rheme) shows the same intonational pattern in narrow and broad focus, but the accentual contrast between the prominent and the surrounding syllables is greater in narrow than in broad focus.

Andreeva et al. [1], Andreeva [2] and Avgustinova & Andreeva [6] adopted the terminology used in the Information Packaging approach in [36], where the basic focus-ground (cf. rheme and theme) articulation of the utterance is further refined by dividing the ground into link (what the focus is about) and tail (how the focus fits in the context). Contrary to the findings in [22, 29] they report that the underlying (phonological) pitch accent pattern for the thematic material is L*+H. Differences in the particular phonetic realizations depend on how the theme is realized on the surface, i.e. as a link (non-final in the intonational phrase) or a tail (final). In the link (pre-nuclear) the underlying pattern is realized phonetically as a gliding (slow) F0 rise from a low target within the accented syllable up to the next syllable (if there is enough syllabic ma-

terial), otherwise only within the syllable itself. In the tail (post-nuclear) the underlying pattern is not realized phonetically, i.e. there is a phonological rule deleting all pitch accents after the nuclear tone. In the opposition narrow vs. broad focus the underlying H* for the nucleus is realized with an emphasis [+raised peak] in the marked member of the opposition (i.e. narrow focus). In the case of a contrastive narrow focus, the phonetic realization of the shape of the underlying H* is also different, namely H*> [+raised peak; +delayed peak].

In this article, the question we would like to address is whether Standard Bulgarian distinguishes between different types of focus: a) non-contrastive and contrastive narrow focus, and b) broad and narrow focus. We first investigate the local acoustic cues in the nuclear syllable in terms of duration, F0 and intensity. Bruce [13] claimed that the focus domain is larger than the focused constituent and can affect the prosodic-acoustic realization of the whole sentence. Therefore, we shall also investigate the global effects of the IS on duration, F0 and intensity in the part of the utterance preceding and following the nuclear accent.

2. Material and Methods

The Bulgarian data that were used in this study were taken from an existing speech corpus consisting of read speech for several languages [4]. The stimulus material consisted of sentences with a fixed, canonical word order *subject* < *verb* < *direct object* < *indirect object* < *oblique*. This increases the role of prosody as an information-structuring factor, allowing us to focus on the acoustic correlates of different focus types. There were two critical words (CWs) in the sentence which could be realized with prominence, one early (CW1) and one late in the sentence (CW2). For each sentence, a number of questions were devised to elicit a) a *broad-focus* response, b) a response with a *non-contrastive narrow focus* on the early and c) on the late CW and d) a *contrastive focus* on the early and e) on the late CW. The sentences (with the critical words underlined) are:

1. Димо Данев гледа две деца.
   Dimo Danev gleda *dve* detsa.
   Dimo Danev looks after two children.
2. Бате Стефан взе седем книги.
   Bate Stefan vze sedem knigi.
   The elder Brother Stefan has taken seven books.
3. Играх на дама без кака ти.
   Igrax na dama bez kaka ti.
   I played draughts without your older sister.
4. Бате Мани пи тъмна бира.
   Bate Mani pi tămna bira.
   The elder Brother was drinking dark beer.
5. Дим Данев пя три пъти.
   Dim Danev pja tri păti.
   Dim Danev has sung three times.
6. Кака Нина търси черен хляб.
   Kaka Nina tărsi čeren xljab.
   The elder sister Nina is looking for dark bread.

The Bulgarian data corpus consists of 1080 sentences in total (6 speakers x 6 sentences x 5 focus conditions x 6 repetitions). In this article we present analysis results for local measurements in the CW for all sentence repetitions. We also present a more detailed analysis of the global prosodic patterns in the entire sentence for the first three of the six available repetitions.

2.1. Recordings and processing

Six regionally homogeneous speakers of Contemporary Standard Bulgarian as spoken in Sofia (3 female, 3 male) were recorded in a sound-treated studio. They read aloud each of the above sentences from a PowerPoint presentation in response to pre-recorded questions. The sentences and the questions eliciting different focus responses were pseudo-randomized and offered to the informants in six blocks, resulting in six repetitions of each sentence for each focus condition. The subjects were paid for participation.

The recordings were made using an AKG C420IIIPP headset on a Tascam DA-P1 DAT recorder and transferred digitally via the optical channel to a PC using the Kay Elemetrics MultiSpeech speech signal processing program.

Segmentation, labelling with SAMPA and further processing were done using the Kiel XASSP speech signal analysis package. Six labelling assistants were allocated different sentences (to maximize labelling consistency across conditions within each sentence) and segmentation problems were regularly discussed and decided with the authors at group level. In addition to the segmental labelling the pitch accents were also labelled by the first author, using BG-ToBI [2], with the peak alignment of the L(ow) and H(igh) targets explicitly specified. The positions of the F0 maxima and minima were double-checked by an automatic procedure for which the Praat pitch tracker was used.

2.2. Acoustic measurements

Local and global acoustic measures were calculated using praat scripts and operationalized as described in the two following subsections.

2.2.1. Local measurements

Local measurements of duration, F0 and intensity were made in the CWs in all the sentences read aloud by the informants.

a) Duration

Durations were measured for the stressed syllables of the CWs. The durations of the vowels in these syllables were also measured. Since all analyses and comparisons were carried out on individual sentences spoken in different focus conditions, it was possible to normalize all durational measurements as a percentage of the mean duration of the corresponding unit in the sentence.

b) Fundamental frequency

F0 was calculated as the mean fundamental frequency [Hz] across the syllable nucleus (vowel or syllabic sonorant) of the lexically stressed syllable of the CW. These values were also normalized by expressing them as percentages of the mean overall F0 of the sentence.

As a measure of peak alignment, the above absolute temporal distance from the F0 peak to syllable onset and rhyme onset were calculated. In order to compensate for the varying segmental durations on peak alignment, the above absolute measures were converted to relative measures, taken as a proportion of syllable and rhyme durations.

c) Energy

Energy was measured in two ways. First, as the mean intensity [dB] of the stressed vowel in the CW. These intensity values were normalized by subtracting the sentence intensity. Second, energy was measured as the spectral balance in the vowel.

This was computed as the difference in energy between the 70-1000 Hz and 1200-5000 Hz frequency bands.

2.2.2. Global measurements

Global measurements of duration, F0 and energy were made for the first three sentence repetitions by each speaker in each condition (focus type x sentence).

a) Duration

Durations were measured for the beginning of the sentence (sb) up to the focused syllable and for the sentence end (se) starting from the end of focused syllable. The values were normalized for speaking rate by calculating the percentage of the total sentence duration.

Since the number of syllables in the sentences varies, the tempo of sb and se were computed by dividing their duration by the number of syllables in the interval.

b) Fundamental frequency

In addition to mean F0 and peak alignment (section 2.2.1), the minimum F0 value preceding (L) and following the peak (Lpost) was measured, and the pitch excursion between the preceding F0 minimum and the peak (LH) and between the peak and the following F0 minimum (HLpost) was computed (s. Figure 1).

Individual F0 differences were removed by converting the obtained measurements to semitones by means of the following formula:

39.863 * log10(Maximum/Minimum)

Mean F0 values for sb and se were also computed and normalized by converting them to percentages of the sentence mean.

c) Energy

The intensity of sb and se were also measured and normalized using the same procedure as for the stressed vowels.

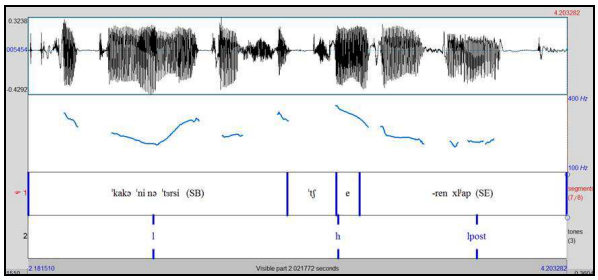

Figure 1: *Labeling example (sentence 6, narrow non-contrastive focus on CW2).*

2.3. Statistical analysis

The effect of focus condition was analyzed as a within-subjects factor separately for the local and global measurements in a mixed between-within MANOVA, with subject as a between-subjects factor. We report univariate tests with Greenhouse-Geisser estimates of F. These were verified with the multivariate Pillai's trace statistic; cells were equal in size. Separate Bonferroni post-hoc tests were carried out, if appropriate. The confidence level was set at α=0.05.

3. Results

In our data, the narrow focus is realized as (L+)H* pitch accents (except by speaker SP6). When the focus is realized on CW1 the H target is mostly reached close to the end of the accented syllable (93 %); when the focus is realized on CW2 die H target is reached close to the beginning of the accented syllable (85%). In broad focus condition, we observe H+!H*/L* with early peak alignment. Speakers vary as to their preferred choice of phonologically specified accent types and their phonetic realization. SP6 exclusively uses downstepped nuclear accents (H+!H*) in the narrow focus condition regardless of the position within the sentence, SP5 has a strong preference for downstepped nuclear accents (H+!H*) in the narrow focus condition on CW2 and speakers 1, 2, 4 and 5 show a preference for late peak alignment in the contrastive focus on CW1. The number of the pitch accents with early and late peak alignment used in the different focus conditions is summarized in Table 1.

Table 1: Distribution early versus late peak alignments (left-hand column) per focus condition and speaker (note: only 2 sentences were analyzed for broad focus).

		speaker						total
		SP1	SP2	SP3	SP4	SP5	SP6	
EARLY	CW2 broad	6	6	6	6	6	6	36
	CW2 nc	18	18	17	17	18	18	106
	CW2 c	16	17	18	13	18	18	100
	CW1 nc	7	5	10	2	0	16	40
	CW1 c	2	4	12	4	1	16	39
total		49	50	63	42	43	74	321
LATE	CW2 broad	0	0	0	0	0	0	0
	CW2 nc	0	0	1	1	0	0	2
	CW2 c	2	1	0	5	0	0	8
	CW1 nc	11	13	8	16	18	2	68
	CW1 c	16	14	6	14	17	2	69
total		29	28	15	36	35	4	147

In Bulgarian broad focus sentences, each content word is accented. In our data, CW2 is the last content word in sentences 3 and 5, while it is followed by another content word in the remaining sentences. To determine whether the acoustic realization of sentences in which only the object (CW2) carries a narrow focus differs systematically from those in which the entire event is focused (broad focus), we analyze sentences 3 and 5 separately from the other sentences. To investigate whether speakers prosodically differentiate non-contrastive and contrastive narrow focus we analyze all sentences, excluding the broad focus conditions. Sentences containing an early focus (on CW1) are analyzed separately from those containing a late focus (on CW2).

3.1. Local acoustic correlates of IS

The results from the statistical analysis of the local acoustic measurements (see section 2.2.1) for all focus conditions are summarized in Table 2.

3.1.1. Broad vs. Narrow

When the nuclear accent falls on CW2, both focus condition ($F[2, 90] = 29.739$, $p<0.001$) and speaker ($F[5, 90] = 35.307$, $p<0.001$) have a significant effect on the peak alignment. Moreover, there is a significant interaction between the two factors ($F[10, 90] = 5.012$, $p<0.00$). Speakers 1–4 align the F0 peak substantially earlier in the broad focus condition than in narrow focus, while speakers 5 and 6 do not differentiate between the two focus conditions.

Broad focus differs from narrow focus in that it has shorter syllable durations ($F[1,724; 51.717] = 211.658$, $p<0.001$), lower vowel intensity ($F [1.458; 41.117] = 539.372$, $p<0.001$), greater spectral tilt in the vowel ($F [2.467; 69.081] = 32.807$,

p<0.001) and a lower F0 in the vowel (F [1.720; 43.005] = 340.662, p<0.001). This F0 difference reflects the use of a different nuclear accent types: H+!H*/L* for broad and (L+)H* for narrow focus.

Table 2: *Main effects for focus condition and subject on local acoustic measurements and interactions (*** p<0.001)*

parameter	focus cond.	subject	interaction
nuclear accent on CW2 (broad vs. late)			
peak alignment	***	***	***
syll. duration	***	n.s.	n.s.
vowel intensity	***	***	***
vowel SpecTilt	***	***	***
vowel F0 mean	***	***	***
nuclear accent on CW1 (contr. vs. non-contr.)			
vowel duration	***	n.s.	n.s.
syll. duration	***	n.s.	n.s.

3.1.2. Contrast vs. Non-Contrast

Contrastive and non-contrastive focus is realized identically on CW2. When the focus is realized on CW1, the pitch accents are identical, but speakers produce a systematically longer vowel (F [2,218; 66.526] = 42.542, p<0.001) and syllable durations (F [2,281; 60.636] = 267.788, p<0.001) in the contrastive focus condition.

3.2. Global acoustic correlates of IS

Table 3 summarizes the results from the statistical analysis of the global acoustic measurements for all focus conditions (see section 2.2.2).

Table 3: *Main effects for focus condition and subject on global acoustic measurements and interactions (*** p<0.001)*

parameter	focus	subject	interaction
pre-nuclear accent on CW1 (broad vs. late)			
vowel intensity	***	n.s.	n.s.
nuclear accent on CW2 (broad vs. late)			
excursion LH	***	***	***
excursion HLpost	***	***	***
tempo pre-nuclear (sb)	***	***	n.s.
intensity pre-nuclear (sb)	***	***	***
intensity post-nuclear (se)	***	***	n.s.

3.2.1. Broad vs. Narrow

Considering non-local (global) effects, we also investigated the realization of CW1 for broad- vs. narrow-focus differences when the nucleus is on CW2. Although the CW1 was not deaccented in narrow focus (compare also [1, 2, 6]), and pitch accents realized in broad and narrow focus conditions were identical (L*+H), we observe a difference in *intensity* in the pre-nuclearly accented CW1 vowel, with a higher vowel intensity in broad than in narrow focus (F [1.717; 51.507] = 631.053, p<0.001), i.e. a measureable weakening of the pre-context in narrow focus on CW2.)

With respect to the pitch excursion (see section 2.2.2), a main effect was found for focus condition for the L-H excursion (F[2, 89] = 33.948, p<0.001) as well as for the H-Lpost excursion (F[2, 89] = 12.607, p<0.001), with larger excursions for narrow focus. There was also a main effect for speaker, both for the L-H excursion (F[5, 89] = 106.959, p<0.001) and for the H-Lpost excursion (F[5, 89] = 122.041, p<0.001). Focus and speaker also interacted significantly (F[10, 89] = 4,932, p<0.001), with only speakers 1-4 differentiating between the broad and narrow focus.

In the broad focus condition, the tempo in the pre-nuclear interval (sb) is lower (F[2, 90] = 6.662, p<0.01) and the intensity is higher than in narrow focus (F[2, 90] = 1.562, p<0.01), while intensity for the post-nuclear interval (se) is lower than in narrow focus (F[2, 90] = 12.582, p<0.001).

Speakers also differed significantly (tempo sb: F[5, 90] = 14.868, p<0.001; intensity sb: F[5, 90] = 55.567, p<0.01; intensity se: F[5, 90] = 11.909, p<0.001). An interaction between speaker and focus condition is only found for intensity in the pre-nuclear interval sb (F[10, 90] = 3.113, p<0.001). Again, speakers 5 and 6 do not differentiate between broad and narrow focus.

3.2.2. Contrast vs. Non-Contrast

No differences were found between the global measurements for contrast versus non-contrast, independent of the position of the nuclear accent.

4. Discussion and Conclusions

We investigated the prosodic realizations of information structure categories in Bulgarian. With regard to the difference between non-contrastive and contrastive focus, we observed that contrastive focus was marked more prominently than non-contrastive focus only locally and only in terms of vowel and syllable duration, when the CW occurs in the first half of the utterance. These results are not captured by a standard ToBI annotation.

With regard to the difference between broad focus and narrow focus on CW2, it was found that both local and global parameters were used. More specifically, narrow-focused syllables in CW2 were consistently realized with a longer duration, later peak alignment (but still early in the syllable), greater F0 excursions and higher energy than syllables with broad focus (local measures). This finding is not surprising, since all subjects but one used different pitch accent types to signal narrow vs. broad focus: (L+)H* vs. H+!H*/L*, respectively.

More important for the issue addressed in this study are the differences found in the global measurements. In agreement with results of previous research [1, 2, 6] no deaccentuation was found for narrow focus on CW2 in pre-nuclear position. Broad and narrow focus are not distinguished by accent type on CW1 (L*+H for both), nor is there a difference in global F0. However, the thematic, pre-nuclear interval (sb) in the narrow focus condition differs from the rhematic, pre-nuclear interval in the broad focus condition in terms of global measures. In responses with broad focus the interval preceding a focused syllable (sb) has a longer duration and a higher intensity than responses with narrow focus on CW2. This intensity difference is also found for the pre-nuclear CW1 vowel alone. Also, the interval following the nuclear accent has a lower intensity in responses with broad focus than responses with narrow focus on CW2. This finding is consistent with the observed post-nuclear vowel devoicing in broad focus conditions observed in [3].

To conclude, the all-important function of intonation, namely to transmit the relative weighting of information in speech communication, cannot be captured by a purely phonological description of realized accent types. Crucially, the IS-related patterns of phonetic prominence which are revealed in this study show a complex interplay between phonological categories and the local and global phonetic signal properties.

Description of Polish speech rhythm using rhythm metrics and the time-delay approach: A comparative study

Agnieszka Wagner

Institute of Linguistics, Adam Mickiewicz University in Poznan, Poland

wagner@amu.edu.pl

Abstract

The goal of this study is to provide a multidimensional description of rhythmic structure of Polish utterances. For this purpose a time-delay approach proposed in [1] is applied and results of qualitative and quantitative analyses based on time-delay plots are compared with results obtained with selected rhythm metrics. The study shows that description that relies on a combination of rhythmic scores is inconclusive and difficult to interpret, because it does not account for rhythmic structuring nor grouping. The time-delay approach, on the contrary, appears to be very efficient in exploring short-time and long-term timing variability that determine Polish speech rhythm.

Index Terms: Polish speech rhythm, time-delay approach, meter, grouping, prominence, rhythm metrics

1. Introduction

1.1. Analysis and description of speech rhythm

For many years, research on speech rhythm was based on *isochrony* paradigm [2, 3] and concept of *rhythmic classification of languages* (i.e. the distinction between syllable-timed, stress-timed and mora-timed languages). The fact that instrumental studies failed to bring evidence for stress- and syllable-based isochrony caused that in rhythm research the focus moved from duration measurements of syllables and feet to investigation of phonemic and phonological factors which affect the timing of syllables and feet. Observed differences in vowel reduction, stress-based lengthening and syllable complexity between stress- and syllable-timed languages motivated the development of *rhythm metrics* – formulas that measure durational variability in consonantal (C) and vocalic (V) intervals. The most widely used metrics include: %V-ΔC [4], PVIs [5] and Varcos [6]. They have been applied in studies on rhythmic classification of languages [7], acquisition of timing patterns in L1 [8] and L2 [9, 10, 11, 12, 13, 14], detection of speech impairments [15] or dialect discrimination [16]. The proponents of rhythm metrics provided experimental results showing that they can be regarded as acoustic correlates of perceived speech rhythm and supporting the hypothesis of rhythmic classification of languages. However, rhythm metrics have been the subject of considerable criticism. First of all, it can be argued that what metrics describe is not rhythm, but timing of utterances [17]. Secondly, metric scores vary considerably within languages, because they are sensitive to a number of factors such as tempo, speech style or method of measurement [18, 19]. Thirdly, rhythmic classification based on the stress-timing vs. syllable-timing dichotomy applies to *some languages in some conditions* (for example, different metrics provide different classifications of the same language [18]) and there are languages, for example Polish, that can not be assigned to any class on the basis of the metric scores and are consequently labelled as "intermediate". At the same time, metrics are incapable of giving information on distinctive features of such intermediate rhythm. In the end, metrics such as PVIs or %V-ΔC describe single aspect of rhythm, i.e. variability in time domain, but "rhythm cannot be described as a one-dimensional property of speech, e.g. as more or less variable or more or less stress timed" ([1], p.145). Rhythm can be regarded as a perceptual impression of a *structure* consisting of more or less prominent (strong, weak) events (beats or syllables) which are *grouped* in a particular manner to form *perceptually distinct patterns* such as iambs or trochees. It is doubtful whether processes underlying rhythmic structuring and grouping can be explained by means of rhythm metrics, but there is evidence from [1] that they can be successfully explored using a multidimensional approach which takes into account short-term and long-term timing variability including, among others, relative timing of functionally distinct transitions (to stressed, to unstressed and to phrase final syllables), acceleration and deceleration tendencies, compensatory shortening and time shrinking (i.e. a psychoacoustic phenomenon which results in perception of decelerating sequences as isochronous). A multidimensional account of rhythm incorporates various levels of the prosodic hierarchy and dimensions other than duration/timing, because intensity, F0 and spectral features also constitute important correlates of prominence. The approach taken in this study makes it possible to analyze and describe speech rhythm in such a multidimensional manner. It is based on *time-delay plots* which provide "a useful tool in order to explore timing relations that are perceived as typical rhythms in speech" and which are "directly interpretable along similar rhythm-related dimensions as have been detected in typological analyses" ([1], p. 155). The time-delay approach seems to be particularly useful to investigate fine-grained timing differences related to rhythmic structure and grouping in non-prototypical – rhythmically "intermediate" or unclassified – languages, such as Polish.

1.2. Polish speech rhythm

As regards phonological properties, Polish can be regarded as rhythmically "mixed" – it has fixed lexical stress, no vocalic reduction in unstressed syllables and subtle stress-related and accentual lengthening, which are considered typical features of syllable-timed rhythm, whereas high phonotactic complexity and presence of compensatory shortening points to stress-timing. Former studies provided evidence for accentual lengthening of vowels [20, 21, 22] and some support for isochrony within narrow rhythm units [23]. The results of recent corpus-based analyses [24, 25] showed that accentual lengthening is limited to vowels and syllables associated with major prominences (phrase accents), whereas durational marking of minor prominences (which coincide with word stress) is very subtle, if any. In [26] overall intensity was regarded as the main acoustic correlate of stress and in [27] – pitch movements. In [25] intensity and F0 features correlated significantly only with major prominences. Prosodic phrase

boundaries in Polish are signaled most of all by increased duration of the phrase-final and the penultimate syllable and vowel (associated most of the time with phrase/nuclear accent), but F0 features also play a significant role [22, 29]. The results of a multidimensional analysis of Polish rhythm in [1] showed only subtle lengthening of stressed syllables, tendency for foot final lengthening, deceleration throughout the foot, some compensatory shortening effects (comparing binary and longer feet) and potential evidence for time shrinking phenomenon that can contribute to impression of isochrony. These results clearly show that Polish can not be easily classified based on the stress-timed/syllable-timed dichotomy. The accounts of Polish rhythm based on rhythm metrics are inconclusive: According to PVIs [5], Polish is close to syllable-timed languages, but, according to %V – ΔC, it is grouped with stress-timed English and Dutch [4].

1.3. Objectives of the study

The objective of the study is to compare two approaches to analysis of speech rhythm in Polish: rhythm metrics [4, 5, 6] and the time-delay approach [1], and to provide explanation of factors underlying the "mixed rhythm effect" in Polish, because existing descriptions are neither informative nor satisfactory in this respect. For this purpose the study explores short-term timing variability in the realization of functionally different prosodic transitions: to stressed, to unstressed, to phrase final syllables, and long-term timing characteristics of rhythmical grouping at various levels of prosodic hierarchy – feet (of different sizes) and prosodic phrases. Rhythmic characteristics of Polish are also compared cross-linguistically by referring to results reported in the literature.

2. Methodology

2.1. Speech data

The speech material includes recordings of a literary fairy tale "The teapot" (by H. Ch. Andersen), read by five speakers – all coming from Poznan and presenting the Poznan-Cracow pronunciation. The text consists of 19 phonetically and prosodically rich sentences (491 syllables). Recordings were carried out in a sound-treated booth, directly to a disk and with a sampling frequency of 16 kHz. The subjects were asked to read the text once (sentence after sentence), at their own pace. Sentences containing disfluencies or mispronunciations were re-recorded. The recorded material constitutes part of a speech database created for the purpose of studying speech rhythm in native and non-native Polish [30]. The whole speech material was subject to automatic phonetic transcription and alignment [31] which were verified and manually corrected following standard segmentation criteria. Syllable boundaries were determined as in [32]. Prosodic annotation consisted in labeling four levels of prominence (unstressed, stressed but unaccented, accented and nuclear accented) and two levels of phrasing (intermediate and intonational phrase) [33, 34, 35]. Annotation and duration measurements were carried out in *Praat*. For statistical analyses *Statistica 10* was used.

2.2. Rhythm metrics

Segmentation into vocalic and consonantal intervals was based on the phonetic transcription and alignment. All vowels were marked as vocalic intervals and all consonants (except for post-vocalic glides) – as consonantal intervals. A vocalic interval could contain a single vowel or 2-3 subsequent vowels, or a vowel followed by a glide. Intervals could span across syllable and word boundaries. As in [18] prepausal intervals were not excluded from measurements and segments separated by a pause were treated as two distinct intervals. For each sentence we calculated the following metrics:

- **%V** – the proportion of vocalic intervals, **ΔV** and **ΔC** – the standard deviation of the duration of vocalic and consonantal intervals respectively [4]
- **rPVI-V** (raw Pairwise Variability Index) and **nPVI-V** (vocalic normalized Pairwise Variability Index): the mean of the duration differences between successive C intervals and the mean of the duration differences between successive V intervals divided by the sum of the same intervals respectively [5]
- **VarcoV/VarcoC**: standard deviation of vocalic/consonantal interval duration divided by mean vocalic/consonantal duration [6]

2.3. Time delay approach

This approach relies on time delay plots which are used to visualize relative timing of *functionally different transitions*, e.g. to stressed, to unstressed and to phrase final syllables. In time-delay plots, the duration of syllable$_i$ is plotted on the x-axis against the duration of syllable$_{i+1}$ plotted on the y-axis. Time delay plots can be applied to explore both short-term (syllable-level) and long-term (foot- and phrase-level) timing variability, and offer the possibility of interpreting continuous data in both continuous and categorical manner. By subtracting the duration of syllable$_i$ from the duration of syllable$_{i+1}$, we get information whether the transition is locally *accelerating*, *decelerating* or *isochronous* (continuous description). Decelerating transitions are plotted above the diagonal, accelerating transitions below it and the isochronous ones – along the diagonal (Figure 1).

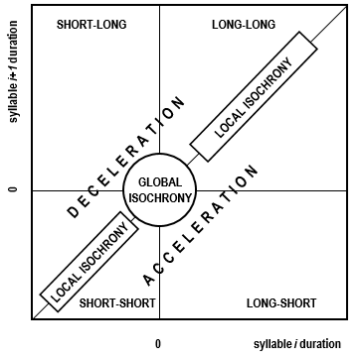

Figure 1: *Interpretation of a time-delay plot (based on [1]).*

Transitions can also be grouped into one of the four categories: short-short, long-long (locally isochronous transitions), short-long and long-short (an alternating rhythm). For example, if durations of *syllable$_i$* and *syllable$_{i+1}$* are both above/below the mean, the transition is categorized as long-long/short-short. A tendency towards global isochrony is indicated by concentration of data points in the center of the time-delay plot. The plots can be interpreted quantitatively, e.g. by performing one-factorial ANOVA with the duration difference *syllable$_{i+1}$* - *syllable$_i$* as dependent variable and transition type as predictor variable (see also [1]). On a higher

level of rhythmic-prosodic organization, i.e. foot level, time-delay plots can be applied to visualize relative timing relations within feet and to observe *compensatory shortening* which contributes to impression of isochrony in stress-timed rhythm.

3. Results

3.1. Quantification using rhythm metrics

Comparison of the metric scores obtained in the current study with those reported in [18] (both studies used the same method of consonantal and vocalic interval measurements) shows that from among six rhythmically different languages, i.e. German, English, Spanish, Italian, Greek and Korean, Polish is characterized by the least variability in vocalic interval duration – it has the lowest nPVI and VarcoV. In terms of amount of vocalic speech (%V) Polish is ranked in between languages traditionally considered stress-timed (German, English) and those regarded as rhythmically unclassified (Greek, Korean) and syllable-timed (Italian, Spanish). High values of the raw consonantal metrics, i.e. ΔC and rPVI, indicate similarity to stress-timed German and English. On the contrary, VarcoC ranks Polish in between Greek, syllable-timed Italian and Spanish on the one hand (low VarcoC – low variability in consonantal interval duration) and stress-timed German and English, and Korean on the other (high VarcoC).

As regards the effect of speech rate (measured in the number of C and V intervals per second, cf. [36]) on the metric scores, significant inverse correlations were found for ΔV, ΔC and rPVI, indicating instability of these metrics. For the purpose of quantification of the actual distances between Polish and the six rhythmically different languages in the rhythm space determined by the most stable metrics, i.e. VarcoV-VarcoC and %V-nPVI (the latter, contrary to %V-VarcoV, were not significantly correlated with each other), Euclidean distances were calculated (Table 1). As they show, according to %V-nPVI, Polish is close to syllable-timed Italian and Spanish, but VarcoV-VarcoC place Polish the closest to German.

Table 1. *Euclidean distances between Polish and six rhythmically different languages.*

rank	VarcoV-VarcoC	%V- nPVI
1	German (7,3)	Spanish (7,4)
2	Spanish (9,3)	Italian (7,6)
3	Italian (10,7)	Greek (11,2)
4	English (10,8)	Korean (12,4)
5	Korean (14,2)	German (13,6)
6	Greek (14,3)	English (17,9)

Unlike VarcoV-VarcoC, the combination of %V-nPVI provides some support for the rhythm typology – values of these metrics (Figure 2) and the Euclidean distances based on them separate syllable-timed Spanish and Italian from stress-timed German and English. The metrics do not provide strong evidence for an "intermediate" rhythm in Polish: while values of %V and VarcoC are indeed intermediate between languages traditionally regarded as stress- and syllable-timed, nPVI and VarcoV place Polish in a very different region from all the other languages (Figure 2).

Generally, it can be assumed that low nPVI and VarcoV in Polish reflect lack of reduction of unstressed vowels on the one hand, and lack of significant stress-based lengthening of vowels on the other (see also discussion in section 1.2).

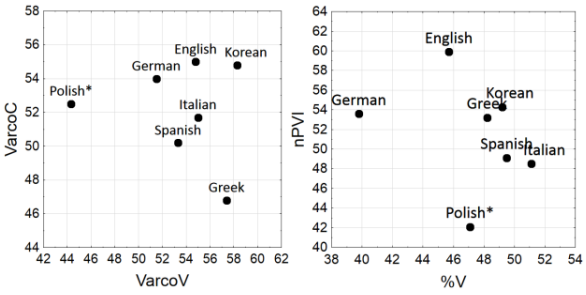

Figure 2: *Rhythm space determined by VarcoV-VarcoC (left) and %V-nPVI (right) for the six languages in [18] and Polish (*current study).*

As for VarcoC in Polish, its values (Figure 2) reflect the phonotactic structure of the utterances: high percentage (about 50%) of simple CV syllables (as in syllable-timed languages), high variation in complex syllable structures (indicating a tendency towards stress-timing) and frequency of very complex syllables even higher than in stress-timed languages.

3.2. Analysis with time-delay plots

3.2.1. Short-term timing variability

Table 2 presents concentrations of functionally different transitions in the four relative timing quadrants: Transitions to stressed syllables are concentrated mainly in the short-long and short-short quadrants, transitions to unstressed syllables – in the short-short quadrant, and transitions to phrase final syllables – in the long-long and short-long quadrants.

Table 2. *Concentrations of functionally different transitions in the four relative timing quadrants (based on z-score normalized syllable durations).*

transition	short-long	long-long	long-short	short-short
to stressed	37%	15%	16%	32%
to unstressed	21%	7%	23%	49%
to phrase final	29%	57%	3%	11%
total:	28%	18%	19%	35%

Generally, it seems that Polish, unlike English or French, *favors short-short sequences* the most. The predominance of short-short sequences in transitions to unstressed syllables, and long-long sequences in transitions to phrase final syllables, indicates a tendency towards *local isochrony* (like in syllable-timed Italian, [1]). At the same time, the high count of short-long transitions to stressed syllables, and to a lesser extent to phrase final syllables, indicates a tendency towards *alternation* (like in stress-timed English, [1]): Such timing patterns may contribute to the impression of an *intermediate* or *mixed* rhythm in Polish. Final lengthening is confined to the syllable at the edge of the phrase, but very often previous syllable is also lengthened (as indicated by high percentage of long-long transitions, see also Figure 3) due to co-occurrence with stress. One-factorial ANOVA showed significant *effect of transition type on relative timing of the sequence of syllables* expressed by the difference $syllabledur_{i+1}$ - $syllabledur_i$ (indicating local acceleration or deceleration): F=50.9, df=2, p<0.01. Post-hoc

comparisons revealed that this effect is due to a strict trend towards *deceleration in transitions to stressed* (mean=0.5, σ=1.3) *and phrase final syllables* (mean=0.45, σ=1.5) on the one hand, and *acceleration in transitions to unstressed syllables* (mean=-0.07, σ=1.1) on the other. Figure 3 shows relative timing of transitions from unstressed to stressed syllables, with a distinction between lexical stress, pitch accent and nuclear accent, and transitions to phrase-final syllables.

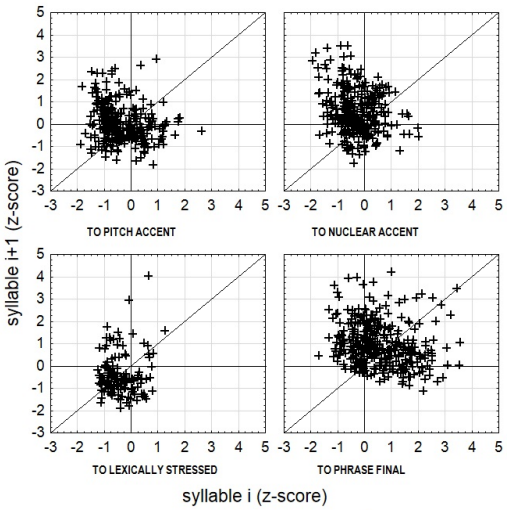

Figure 3: *Relative timing in functionally different transitions.*

Transitions to pitch accents have very similar distribution to the general one (when all prominent syllables are classified as stressed, see Table 2), whereas transitions to nuclear accents and lexically stressed syllables are concentrated mostly in the short-long and short-short quadrants respectively. These distributions indicate that durational marking is reserved mostly for nuclear accents – major prominences. One-factorial ANOVA showed significant differences in the relative timing between the three transition types, i.e. to lexically stressed, pitch accented and nuclear accented syllables: F=23, df=2, p<0.01. There is a strong *deceleration trend that increases with the level of prominence* from lexical stress (mean=0.02, σ=1) to nuclear accent (mean=0.86, σ=1.3), with pitch accents in between (mean=0.4, σ=1.2).

3.2.2. Long-term timing variability

The goal of the analysis of long-term characteristics of feet of different sizes is to "detect timing regularities that listeners can learn in order to form certain expectations concerning upcoming rhythmical events. Such long-term expectations are what we defined as *meter*" ([1], p. 162). It can be seen in Figure 4a, that in binary non-final feet, the stressed and the following unstressed syllable are almost identical in length, which indicates a tendency towards local isochrony. In this respect, Polish differs from both stress-timed English (-> increased duration on foot-initial stressed syllables) and syllable-timed French (-> a strong tendency towards foot-final lengthening) [1]. Binary phrase-final feet in Polish have a very similar timing pattern to that observed in French i.e., foot-final lengthening [1]. Ternary and quaternary feet have a tendency of acceleration after the foot-initial, stressed syllable and deceleration at foot boundary. Foot internal syllables (syl2 in ternary and syl3 in quaternary feet) are significantly shorter than foot-initial and foot-final syllables.

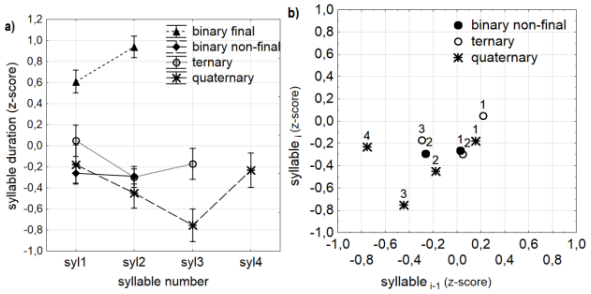

Figure 4: *Long-term timing patterns across different feet.*

These timing patterns are similar to those found in German longer feet [1]. Deceleration at foot boundary may cause the effect of *time shrinking* of the pre-final syllable and may lead to the *impression of isochrony and a lack of variation* in longer feet. Time shrinking may also concern stressed syllables in binary phrase-final feet. What can be traced in Figure 4b is the *compensatory shortening* – distribution of average relative durations of foot-internal syllables in binary non-final, ternary and quaternary feet shows tendency to shorten syllables with increasing foot length, but foot-final syllables are not affected by this phenomenon.

4. Discussion and conclusions

The results of the analysis with rhythm metrics indicated very low variability in vocalic interval duration (VarcoV and nPVI) in Polish comparing to six rhythmically different languages. In terms of variability in consonantal interval duration (VarcoC) and the amount of vocalic speech (%V) Polish can be regarded as *intermediate* between syllable- and stress-timed languages. Euclidean distances showed that according to %V-nPVI, Polish is close to Italian and Spanish, but VarcoV-VarcoC place Polish the closest to German. The description of Polish rhythm provided by the metrics is thus inconclusive and hard to interpret. On the contrary, time-delay approach appeared to be a very efficient method for visualization and analysis, both quantitative and qualitative, of the contribution of short-term and long-term timing variability to rhythmic structure and rhythmic grouping at different hierarchical levels (syllable, foot and phrase level). The time-delay analysis provided some evidence for "mixed" rhythm in Polish which is characterized by *as much local isochrony* (-> syllable-timing) *as alternation* (-> stress-timing). Speech rhythm in Polish is also determined by *deceleration* in transitions to *phrase-final and stressed syllables* (the trend increases with the level of prominence), and *acceleration* in transitions to *unstressed syllables*. The analysis of long-term timing variability brought some evidence of *time shrinking* and *compensatory shortening*, which may lead to the impression of syllable- and stress-based isochrony respectively. The analyses showed that rhythmic grouping is determined by *deceleration* at the foot and phrase boundary. As regards rhythmic structure in Polish, it is necessary to go beyond the dimension of timing, because the current study showed that durational marking of prominence is very weak, if any.

Abstract

This study investigates stress processing through the Event-Related brain Potential (ERP) technique. It aims at evaluating whether French listeners can perceive and discriminate the Initial Accent (IA) and whether IA is encoded in the phonological representation. Participants listened to trisyllabic words in two stress-pattern conditions, with (+IA) or without (-IA) initial accenting, in an oddball paradigm. The EEG was recorded in both a passive and an active listening task, and in two different oddball versions: one where standard stimuli were +IA words and deviants -IA words, and the reverse for the other version (-IA standard, +IA deviant). Behavioral results show faster processing and less errors for +IA stimuli. ERP results show larger MisMatch Negativity component for -IA words, pointing out 1) that French listeners are sensitive to *f0* manipulation, and 2) that +IA is the preferred stress template in French. Altogether, our results indicate that French listeners not only discriminate stress patterns but that IA is encoded in long-term memory, hence phonologically relevant.

Index Terms: stress-pattern processing, initial accent, MisMatch Negativity, French

1. Introduction

French prosody presents some peculiarities, which makes its phonological description difficult to fully apprehend and which has consequences on effective propositions for speech processing models. Traditionally, descriptions of the French accentuation system account for a primary Final Accent (FA) co-occurring with intonational boundaries, and a secondary, optional Initial Accent (IA), essentially seen as an extra-metrical phenomenon [1; 2; 5]. Because accentuation (FA) in French is post-lexical and not lexically distinctive, it has been described as a 'language without accent' [1] or a 'boundary language' [2; 3]. In this view, it is also said that French listeners are 'deaf' to accentuation and have no long-term memory representation of stress patterns [4; *inter alia*]. Although FA is now undisputedly seen as a pitch accent [5], IA's phonological status is still unclear. While some models describe it as a pitch accent [6], most models in the frame of the AutoSegmental Metric approach consider IA as a 'loose boundary marker', which peak can be aligned to the first, second or even third syllable of the content word or accentual phrase in some cases [5; 7]. As such, IA is not clearly phonologically implemented in the French prosodic system: its role is that of a secondary, rhythmical balancing device, yielding to FA in case of tonal crowding [5; 8].

However, diverse studies point out systematic use of IA in prosodic structure marking and speech segmentation. Recently for example, IA has been shown to be a more reliable cue to prosodic structuring than FA in the marking of content words and accentual phrases [9]. Namely, IA very commonly marks lexical words inside larger prosodic units, more so than FA, and is a marker of left prosodic boundaries even when in close vicinity to FA and not rhythmically necessary. Other studies indicate that the cohesive prosodic units formed by IA and FA, also described as 'accentual arches' [10] strongly enhance the encoding and segmentation of linguistic units, over units marked by FA alone [11; 12]. Finally, IA ('early rise') is used to segment lexical units in the speech flow [13]. Despite potential 'looseness' of this 'early rise', naïve French listeners systematically perceive IA *on the first syllable* of content words and accentual phrases, even when its peak reaches its maximum further in the unit [14]. This may indicate that IA is strongly linked to the representation of lexical words. Altogether, these production and perception findings point out a more important role of IA than described in prosodic models. Namely, they are in keeping with a possible strong phonological role of IA as a left marker of small units, i.e. accentual phrases and possibly the level of the lexical word.

It is thus interesting to further investigate whether IA is *encoded* at some level of the linguistic representation. The Metrical Segmentation Strategy [15] states that the mental lexicon is accessed through pre-lexical, language-specific stress templates. Finding neural bases for IA processing in French would give further insights as to its phonological role in French. Very few studies have to date investigated the neural bases of accentuation, and mostly do so through the exploration of Event-Related Potential (ERP) components. Stress pattern violations in Dutch in an AX paradigm elicited a N325 component indicating pre-lexical processing of stress [16]. In French, violation of metrical patterns induced by artificial lengthening of the medial syllable in trisyllabic words induced delayed lexical decision. Indeed, lexically *congruent* words in the sentence elicited a larger N400 component when metrically incongruent, indicating that French listeners do have pre-lexical stress template representations [17]. Similar results were found for Chinese [18]. Other results using the oddball paradigm allow investigation of short-term and long-term memory processing of stress patterns, through the MisMatch Negativity ERP component [19; 20; 21].

The oddball paradigm allows presenting listeners with deviant stimuli in a background of standard stimuli, which processing elicits an early negativity in the context. The MisMatch Negativity (MMN) is thus a reconstructed ERP component obtained by subtracting deviants' elicited brainwaves from standards'. The oddball paradigm allows measuring the mnemonic trace that the repetition of standard stimuli leaves in short-term memory [22]. A MMN component emerges on the deviant stimuli when the standard stimuli leave a strong mnemonic trace in short-term memory. This effect is

emphasized by linguistic experience of phonological representations in the native language, i.e. by comparing the auditory stimuli with those representations in the long-term memory. Thus, while the oddball paradigm helps determining whether an auditory stimulus is perceptually discriminated, it can also help reveal whether this discrimination goes beyond lower processing levels [23]. In its pre-attentive version (*passive listening condition*), the MMN allows examining how the brain processes linguistic information online, without requiring listeners to make conscious decisions about the speech stimuli. Hence, results can be interpreted independently from other linguistic levels.

While most studies using MMN manipulate stress patterns' legality in words and pseudo-words [20; 21], the first step of our investigation concerns IA processing at the word level. By manipulating presence or absence of IA on words, our experiment is designed to test 1) whether French listeners *can* perceive and discriminate IA (acoustical low-level processing or salience discrimination), and 2) whether IA is encoded at the word-level (phonological, higher cognitive level or stress template processing). Indeed, although words can sometimes be pronounced without systematic IA in the speech flow, we hypothesize that IA stress patterns are the preferred, expected stress templates in French. Hence, we predict that ± IA stimuli are discriminated (short-term memory) and that a larger MMN will be elicited by -IA deviant patterns in a +IA standards background because they are less expected stress patterns (long-term memory stress pattern representation).

2. Method

2.1. Speech stimuli

The stimuli consisted of two words (*candidat* ('candidate') and *diffusion* ('broadcast')) that were naturally uttered with **IA (+IA)** in a sentence context by a naïve speaker. The words were placed in the sentence so as to appear at the beginning of a major intonation phrase (eg. *Le principe de cette nouvelle émission, dit-elle, et sa* ***diffusion****, pourraient être très mal accueillis par le public* ('the concept of this new program, she said, and its **broadcast,** may not be well accepted by the audience')), hence reinforcing the probability of clear marking of the target word by IA and FA [9].

The words were then extracted and resynthesized *without* **IA (-IA).** FA was kept constant and natural (see Figure 1).

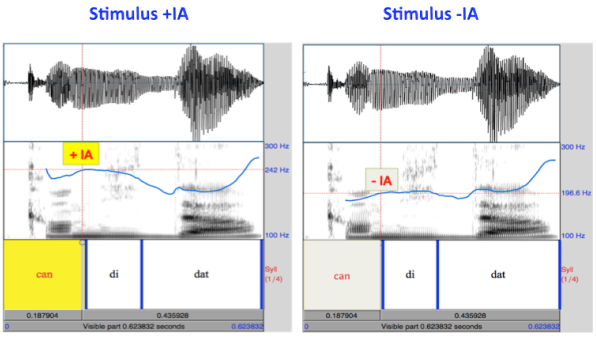

Figure 1: *Example of f0 resynthesis with (+IA) and without (-IA) on the word 'candidat', with quadratic interpolation from the f0 value of the preceding determinant to the f0 value at the beginning of the last stressed syllable for -IA words.*

The *f0* value of the first vowel was lowered near the *f0* value of the preceding (unaccented) determinant ('*le'* or *'sa')*. A quadratic transformation modified the *f0* values to reach progressively the *f0* value at the beginning of the last (accented) vowel, in order to maintain naturalness (micro-prosodic variations and some features of the original *f0* pattern). The +IA stimuli were forward and back transformed to equalize the speech quality between +IA and -IA stimuli.

The duration of the target words was held constant in both stress conditions (+IA; -IA), since only the *f0* parameter was manipulated (*candidat*: 624 ms; *diffusion*: 741 ms).

2.2. Participants and experimental tasks

30 healthy right-handed French native speakers, aged 18-35 (mean age 23,8; 27 females), participated in 2 versions of the Oddball paradigm in the same sequential order: a Passive *then* an Active listening task. Task order was not randomized throughout participants because doing the Active task before would have drawn attention to our stress manipulation. During the Passive task, subjects were watching a silent movie while listening to the repetition of the stimulus *'candidat*', in either of the two stress conditions (+IA; -IA). A total of 1092 words were presented with a pseudo-random combination of 106 deviant words and 986 standard words. The Inter Stimuli Interval (ISI) was 576 ms. The total experiment duration was 23 mns, in one single block. After a 10 mns' break, participants performed the Active task, where they were told to press a button as soon as they detected a deviant stimulus. In this task, the stimulus was '*diffusion*' in either of the two stress conditions (+IA; -IA), with the same total number of words and the same proportion of deviant and standard stimuli as in the previous task. The ISI was 459 ms and the experiment lasted 28 mns in total, throughout two blocks of 14 mns each with a 5 mns' break between the two blocks.

The participants were divided into two groups according to the Oddball version presented (see Figure 2): the first group (n= 14) performed the passive and the active task with -IA words as deviants and +IA words as standards (Version1); the reverse was true for the second group (n= 16) who performed both tasks with +IA as deviants and -IA as standards (Version2).

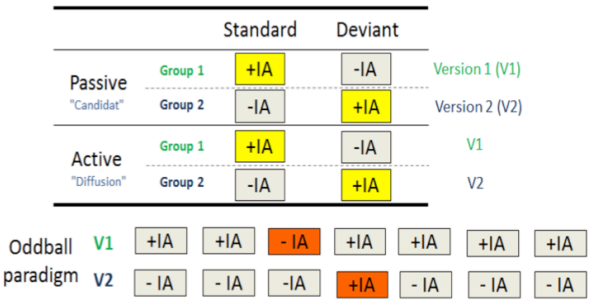

Figure 2: *Two versions of the Oddball Paradigm, where either -IA or +IA is the deviant. Participants are in 2 groups, each group having the same deviant condition in the Passive and the Active condition.*

2.3. EEG recordings

The EEG was recorded in both passive and active tasks, with 32 Ag/AgCl-sintered electrodes mounted on an elastic cap and located at standard left and right hemisphere positions over

frontal, central, parietal, occipital and temporal areas (International 10/20 System; Jasper, 1958) at : Fz, Cz, Pz, Oz, Fp1, Fp2, AF3, F3, AF4, F4, C3, C4, P3, P4, PO3, PO4, P5, P6, O1, O2, F7, F8, T3, T4, T5, T6, FC5, FC6, CP1, CP2, CP5 and CP6. The Horizontal ElectroOculoGram (HEOG) was recorded from a bipolar montage with electrodes placed 1 cm to the left and right of the external canthi; the Vertical ElectroOculoGram (VEOG) was recorded from a bipolar montage with electrodes placed beneath and above the left eye, to detect blinks and vertical eye movements. The EEG and EOG were amplified by BioSemi amplifiers (ActiveTwo System) with a band-pass filter of 0.01-30 Hz and was digitized at 512 Hz. Trials containing ocular artefacts, movement artefacts, or amplifier saturation were corrected from averaged ERP waveforms. The data were analysed using Brain Vision Analyser software version 2.0 (Brain Products, Munich, Germany). Each electrode was re-referenced off-line to the algebraic average of the left and right mastoids. Continuous recordings were segmented into 1100 ms duration starting 200 ms before stimulus onset (baseline). Trials were averaged within each of the two stress conditions. Finally, data were averaged across participants to obtain the grand-averages. Subject-averages were aligned to the 200 ms baseline preceding the auditory target. EEG results are presented in the Passive task, while only behavioural data (error rates and RTs) are presented for the Active task.

ERP data were statistically analysed by computing the mean ERP amplitude relative to a 80 ms window centred at the peak latency [100-250 ms] on 9 electrodes (F3, Fz, F4, C3, Cz, C4, P3, Pz and P4). For each comparison (within and between participants) ANOVAs were conducted with Stimulus Type (standard *vs* deviant) and Stress Condition (+IA *vs* -IA). All *p*-values were adjusted with the Greenhouse–Geisser epsilon correction for nonsphericity.

3. Results

Because of an abnormal error rates (>40%), data from five participants were excluded from the analyses. Moreover, one more participant was excluded due to a large number of artifacts on the ERP data. Thus, a total of 24 participants (version -IA: n=12; version +IA: n=12) were included on the behavioral data analyses and the ERP grand averages.

3.1. Behavioural results from the Active Task: Reaction Times and Errors Rates by deviant type

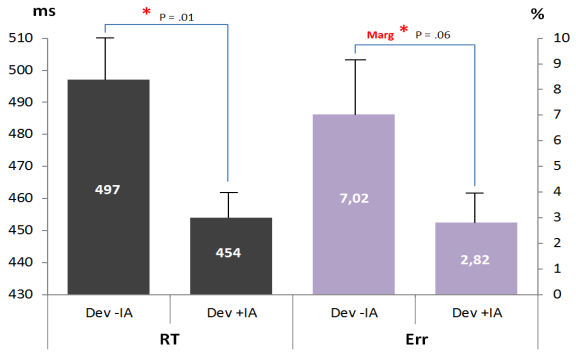

Figure 3: *Reaction Times (left; in ms) and Error Rates (right; in %) for -IA and +IA deviants. * indicates statistic significance.*

Paired two-tailed t tests revealed that RTs were significantly faster for detecting +IA deviants than for -IA deviants (454 ms vs. 497 ms; $t(23) = 3.27$, $p < .01$). Moreover, error rates differences between the two stress conditions were marginally significant ($t(23) = 1.1$, $p = .06$), -IA deviants being slightly more prone to errors than +IA deviants (7.02% *vs* 2.82%; see Figure 3).

3.2. Event-Related Potential results from the Passive Task

3.2.1. Within participants' MMN comparison

Results show a significantly larger MMN amplitude for -IA deviants than for +IA deviants ($F(1, 23) = 6.52$, $p < .01$), indicating that participants not only process the acoustic cues to stress, but that -IA deviants in a +IA standards environment are less expected than +IA deviants in a -IA standards environment.

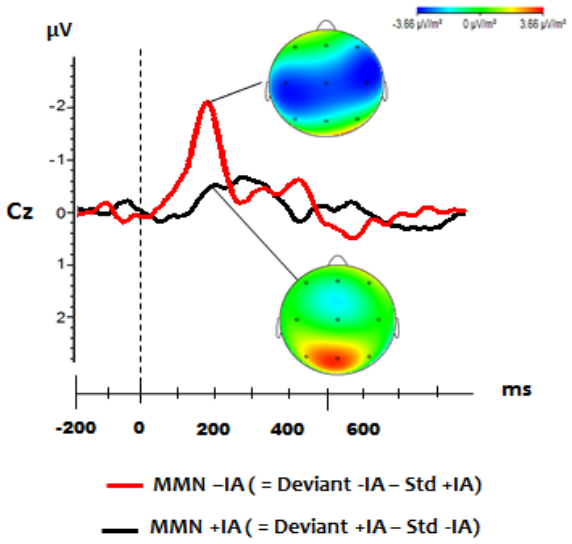

Figure 4: *MMN component for -IA and +IA deviants, for each participants' group. Grand average ERPs recorded at the Cz (central) electrode. Amplitude (µV) is represented on the ordinate, with negative voltage up, and time (msec) on the abscissa. Topographical maps are computed at the MMN peak latency.*

3.2.2. Between participants' MMN comparison

The previous within participants' results indicate that +IA deviants do not elicit an MMN. In order to unravel whether it is merely due to low-level, acoustic processing or whether it reflects higher-level processes (stress pattern rarity processing), we calculated MMN effects between identical deviant and standard stimuli (-IA deviants subtracted from -IA standards, and same procedure for +IA stimuli) across participant groups.

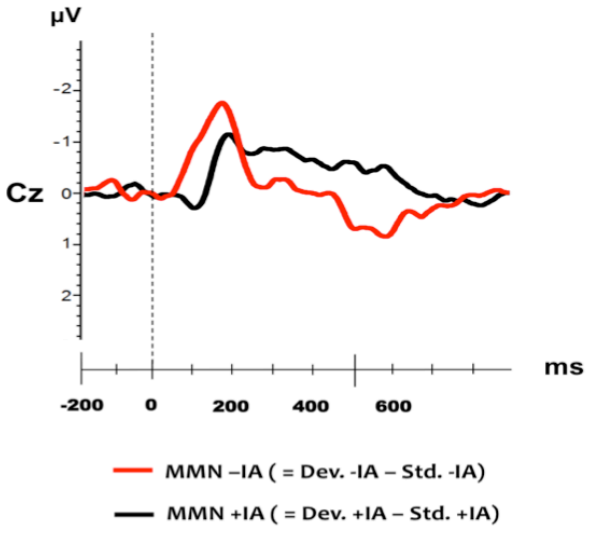

Figure 5: *Difference waves for (deviant – standard) -IA stimuli, and +IA stimuli respectively, across participants. Identical ERPs' graph and statistical settings than for Figure 4.*

Results for deviants and standards ± IA identical stimuli show a significantly larger MMN amplitude for -IA stimuli than for +IA stimuli ($F(1, 23) = 2.94$, $p < .05$).

4. Discussion

The aim of this study was to determine whether French listeners discriminate and process stress patterns in French. Since initial accents (IA) seem to play an important role in prosodic structuring and speech segmentation, the focus of this study was on IA processing at the word level. Despite still inconsistent accounts in prosodic models as to its phonological role, and its description as a 'loose boundary marker', our results indicate that French listeners readily perceive IA and that +IA stress patterns on lexical words are the expected, preferred patterns.

We chose to investigate IA processing through the MisMatch Negativity ERP component because it allows accounting for stress pattern processing at a pre-attentive level and independently from other levels of linguistic processing. In our study, participants were also submitted to an active version of the task in order to enrich the electrophysiological investigation with behavioral data.

Behavioral results show significantly faster Reaction Times to detect +IA deviants in a -IA standard background than to detect -IA deviants in a +IA standard background, which indicates facilitating processing for +IA stimuli. Error rates are also informative insofar as +IA deviants are significantly less numerous than -IA deviants. Altogether, behavioral results revealed that +IA words are discriminated and processed more easily and automatically than -IA words.

ERP data analysis revealed that French listeners process -IA and +IA word stimuli differently. If French listeners did not process stress and were 'deaf' to accentuation, both oddball versions would have yielded similar results, i.e. no MMN component would have emerged when -IA were deviants in +IA stimuli background and vice-versa. The presence or absence of f0 acoustical saliency would not have been discriminated. On the contrary, our results not only indicate that listeners process saliency differences but that they have a preferred stress pattern. Indeed, a large MMN emerges for -IA deviants, indicating that -IA deviants are surprising in a +IA context and showing that the absence of f0 variation on the word was processed (Figure 4). But if listeners were sensitive to low-level acoustic features only, a similar MMN should emerge when +IA deviants occur in a -IA context, indicating a mere processing of acoustic difference. However, Figure 4 shows no such MMN for +IA deviants. Because the MMN is a difference wave between deviant and standard stimuli, this latter result calls for further investigation. The MMN is a measure of the rarity of a stimulus in a context. This short-term memory rarity processing may be emphasized by pattern comparison in long-term memory. It may be that -IA patterns are not expected stress patterns and elicit a negativity wave even when presented as standards. Or it could be that -IA stimuli do not leave a strong enough trace in the short-term memory so as to elicit an ample MMN for +IA deviants, because they do not call upon long-term memory representations. Hence, the rarity processing of +IA deviant stimuli is reduced in the difference wave and no MMN emerges. To explore the rarity processing effect independently from acoustic and prosodic phonological effects, we calculated MMN for identical deviant and standard stimuli *across* participants. Figure 5 reveals a MMN for +IA rare stimuli but this MMN is significantly less ample than for -IA stimuli. Rare -IA stimuli thus remain more surprising than +IA deviants in matched contexts. Thus, a mere acoustic interpretation of ±IA processing has to be ruled out, because a MMN is still present between similar acoustical stimuli. On the contrary, our results show that ±IA stimuli both rely on short-term memory processing (the *absence* of saliency is surprising) and on long-term memory representation (-IA stress patterns are more surprising than +IA stress patterns and mismatch the long-term stress pattern representation).

Altogether, these results point out a preference for +IA stress patterns in French.

5. Conclusions and Perspectives

This study is, to our knowledge, the first investigation of stress pattern processing in French using the oddball paradigm. Results indicate that French listeners not only discriminate stress patterns but show preference for +IA stress patterns. This is a first step towards showing that IA is encoded at the lexical word level and it reinforces its role in speech encoding and decoding processes. These results echo similar findings in other languages [19; 20; 21]. Further MMN investigations will be conducted with more ±IA lexical items in order to generalize our interpretation of a phonological representation of +IA stress patterns. Following Honbolygo [21], we will also extend our investigation to pseudo-words, to emphasize the interpretation of +IA stress templates in long-term memory. Finally, this paradigm will also be extended to FA processing to address the potential similar role of IA and FA in French prosodic phonology.

Effects of dynamic pitch and relative scaling on the perception of duration and prosodic grouping in American English

Alejna Brugos and Jonathan Barnes

Boston University, Boston, Massachusetts, USA

abrugos@bu.edu

Abstract

Results of two perception experiments suggest that using timing measures alone to compute prosodic structure misses valuable information from pitch. Previous research showed that pitch can distort perceived duration: tokens with dynamic or higher f0 are perceived as longer than comparable level-f0 or lower-f0 tokens, and silent intervals bounded by tokens of widely differing pitch are heard as longer than those bounded by tokens closer in pitch (the kappa effect). Phrase edges (signalled by increased duration, pause, phrase tones, and f0 reset) set the scene for pitch to modulate perceived duration. Two new experiments used the same duration and f0 manipulations (level vs. varying-slope rises, at varying pitch ranges) of segmentally-identical base files, in two separate tasks: 1) a linguistic grouping task using an ambiguously-structured phrase and 2) a psychoacoustic study on perceived duration. Results show that effects on perceived duration due to dynamic pitch can be either strengthened or nullified depending on relative scaling of compared tokens. These same manipulations push grouping judgments beyond what would be expected from distortions of perceived duration. This suggests that listeners integrate pitch and timing cues when judging linguistic structure, supporting measures of relative boundary size that combine duration and pitch measures.

Index Terms: duration perception, auditory illusions, dynamic pitch, timing, prosodic grouping, boundary tones

1. Introduction

Edges of prosodic groups are known to be marked (at least in many languages, Fon (2012) [1]) by pre-boundary lengthening, silent pauses, phrase tones and reset. Phonetic measures of these features are typically taken independently, without consideration of how they may interact in perception. However, perception of time can be systematically affected by a range of contextual factors (Brown, 2008) [2], including pitch (Hoopen, 2008) [3]. A growing body of work from a diverse range of fields shows that pitch and timing are not entirely perceptually independent.

1.1. Pitch-time interaction

Since Lehiste (1976) [4] showed that subjects perceived vowels with dynamic f0 as longer in duration than static-f0 vowels of the same objective duration, many studies have tried to replicate this finding, with varying results (see Cumming, 2011 [5] for an overview). Cumming (2011) [5] and Yu (2010) [6] both reproduced this effect, with differing methodologies and languages; Yu also found that vowels with higher f0 were perceived as longer than lower-f0 vowels.

Outside of speech research, there is a substantial body of experimental work on pitch-timing interaction in perception. Henry (2011) [7] showed that perception of duration of non-speech tone glides can be modulated by the pitch change

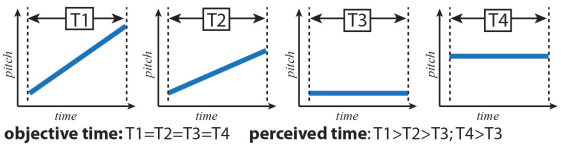

Figure 1: *Schematic of dynamic pitch & scaling effects on perceived duration of filled intervals. The intervals (T1, T2, T3 & T4) are objectively equal in duration; those with dynamic pitch sound longer than level, and more so with steeper pitch. Higher pitch intervals are also perceived as longer than those with lower pitch.*

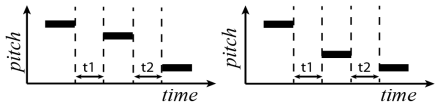

Figure 2*: Schematic example of the auditory kappa effect, whereby relative tone height affects timing perception. Silent intervals (t1, t2) are equal, but t1 sounds shorter at left, longer at right.*

velocity of the target glide and of the standards: glides with greater pitch change velocity are perceived as longer than those with lesser pitch change velocity, or level-pitch tones.

Other work has focused on the effects on perceived duration of silent intervals bounded by filled intervals of varying pitch distance, a phenomenon known as the auditory kappa effect: Silent intervals bounded by tones of closer pitch proximity are perceived as shorter in time than those of equal objective duration bounded by tones of a greater pitch distance (Cohen et al., 1953[8], 1954[9]). While typically demonstrated using non-speech tones (Shigeno, 1993 [10], Crowder & Neath, 1995 [11]; MacKenzie, 2007 [12]; *inter alia*), Brugos & Barnes (2012b) [13] showed that the auditory kappa effect also obtains for spoken language, such that the perceived duration of silent pauses in speech was modulated by the pitch distance across those pauses. In a second study using identical materials, Brugos & Barnes (2012a) [14] found that the effect of these pitch manipulations was even greater on perceived prosodic grouping of these phrases: even effects of objective duration differences on grouping perception were in some cases overridden. These results suggest that relative pitch proximity of neighboring prosodic phrases, described in the literature as phrase-initial reset (Jun, 2003) [15], should be taken into account for estimating boundary size, and support a trading relationship between pitch and timing cues in prosodic grouping (Beach, 1991 [16]; Cumming, 2011b [17]; Jeon & Nolan, 2013 [18]).

Of course, since phrase boundaries in natural speech commonly play host to dynamic pitch (e.g., boundary tones), pitch jumps (e.g., reset), and durational variation (phrase-final lengthening/pauses), we might expect all these pitch and timing cues to enter into cue-trading relationships for the signalling of prosodic grouping. In fact, something of this sort has been shown in a variety of studies. When f0 cues are neutral, grouping can be cued by duration cues alone (Scott,

1982 [19]; Wagner & Crivellaro, 2010 [20]); likewise f0 cues alone can cue grouping when pitch cues are held constant (House, 1990 [21]). When pitch and timing are manipulated together, the picture of cue interactions for prosodic grouping becomes more complex (Beach, 1991 [16]; Jeon & Nolan, 2013 [18], 2010 [22]; Cumming, 2011b [17]).

2. Two experiments

To investigate how dynamic pitch and duration might interact in both duration and grouping perception in American English, a pair of experiments was designed using the same stimuli in two different tasks: 1) a linguistic judgment of grouping in an ambiguous phrase based on cue interpretation and 2) a psychoacoustic judgment of perceived duration.

2.1. Methods

The ambiguous phrase chosen as context for the linguistic grouping task was a string of color terms *blue and green and purple* (following methodology of Beach et al., 1996 [23]). This phrase can be parsed variously: 1) ungrouped (a simple list of 3 colors) or 2) two groups, one pair of colors and a third color on its own, i.e.: *blue and (green and purple)* (B-GP) or *(blue and green) and purple* (BG-P).[1]
